IN a short note contributed to the Paris Academy of Sciences on December 30, Prof. Suess calls attention to the striking geographical results of the researches of his Vienna colleagues on the marine Triassic fauna. While to English geologists the Trias is the typical example of an unfossiliferous land-deposit, the work of Mojsisovics on the contemporaneous deposits of the Alpine region has been the starting-point for a series of dis-

coveries in many parts of the world. A rich marine Triassic fauna is now known extending from Spain to Japan and California, and from Spitzbergen to New Zealand. Yet among the thousands of these fossils gathered together in Vienna from all parts, there is not a single marine fossil from the regions bordering the Atlantic or Indian Oceans. The conclusion is obvious, that the regions of these modern oceans were not covered by sea in Triassic times. On the other hand, all the districts bordering the Pacific and Mediterranean yield the marine forms, as does a great stretch of land extending from the Mediterranean to the Pacific through Central Asia, and another extending from the Pacific through Eastern Siberia to the Arctic Ocean. Thus the Pacific Ocean was the main ocean in Triassic times, and stretched out two arms across the continental region—the one called the *Tethyan* ocean, of which the Mediterranean is the last remnant, the other the Arctic branch. This distribution of the Triassic seas strikingly agrees with that of the structural features of modern coast-lines indicated by Neumayr: the oceans bordered by lands with marine Trias are the oceans of the *Pacific type*, of which the coasts are determined by the convex margins of earth-folds; while the oceans of *Atlantic type*, of which the margins cut across the mountain-folds, are those around which only the fresh-water Triassic strata are found. Thus is confirmed the opinion that the latter oceans are of comparatively recent origin, and have been produced by a process of wholesale depression, which has cut out the three great triangular upstanding masses (or *horsts*) of Greenland, Africa, and India, which form so striking a feature on the surface of our planet.

The Geological Survey has generally been successful with its index maps, and the beautiful hand-coloured index of Wales, on the scale of four miles to an inch, has a great reputation for correctness of topography, clearness and accuracy of colouring, and beauty of appearance. After the lapse of a long period, the Survey, about two years ago, began the issue of an index map of England and Wales on the same scale, and of this several sheets have been already issued. These sheets were also coloured by hand; but on account of their complicated structure they were necessarily very expensive to produce, and hence, although sold with the barest possible margin of profit, or, indeed, with none at all, they could never become very widely used in consequence of their high price. Now, however, an important experiment has been tried, the issue of Sheet 12 printed in colours. This map includes the London Basin and the greater part of the Weald, and it is identical with the hand-coloured sheet; but whereas the price of the latter was 10*s*. 6*d*., that of the former is 2*s*. 6*d*. Printing the map in colours brings with it practically no disadvantage. The topography is clear and correct, the latest railways being inserted; the colours are transparent, clean, harmonious, and well-defined; each colour is lettered at all critical points; the registration is wonderfully exact, although such minute delineation is a very severe test of the workmanship; and the detail is quite as full as on the hand-coloured map, which, it will be remembered, contained many revisions not as yet shown on the original 1-inch sheets. On the other hand, printing in colours has two inestimable advantages, which those familiar with the hand-coloured maps will realise to the full; the inevitable omissions of the colourist will disappear, and, as the colour-proofs come to hand, there is every encouragement for the makers of the map to exercise the minutest care in delineations of details, which, once inserted, cannot again drop out by accidental omissions of the draughtsman, engraver, or colourist. It is to be hoped that this is only the beginning of good things, and that the Survey will persevere until it has the rest of the index similarly printed, thus providing an unequalled and authoritative map of the whole country. If this is successful, we cannot stop here, but must look forward to having reproduced by colour-printing at least such of the 1-inch sheets as are sufficiently used to justify the expenditure. Indeed, it would doubtless be wisest, and really cheapest in the end, to undertake this course with all the sheets of the new series as they come out, irrespective of the demand upon each particular one. If these could be produced at the price of 1*s*., instead of 4*s*., a brisk demand would be at once created. The public must, however, do its share. We have already stated that the index-sheet is issued as an experiment. If the issue is well supported, this will furnish a great encouragement to the Stationery Office to follow the good course it has begun.

A graphic method of determining the focal lengths of lenses and mirrors is described by Dr. E. H. Barton in the *Philosophical Magazine*. For a concave mirror, cut off the distances of the object and the image respectively on the two axes of Cartesian coordinates, and join the two points. Two separate observations will give two lines intersecting in a point equidistant from the two axes. The coordinates of this point are both equal to the focal length required. The measurements may be controlled by another observation, and the line now obtained should intersect the other two in the same point. A line passing through this point and rotating about it will cut off in succession all the possible values of the conjugate focal distances. For a convex lens, the point is situated in the right hand lower quarter, for a convex mirror in the left-hand lower, and for a concave lens in the left-hand upper quarter of the plane of coordinates.

On no other frequented trade route are vessels so liable to be obstructed by drift ice as in that portion of the South Atlantic lying to the east of Cape Horn and the Falkland Islands. A chart just issued by the U.S. Hydrographic Office, to show the limits of the enormous ice fields encountered by mariners in those waters, will therefore be of great service. The chart also gives for the months of March, April, and May the isotherms or lines of equal temperature of the surface water. It is stated, however, that these lines are of doubtful value to the navigator in announcing the proximity of ice, as practical experience has shown that the temperature of the surface is little affected thereby. The report of Captain Macmillan, of the ship *Dudhope*, is especially interesting in this connection: "Careful thermometric observations of air and water were regularly taken, but our approach to ice, always from windward, was not once indicated by any appreciable change of temperature, in either air or water. On passing to leeward of the bergs, a fall of a few degrees was generally observed *in the air*. On one occasion we passed within a cable's length of a berg, and found the temperature to be the same there as at several miles' distance. This would go to show that in thick weather—or in any other—even temperature and thermometer at normal height should not be accepted as a trustworthy guarantee of immunity from ice. Care and a most vigilant look-out are the only trustworthy safeguards. To depend on the thermometer would mean disaster, as I am convinced that a ship would be too close to the ice to extricate herself by the time the thermometer would indicate its presence."

Recent progress in the chlorination process for the extraction of gold from its ores lies mainly in the direction of improvements in the mechanical appliances which are used. The repeated efforts to prevent the oxidising action exercised by chlorine on the unroasted sulphides in ores, by adding salts such as nitre to the mixture, have now apparently been abandoned. Most chemists have always regarded the hopes of the experimenters in this direction as chimerical. Among the mechanical improvements of the last year have been the enlarging of the lead-lined steel barrels used in Western America. As now made, these

barrels take a charge of ten tons of ore, instead of only five. The filter inside the barrel is retained, but the expensive asbestos cloth, which lasted for only a few charges, is replaced by a cheap sand-filter, which, it is stated, is not shifted by the rotation of the barrel, and does not become clogged until after it has been used for about 100 charges, or say a month. While the Americans are thus engaged in perfecting the barrel process, the Australians have abandoned it altogether. At the Mount Morgan Mine, where there is the largest chlorination plant in the world, the vats have been reintroduced, but are much enlarged, each having a capacity of twenty-five tons. Chlorine water is used, the consumption of chemicals being less, and the reagent more under control than if gas is pumped into the charge. The use of bleaching powder and sulphuric acid for generating the gas has been superseded again by manganese dioxide, salt and sulphuric acid, and the installation of chlorine stills, towers, and solution tanks. The extraction of gold at Mount Morgan is about 95 per cent. of the total amount in the ore, and the cost of treatment, now about 15*s.* per ton, is expected to be reduced to 12*s.* per ton by the more extended use of revolving furnaces. The total production at the mine is at the rate of over 100,000 ounces of gold per annum. The impetus given to the barrel chlorination process a few years ago seems, from the above facts, to have spent its force.

THE *Bulletin* of the Kansas Experimental Station records instances of the poisoning of cattle by eating the stalks of Indian corn, from the very large amount of potassium nitrate which they contain.

OUR attention has been drawn to two laborious investigations by E. Mazelle, of the Trieste Observatory, recently presented to the Vienna Academy of Science, relating to the daily and yearly range of variability of temperature, and to the relations between the usual mean value and the "most frequent" values of temperature, as deduced from the records of fifty years, 1841–90. The difference between the mean and most frequent values has been discussed by various authorities, notably by Dr. J. Hann in the second edition of his "Climatology." The observations for each month, or year, are grouped so as to show how often a certain value, or interval of temperature occurs, and from these a curve is drawn which differs, according to circumstances, from one showing the mean values, and, while not superseding the latter, is of considerable interest for comparison with it. For various interesting details we refer our readers to the original papers.

THE third edition of M. Faye's "L'Origine du Monde' (Gauthier-Villars, Paris) has lately been published. In this volume M. Faye states and discusses various theories and beliefs held as to the mode of the genesis of worlds, from the Mosaic record to the views of Kant and Laplace, and of their successors. Within the past ten years much work bearing upon the evolution of worlds has been done. Long-exposure photographs of nebulæ have given astronomers more information upon cosmical genesis than all that was known before their era, and photographs of spectra have enabled spectroscopists to arrange celestial objects in order from the youngest to the oldest. We naturally turned to the new edition of M. Faye's book expecting to find the work of recent years set down with the fulness which it deserves. But we were disappointed. Instead of a picture of Dr. Roberts' photograph of the Andromeda nebula, there appears a venerable cliche which ought to be banished from every book that pretends to represent astronomical knowledge of to-day. The same remark applies to the picture and the spectrum of the Orion nebula, of the spectrum of Sirius, and to most of those in the volume. When the first edition of the book appeared, such illustrations might have passed muster; but in these days of abundant photographs and cheap process-blocks, there is no excuse for offending the sight with them. We cannot see any difference between the third edition of M. Faye's book and the first edition, as regards illustration, and little difference as regards the text.

THE additions to the Zoological Society's Gardens during the past week include a Persian Gazelle (*Gazella subgutturosa*, ♂) from Persia, presented by Mr. F. Greswolde-Williams; two Polecats (*Mustela putorius*, ♂ ♀), British, presented by Mr. A. H. Cocks; a Yellow-fronted Amazon (*Chrysotis ochrocephala*) from Guiana, presented by Lieut.-General Arthur Lyttleton-Annesley; two West African Love-Birds (*Agapornis pullaria*) from West Africa, presented by Mrs. Otto Fell; a Crowned Duyker-Bok (*Cephalophus coronatus*, ♀) from West Africa, two King Penguins (*Aptenodytes pennanti*) from the Macquari Islands, purchased.

ERRATUM.—In the article on "The Habits of the Cuckoo" (p. 176), for Dr. Reh read Dr. Rey.

OUR ASTRONOMICAL COLUMN.

HIND'S VARIABLE NEBULA.—Further confirmation of the variability of the nebula N.G.C. 1555, discovered by Dr. Hind in 1852, has been obtained by Prof. Barnard (*Monthly Notices*, vol. lvi. p. 66). It may be remembered that so recently as February 1895, the nebula was an easy object in the Lick telescope, while Struve's nebula, in the immediate neighbourhood, was absent, and the nebulosity round τ Tauri was imperceptible (NATURE, vol. lii. p. 180). Under the very best conditions of observation in September last, however, Hind's nebula seemed to have entirely vanished, although every means was tried to see it. This appears to definitely prove that the light of the nebula fluctuates, and it is therefore desirable that the place of this object should receive careful attention. τ Tauri was involved in a small hazy nebulosity, but the definite nebula in which it shone in 1890 did not exist four months ago.

o CETI.—The last two or three maxima of this well-known variable star have occurred considerably later than the computed times, and the present, or perhaps approaching, maximum is similarly behindhand. According to the ephemeris in the *Companion to the Observatory*, there should have been a maximum on December 9, but on January 8, the star had barely reached 4th magnitude. The star is now much more favourably situated for observation than during several preceding maxima; and, in view of the irregularity to which reference has been made, it is important that the magnitude should be recorded as frequently as possible. Spectroscopic observations will also be valuable, and it may not be out of place to suggest a special look-out for bright lines of helium and the associated gases, as well as observations of the varying relative brightness of the carbon fluting slightly more refrangible than the *b* group of magnesium.

STELLAR VELOCITIES WITH OBJECTIVE PRISM.—The great advantages of the objective prism over the slit spectroscope for photographing the spectra of stars have been abundantly demonstrated, but hitherto the latter form of instrument has been considered essential for precise determinations of velocities in the line of sight. An adaptation of the objective prism for the latter purpose is proposed by M. Deslandres (*Observatory*, January). In the arrangement suggested, the collimator of an ordinary spectroscope is placed in a direction perpendicular to the rays proceeding from the star, and the light passing through the slit from the comparison spark is reflected upon the objective prism by a small totally-reflecting prism. The collimator, objective prism, and photographic telescope, thus constitute a complete slit spectroscope. With the aid of the auxiliary visual telescope, the spectrum of the star is photographed with the objective prism in the ordinary way, and during the exposure the terrestrial spectrum is photographed nearly alongside that of the star, the adjustments having been so made that lines of equal refrangibility in the two spectra are in the same straight line. The spectrum of a star with which a comparison of velocity is desired, or may be that of the same star after an interval, is then photographed adjacent to the first, with the help of the visual telescope; and another terrestrial spectrum is photographed alongside the previous one, a different part of the

slit being exposed to the spark. This comparison of terrestrial spectra enables the errors due to temperature and flexure to be determined, and the difference of velocity of the two stars is given by the displacement of the two stellar spectra minus that of the two terrestrial. Evidently the accuracy will depend very largely upon the precision in setting the two stars in the visual telescope; to secure this it is proposed to attach a small photographic telescope to the guiding telescope, and to photograph the two stars, together with a reticule, which will enable the deviation, if any, to be measured and allowed for. To get the absolute velocity of a star, it must be compared with a star of known velocity, or Orbinsky's method (NATURE, vol. lii. p. 155) of measuring the contraction or dilatation of the whole spectrum may be applied. In the latter case, the absolute velocity could be determined directly, since effects of temperature, &c., would be eliminated.

A NEW STAR IN CENTAURUS.[1]

A NEW star in the constellation Centaurus was found by Mrs. Fleming on December 12, 1895, from an examination of the Draper Memorial photographs. Its approximate position for 1900 is in R.A. 13h. 34·3m., Dec. − 31° 8′. Attention was called to it from the peculiarity of the spectrum on a plate taken at Arequipa on July 18, 1895, with the Bache Telescope, exposure 52 mins. The spectrum resembles that of the nebula surrounding 30 Doradus, and also that of the star A.G.C. 20937, and is unlike that of an ordinary nebula or of the new stars in Auriga, Norma, and Carina. This object is very near the nebula N.G.C. 5253, which follows 1·28s., and is north 23″. No trace of it can be found on 55 plates taken from May 21, 1889, to June 14, 1895, inclusive. On July 8, 1895, it appeared on a chart plate, and its magnitude was 7·2. On a plate taken July 10, 1895, its magnitude was also 7·2. On December 16, 1895, a faint photographic image of it, magnitude 10·9, was obtained with the 11-inch Draper Telescope, although it was very low, faint, and near the sun. On this date, and on December 19, it was also seen by Mr. O. C. Wendell with the 15-inch Equatorial as a star of about the eleventh magnitude. An examination with a prism showed that the spectrum was monochromatic, and closely resembled that of the adjacent nebula. Although the spectrum is unlike those of the new stars in Auriga, Norma, and Carina, yet this object is like them in other respects. All were very faint or invisible for several years preceding their first known appearance. They suddenly attained their full brightness and soon began to fade. Like the new stars in Cygnus, Auriga, and Norma, this star appears to have changed into a gaseous nebula.

The star which was photographed in 1887 in the constellation Perseus apparently belongs to the same class. Its approximate position for 1900 was in R.A. 1h. 55·1m., Dec. + 56° 15′. Eight images of it were obtained on the Draper Memorial photographs in 1887, all in exactly the same place. Its photographic spectrum showed the hydrogen lines $H\beta$, $H\gamma$, $H\epsilon$, and a line near 4060, bright, and from this property it was discovered by Mrs. Fleming and assumed to be an ordinary variable star of long period. The spectrum is so faint that it is impossible to decide from it whether it should be regarded as a new star of the class of Nova Aurigæ, or as a variable star of long period like *o* Ceti, as the hydrogen lines are bright in both these classes of objects. This star soon faded away and does not appear on 81 photographs taken during the last eight years. It has also been repeatedly looked for in the sky without success. No trace of this star appears on two photographs taken November 3, 1885, and December 21, 1886.

A list of the new stars hitherto discovered is given in the annexed table. Some changes would occur in it, if changes were made in the definition assumed for this class of objects. Early observations of several objects frequently called new stars, but which may have been comets, and whose positions are uncertain, have not been included. The stars T Bootis and U Scorpii have not been included, although they also may be new stars, as only one appearance of each has been noted. The name of the constellation is followed by the right ascension and declination for 1900, and the greatest brightness. The year of appearance is followed by the name of the discoverer; or, in the case of the earlier stars, of the principal observer.

THE ETHNOLOGY OF THE BRITISH UPPER CLASSES.

IN "L'Anthropologie," tome v. (1894) Dr. Beddoe has published the results of his work on the cephalic index of the inhabitants of Great Britain and Ireland. Part of his work deals with the cephalic indices of the Cambridge undergraduates, which were placed at his disposal by J. Venn, F.R.S. He has also inquired into their height and weight, classing them in accordance with their place of origin; but he has taken no account of the colour of the eyes of these undergraduates, and so I thought it would be as well to continue his researches, now that there is more material to hand, paying especial regard to the colour of the eyes. It will be seen by a glance at the table appended that it is in a mere fraction of the total number that the eyes are described as "light." This is due to the standard of comparison afforded by the Anthropometrical Committee of the Cambridge Philosophical Society, and is a disadvantage which does not apply to the dark eyes, and it is therefore by confining our attention to the percentages of the dark eyes in the various groups that we get our best results.

I have examined, through the kindness of Dr. Venn, some 1400 more instances since Dr. Beddoe published his results in "L'Anthropologie." In the three special cases of cephalic index, height and weight, where my results are only a continuation of Dr. Beddoe's, I have, in the following table, incorporated his results in mine, so as to gain the advantage of having a larger number of instances to deal with. On glancing at the figures below, one is at first inclined to think that the upper classes of the various races, which have given rise to the present population of Great Britain and Ireland, have entirely fused with one another, as the differences between their respective indices are but small; but the following two points indicate, I think, that the fusion is still incomplete:—

(1) *Stature.*—The Welsh are about ·8 inch shorter than the English, and as much as 1·5 inches shorter than the Scotch. They are also a slighter race, they weigh less, are less strong muscularly, and have a smaller breathing capacity.

The English, again, are about ·7 inch. shorter than the Scotch, weigh about 4 lb. less, and are less strong.

(2) *Colour of Eyes.*—The greatest percentage of dark eyes is to be found in those undergraduates whose origin is in the west and south-west (34·76 per cent.). The smallest among those who come from the east and south-east (18·75 and 15·38 respectively).

The cephalic indices of the various groups do not show much difference. The chief point of interest is the fact that the dark-eyed English have broader and loftier heads than is the case elsewhere in England. This is just the reverse of what Dr. Beddoe found: "L'association," he says (p. 662), "de la couleur brune ou foncée des cheveux avec la dolichocéphalie paraît être à peu près générale."

I may perhaps incidentally touch on a curious point, which is possibly due to nothing more than the instrument used, and that is, that one can, on the average, see further with the right eye than with the left. The average difference is fairly constant, and amounts to about two centimetres. Whether it is due to anything beyond external causes, I hardly like to say.

The table in the adjoining column shows, in each case, the number of instances examined, and the averages calculated from them.

R. J. HORTON-SMITH.

THE SMITHSONIAN INSTITUTION.[1]

I.

Promote, as an object of primary importance, *institutions for the increase and diffusion of knowledge*: in proportion as the structure of a government gives force to public opinion, it is essential that public opinion should be enlightened.—GEORGE WASHINGTON, 1796.

I bequeath the whole of my property to the United States of America to found at Washington *an establishment for the increase and diffusion of knowledge among men*.—JAMES SMITHSON, 1826.

Let the trust of James Smithson to the United States of America be faithfully executed by their representatives in Congress: let this result accomplish his object—*the increase and diffusion of knowledge among men*. —JOHN QUINCY ADAMS, 1846.

THE name of the Smithsonian Institution is a household word in America, while in every centre of intellectual activity abroad, it is regarded as the chief exponent of the scientific thought of the people of the United States, thus representing that which is deemed in other lands to be a chief glory of our nation; for, whatever may be thought of American art and literature, or of American instituttons in general, the science of America is everywhere accepted as sound, vigorous, and progressive.

Its activities embrace every branch of human knowledge, for it was the intention of its organisers that art as well as science —the beautiful as well as the true—should receive its fostering care.

The Smithsonian Institution, although it bears the name of a foreigner, has for half a century been one of the most important agencies in the intellectual life of our people. It has been a rallying-point for the workers in every department of scientific and educational work, and the chief agency for the free exchange of books, apparatus of research and of scientific intelligence between this and other countries. Its publications, which include more than two hundred volumes, are to be found in all the important libraries in the world, and some of them, it is safe to say, on the work-table of every scientific investigator. Its great library constitutes an integral and very important part of the national collection at the Capitol, and its museum is the richest in existence in many branches of the natural history and ethnology of the New World. Many wise and enlightened scholars have given their best years to its service, and some of the most eminent men of science to whom our country has given birth, have passed their entire lifetime in working for its success.

The most important service, however, which the Smithsonian Institution has rendered to the nation—intangible, but none the less appreciable—has been its fifty years of constant co-operation with the Government, with public institutions, and with individuals in every enterprise, scientific or educational, which needed its advice, support, or aid from its manifold resources.

Visitors to the city of Washington carry away pleasant memories of the quiet group of buildings among the trees in the Mall, filled with the wonders of nature and art, and the trophies of scientific discovery. Few of them, however, have had the opportunity to visit the administrative offices and laboratories, or to gain any idea of the real significance and value of the work which is being carried on within those walls.

It is probable that no class of the American people appreciates the work of the Institution more fully than the members of Congress. This has been clearly shown by the uniform liberality with which, throughout many successive terms, regardless of changes in the political complexion of the administration, they have supported its policy; by the care with which they disseminate its reports; by the judgment with which they select their representatives upon its Board of Regents, and, above all, by the scrupulous care with which they protect the Institution in its independence of political entanglements. That the Institution has accomplished so much in the past is largely due to the support which it has received from these practical men of

1 By Dr. G. Brown Goode. This paper was printed for distribution at the Atlanta Exposition, and has since been revised and extended for NATURE. It is based upon the author's essay on "The Smithsonian Institution," printed in 1885, in "The Chautauquan" (vol. v. pp. 275-79), and upon later writings, especially "The Origin of the National Scientific and Educational Institutions of the United States" (Report American Historical Association, 1889, pp. 53-100); "The Genesis of the National Museum" (Smithsonian Report, 1891, ii. pp. 273-380), and the article "Smithsonian Institution" in Johnson's Cyclopædia, new edition (vol. vii. 1895).

business, and through them from the people of the United States; since the comparatively small income of the Institution has been made a nucleus for very considerable annual appropriations granted by the United States Congress, for the support of the manifold interests the administration of which have been entrusted to it. It is to such support that it will owe its efficiency in the future, and it seems right that every opportunity should be taken to explain its operations to the public. No intelligent American can fail to appreciate the benefits which the highest interests of the American people receive through the proper administration of the Smithsonian bequest.

THE ORIGIN OF THE INSTITUTION.

The story of the foundation of the Smithsonian Institution sounds more like romance than fact. It seems like the fulfilment of some prophecy, and all the more so because of the promise of the future.

The father of the founder of the Smithsonian Institution, in early life known as Sir Hugh Smithson, was one of the most distinguished members of the English peerage. Upon the plate of his coffin in Westminster Abbey, where he was buried "in great pomp" in 1786, he was described as "the most high, puissant and most noble prince Hugh Percy, Duke and Earl of Northumberland, Earl Percy, Baron Warkworth and Lovaine, Lord Lieutenant and Custos Rotulorum of the Counties of Middlesex and Northumberland and of all America, one of the Lords of his Majesty's most Honourable and Privy Council, and Knight of the most noble Order of the Garter, &c., &c., &c."

While his aged father was supporting this overwhelming burden of honours and dignities, and while his half-brother, Earl Percy, was serving as a Lieutenant-General in the war against the rebellious British colonies in North America,[1] James Smithson, a youth of modest fortune, was acquiring the rudiments of a scientific education in English schools and colleges. He received the degree of Master of Arts from Pembroke College, Oxford, in 1786, the year of his father's death. He was then known as James Lewis Macie, for he did not assume the name of Smithson until several years later, after he had attained to some reputation as a man of science. His mother was not the Duchess of Northumberland, but her cousin, Elizabeth Keate Macie, of Weston, near Bath (widow of James Macie), great-granddaughter of Sir George Hungerford of Studley, and his wife, Lady Frances Seymour, sister of the sixth Duke of Somerset and aunt of Algernon Seymour, Lord Percy, whose daughter Sir Hugh Smithson married, and was thus enabled to assume the name of Percy and the title of Duke of Northumberland.[1]

[1] Lord Algernon Percy, afterwards Duke of Northumberland, commanded the reinforcements at the battle of Lexington in 1775, and led the column which reduced Fort Washington, near New York, in 1776.

The Smithsons were an old Yorkshire family; Sir Hugh, the great-grandfather of James Smithson, having been created baronet by Charles II. in 1660.

James Smithson was undoubtedly proud of his illustrious ancestry, for in his will he described himself as "son of Hugh, first Duke of Northumberland and Elizabeth, heiress of the Hungerfords of Studley, and niece of Charles, the Proud Duke of Somerset."

He was, however, a man of broad, philosophic mind, and his training in the best scientific methods of his day, and association with leading investigators in Germany and France, and with his brother Fellows of the Royal Society of London, had developed in his mind a generous appreciation of the value of scholarship and scientific culture, and of the still greater importance which these were to have in coming years.

"The best blood of England flows in my veins," he once wrote; "on my father's side I am a Northumberland, on my mother's I am related to kings,[2] but this avails me not. *My name shall live in the memory of man when the titles of the Northumberlands and the Percys are extinct and forgotten.*"

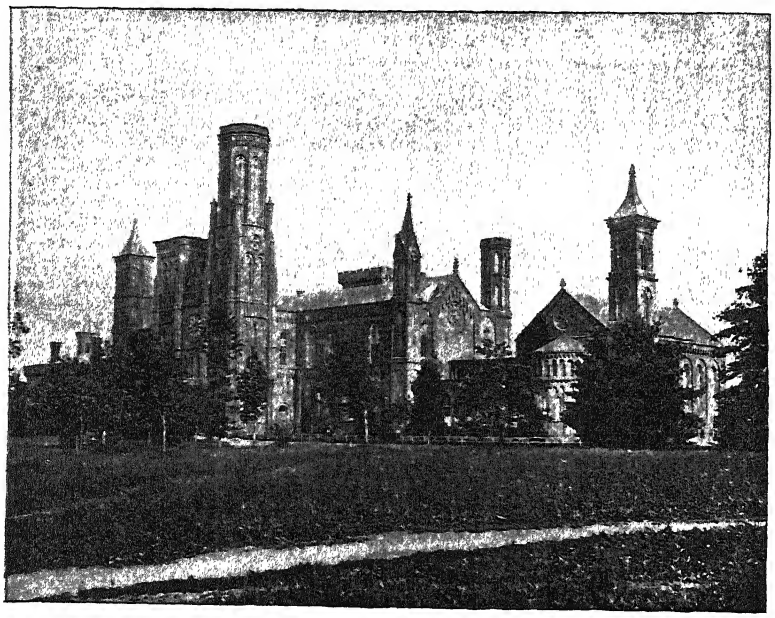

FIG. 1.—The Smithsonian Building.

These words seem little less than prophetic. The founder of the Smithsonian Institution has already earned perpetual fame.

The names of the successive Dukes of Northumberland, his kinsmen, have, as a rule, been little known outside Great Britain, though several of them have been munificent patrons of science.

Smithson seems, early in life, to have come fully into harmony with the scientific spirit of his time. In 1784, while still an undergraduate at Oxford, he made a scientific exploration of the coasts of Scotland in company with a party of geologists. In 1787 he was admitted a Fellow of the Royal Society, and during the remaining forty-two years of his life, in Berlin, Paris, Rome, Florence, and Geneva, he was an associate of the leading men of science, and devoted himself to research. He made an extensive collection of minerals, which was destroyed by the burning of a portion of the Smithsonian building in 1865, and he always carried with him in his travels a portable laboratory for chemical research.

His contributions to science are included in twenty-seven memoirs, chiefly upon topics in mineralogy and organic chemistry, though some of them relate to applied science and the industrial arts. His work, though not of an epoch-making character, was remarkable for its minute accuracy.

Smithson was a greater man than is indicated by his published writings alone. Berzelius declared that he was one of the most accomplished mineralogists in all Europe.

He was a man of generous culture who understood thoroughly the needs of the world in the direction of scientific endowment,

[1] Smithson was born in France in 1765. The date 1754 usually given for his birth and engraved upon his tomb is wrong, as is shown by his Oxford matriculation records. The source of his fortune is not certainly known. At Oxford, where he was entered as a Gentleman Commoner, he was understood to have succeeded to the estate of his mother's husband, Macie, and in 1794 he received a bequest of £3000 from his half-sister, Dorothy Percy. The major portion of his estate, however, came to him by the bequest of his half-brother, Colonel Henry Louis Dickinson, of the 84th Regiment of Foot, who died in Paris in 1820. The statement of Smithson that his mother was "heiress of the Hungerfords of Studley," probably indicates the source of a considerable portion of the wealth of which that document made disposition.

[2] Smithson was of royal descent, through his maternal ancestor, the ill-fated Lady Catharine Grey, great-granddaughter of King Henry VII., grandniece of Henry VIII., and cousin of Elizabeth. His ancestor in the ninth generation, Edward Seymour, the first Duke of Somerset and Protector of England, was the brother of Queen Jane Seymour and the uncle of King Edward VI.

and his action in bequeathing his estate to the people of America was deliberate and well considered.

In that admirable little monograph entitled "Smithson and his Bequest," Mr. W. J. Rhees has pointed out that the tendency of the time of Smithson was towards the establishment of permanent scientific institutions. Between 1782 and 1826, over twenty of the most important academies and societies now in existence were organised. "This period," he writes, "was not less marked by the gloom occasioned by long, protracted and almost universal war, and the extent and rapidity of its social changes, than by the lustre of its brilliant discoveries in science, and its useful inventions in the arts. Pure science had many illustrious votaries, and the practical application of its truths gave to the world many of the great inventions by means of which civilisation has made such immense and rapid progress." In support of these statements he quotes the words of Lord Brougham, who said that "to instruct the people in the rudiments of philosophy would of itself be an object sufficiently brilliant to allure the noblest ambition."

It was with a mind full of such thoughts as these, with perhaps the support and inspiration of Lord Brougham's words quoted above from his "Treatise on Popular Education," printed in 1825, with such models in mind as the Royal Society, whose object is "the improvement of natural knowledge," the Royal Institution "for diffusing the knowledge and facilitating the general introduction of useful mechanical inventions and improvements, and for teaching the application of science to the common purposes of life," and the Society for the Diffusion of Useful Knowledge, established in London in 1825, that in 1826 Smithson drew up his will, containing this most significant provision:—

"I BEQUEATH THE WHOLE OF MY PROPERTY TO THE UNITED STATES OF AMERICA TO FOUND AT WASHINGTON, UNDER THE NAME OF THE SMITHSONIAN INSTITUTION, AN ESTABLISHMENT FOR THE INCREASE AND DIFFUSION OF KNOWLEDGE AMONG MEN."

There is no reason known why he should have selected the United States as the seat of his foundation, though it is certain

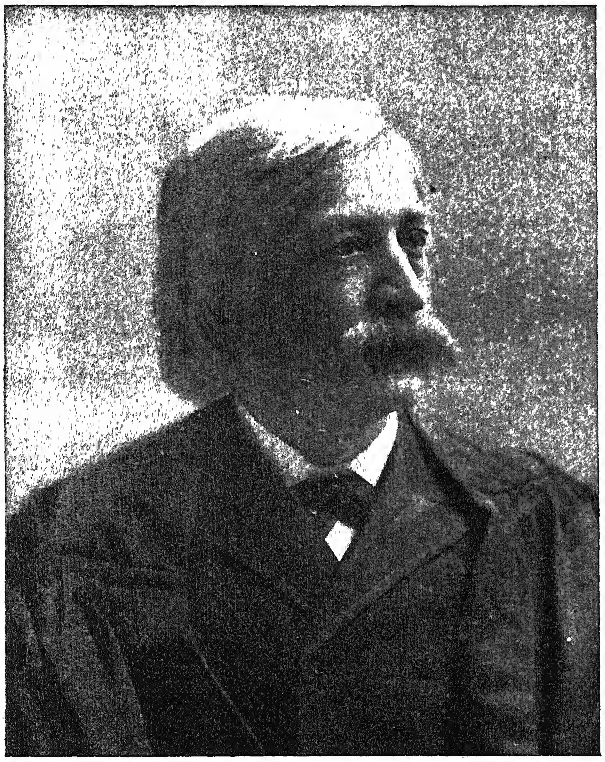

FIG. 2.—Chief Justice Fuller, Chancellor of the Smithsonian Institution.

FIG. 3.—Joseph Henry, First Secretary of the Smithsonian Institution, 1846-78.

Brougham forcibly recommended this idea to the wealthy men of England, pointing out that by the promotion of such ends, a man, however averse to the turmoil of public affairs, might enjoy the noblest gratification of which the most aspiring nature is susceptible, and influence by his single exertions the fortunes of a whole generation.

Very closely do these thoughts correspond to those expressed by Smithson in various passages in his note-books, and especially with that which is used for a motto upon the publications of the Institution:—

"*Every man is a valuable member of society, who by his observations, researches, and experiments, procures knowledge for men.*"

Another sentence of his is still more pregnant with meaning. It is this:—

"*It is in his knowledge that man has found his greatness and his happiness, the high superiority which he holds over the other animals who inherit the earth with him, and consequently, no ignorance is probably without loss to him, no error without evil.*"

that he was in full sympathy with republican governments and the liberty of the people. His library contained only two books relating to America. Rhees quotes from one of these, "Travels Through North America," by Isaac Weld, secretary of the Royal Society, a paragraph concerning Washington, then a small town of 5000 inhabitants, in which it is predicted that "the Federal city, as soon as navigation is perfected, will increase most rapidly, and that at a future day, if the affairs of the United States go on as prosperously as they have done, it will become the grand emporium of the West, and rival in magnitude and splendour the cities of the whole world."

It is probable that he knew Joel Barlow in Paris, and was familiar with his plan for a realisation of Washington's project for a great national institution of learning in the Federal city.

Inspired by a belief in the future greatness of the new nation, realising that while the needs of England were well met by existing organisations such as would not be likely to spring up for many years in a new, poor, and growing country, Smithson founded in the new England an institution of learning, the civilising power of which has been of incalculable value. Who

can attempt to say what the condition of the United States would have been to-day without his bequest? Well did John Quincy Adams say:—

"*Of all the foundations of establishments for pious or charitable uses which ever signalised the spirit of the age or the comprehensive beneficence of the founder, none can be named more deserving the approbation of mankind.*"

In 1835, six years after Smithson's death, the United States legation in London was notified that his estate, amounting in value to about £100,000, was held in possession of the accountant-general of the British Court of Chancery.

As soon as the facts became public, great opposition to the acceptance of the gift arose in Congress. Eminent statesmen, led by Calhoun and Preston, argued that it was beneath the dignity of the United States to receive presents, and that the donor was seeking immortality for too moderate an equivalent. The wise counsels and enthusiastic labours of John Quincy Adams, who seems to have had from the first a thorough appreciation of the importance of the occasion, finally prevailed, and the Honourable Richard Rush was sent to England to prosecute the claim. He entered a friendly suit in the Courts of Chancery in the name of the President of the United States, and obtained, in less than two years, an event unparalleled in the history of Chancery, a favourable decision. The legacy was brought over in the clipper ship *Mediator*, in the form of 104,960 gold sovereigns. These were delivered September 1, 1838, to the Philadelphia Mint, and immediately recoined into American money, yielding 508,318.46 dols. as the first instalment of the legacy. This was soon after increased to 515,169 dols., and in 1867, by a residuary legacy of 26,210.63 dols., the total sum derived from the founder's beneficence, which by careful management had been in 1867 increased to 650,000 dols., a sum which, as has already been shown, derives its significance, not from its own magnitude, but from the manner in which it has been utilised to stimulate the interest of the Government, and to draw to itself larger amounts through special appropriations from Congress. At one time in the early history of the Institution a large portion of its fund was in certain State bonds which became worthless. Congress appropriated money to make good the loss, and the permanent fund, which, swelled by recent bequests, now amounts to 911,000 dols., is held as a deposit at 6 per cent. in the United States Treasury.

For eight years the original legacy lay in the Treasury, while the wise men of the nation tried to decide what to do with it. At the time, the adage that in a multitude of counsellors there is wisdom, did not appear to be applicable; yet the delay, though irksome to those who desired to see immediate results, proved to be the best thing for the interests of the trust. Every imaginable disposition of the legacy was proposed and discussed in Congress; the debates fill nearly three hundred and fifty pages of Rhees' compilation of Smithsonian documents. Hundreds of letters advisory, expostulatory, and dissuasive were received from representative thinkers and from societies at home and abroad. Every man had a scheme peculiar to himself, and opposed all other schemes with a vigour proportionate to their dissimilarity to his own. Schools of every grade, from a national university to an agricultural school, a normal school and a school for the blind, were proposed. A library, a botanical garden, an observatory, a chemical laboratory, a popular publishing house, a lecture lyceum, an art museum, any and all of these and many more were proposed and advocated by this voluntary congress of many men of many minds.

THE THREE SECRETARIES.

The successful organisation of the Institution has been the result of long-continued effort on the part of men of unusual ability, energy, and personal influence. No board of trustees or regents, no succession of officers serving out their terms in rotation could have developed from a chaos of conflicting opinions, a strongly individualised establishment like the Smithsonian Institution. Especially effective in this respect has been the influence of the three men who have in succession held the office of "Secretary." The name of "Secretary," it should be stated, is that which in Washington designates the highest grade of executive responsibility. The Secretary of the Institution makes all appointments on the staff, is responsible for the expenditure and disbursement of all funds, is the legal custodian of all its property, and, *ex officio*, its librarian and the keeper of its museum.

The names of Henry and Baird are so thoroughly identified with the history of the Institution during its first four decades, that their biographies would together form an almost complete history of its operations. A thirty-two years' term of uninterrupted administrative service was rendered by one, thirty-seven years by the other. Perhaps no other organisation has had the benefit of so uninterrupted an administration of forty years, beginning with its birth and continuing in an unbroken line of consistent policy a career of growing usefulness and enterprise.

The first meeting of the Board of Regents took place on September 7, 1846, and before the end of the year the policy of the Regents was practically determined upon, for, after deciding upon the plan of the building now occupied, they elected to the secretaryship Prof. Joseph Henry, and thus approved his plan for the organisation of the Institution which had previously been submitted to them.

Henry was a man greatly distinguished in science through his epoch-making discoveries, which had already given to the world the electro-magnetic telegraph, and which form the foundation of all systems of electric lighting and power.[1] From the age of forty-seven to that of seventy-nine, he merged his life in that of the Institution. Prof. Asa Gray has shown so clearly the deep impression which he made upon the organisation while it was yet plastic, that I quote his words as the best explanation of the character of this element in its history:

Fig. 4.—Spencer Fullerton Baird, Second Secretary of the Smithsonian Institution, 1878-87.

"Some time before his appointment," writes Prof. Gray, "he had been requested by the members of the Board of Regents to examine the will of Smithson, and to suggest a plan of organisation by which the object of the bequest might, in his opinion, best be realised. He did so, and the plan he drew was in their hands when he was chosen Secretary. The plan was based on the conviction 'that the intention of the donor was to advance science by original research and publication; that the establishment was for the benefit of mankind generally, and that all unnecessary expenditure on local objects would be violations of the

[1] Self-induction, and the intensity magnet, with which Henry and Faraday subsequently discovered magneto-electricity

trust.' His 'Programme of Organisation' was submitted to the Board of Regents in the following year, was adopted as its governing policy, and has been reprinted in full or in part in almost every annual report. If the Institution is now known and praised throughout the world of science and letters, it is fulfilling the will of its founder and the reasonable expectations of the nation which accepted and established the trust, the credit is mainly due to the practical wisdom, and the catholic spirit, and the indomitable perseverance of its first Secretary, to whom the establishing act gave much power of shaping ends, which as rough-hewn by Congress were susceptible of various diversion. Henry took his stand on the broad and ample terms of the bequest, 'for the increase and diffusion of knowledge among men,' and he never narrowed his mind, and to *locality* gave what was meant for mankind. He proposed only one restriction, of wisdom and necessity, that in view of the limited means of the Institution, it ought not to undertake anything which could be done,

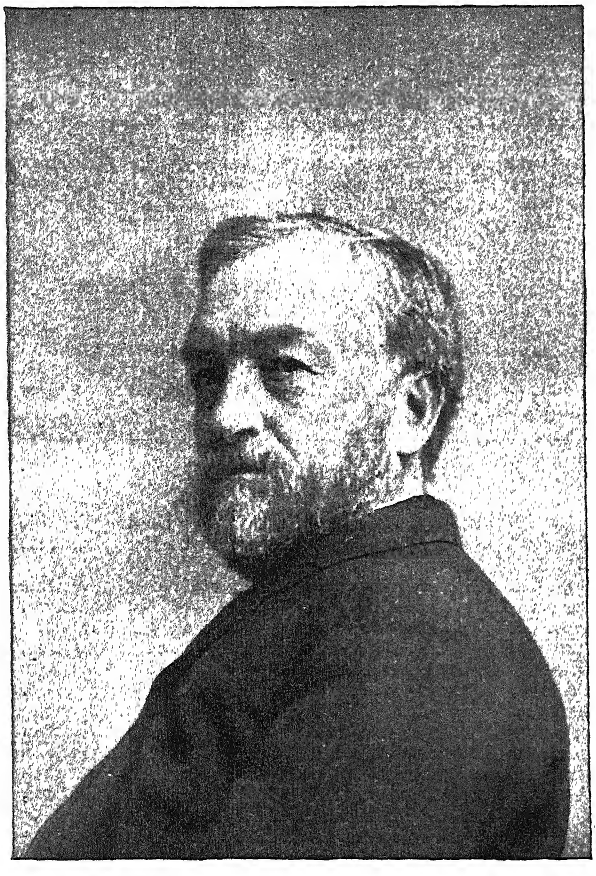

FIG. 5.—Samuel Pierpont Langley, Third Secretary of the Smithsonian Institution.

and well done, by other existing instrumentalities. So as occasion arose he lightened its load and saved its energies by giving over to other agencies some of its cherished work."

His statue, erected by order of Congress, stands in the Smithsonian Park.

Henry was succeeded in the office of Secretary by Prof. Spencer Fullerton Baird, then the leading authority on the mammals, birds, fishes, and reptiles of America, the founder of the U.S. Fish Commission, and of "public fish culture," elected in 1878; and he in his turn, by Samuel Pierpont Langley, pre-eminent as physicist and astronomer, the inventor of the bolometer, the discoverer of a great portion of the infra-red spectrum, and a high authority upon the physics of the atmosphere, elected in 1887.

Each of the three Secretaries, in addition to his general administrative work, has made some feature of the general plan peculiarly his own. Secretary Henry gave especial attention to the publications, the system of international exchanges, and the development of that great system of meteorological observation and weather prediction which has since become the Weather Bureau.

Secretary Baird continued the development of the museum, which had been under his special charge during his twenty-seven years of service as assistant secretary, secured the erection of the new museum building, gave much attention to zoological and ethnological explorations and, in connection with his special work as Commissioner of Fisheries, secured the construction of the exploring ship *Albatross*, and carried on extensive investigations in American waters.

To Secretary Langley is due the establishment of the Nationa Zoological Park and the Astro-physical Observatory, renewed activity in the library and exchange work, and a new system of encouragement of original research in the physical as well as the biological sciences. Under his administration, also, important donations and bequests have been added to the permanent fund of the Institution. The limit of 1,000,000 dols. which may by law be permanently deposited in the United States Treasury at 6 per cent., having nearly been reached, Congress has recognised the authority of the Institution to receive and administer other funds beyond this limit, thus making it possible for it to undertake the administration of financial trusts for any purpose within the scope of its general plan.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—A memorial is being circulated for the signature of members of the Senate, asking the Council of the Senate to sanction the formation of a Syndicate to consider on what conditions and with what restrictions, if any, women should be admitted to degrees in the University. It states that "for nearly fifteen years, since February 1881, the University has formally admitted the students of Girton and Newnham to its Honour examinations, and has practically co-operated in their instruction by permitting them to attend the lectures of its teaching staff, and to share the advantages of the University Library and other institutions. At the present time, eight out of the ten universities of Great Britain—viz., the University of London, the Victoria University, the new University of Wales, the four Scottish Universities, and the University of Durham—admit women to degrees. The result is that the women to whom Cambridge now awards only certificates, feel the inferiority of their position in this respect as compared with that of women who pass the examinations of these other Universities. Further, a committee of the Council of the University of Oxford was appointed some months ago to consider the desirability of granting degrees to the women students at Oxford, whose position is now somewhat similar to that of the students of Girton and Newnham. There seems, in short, to be a danger lest Cambridge—which twenty years ago was acting as pioneer in the movement for extending the advantages of academic education to women—should be actually the last to grant them the traditional and customary recognition of their work. The conditions under which degrees should be granted require very careful consideration. It is hoped that the syndicate of which we desire the appointment may be able to frame proposals which will command the assent of all who are interested in the academic education of women."

WE are informed that Mr. N. Busch has not been appointed Director of the Botanic Garden of the University of Dorpat, but assistant to Mr. N. Kuznetzov, formerly Assistant Secretary of the Imperial Russian Geographical Society, who has been also appointed Extraordinary Professor of Botany at the same University, instead of Dr. Russow retired.

DR. G. P. GRIMSBY has been appointed to the chair of Geology and Natural History in Washburn University; Dr. W. B. Rankin and C. F. W. McClure have been appointed to Professorships of Biology in the College of New Jersey; Dr. W. S. Strong has been called to the chair of Geology in Bates College, Lewiston, Maine; and Dr. R. de Girard, privat-docent in Geology at the Zürich Polytechnikum, has been promoted to an Extraordinary Professorship.

At the annual meeting of the Incorporated Association of Headmasters of Secondary Schools, held on January 8, two resolutions were passed with regard to science teaching, which it is to be hoped may bear fruit in the form of an improved method in many of our schools. At the previous annual meeting a discussion had taken place on the subject; and as a result of this a memorial was sent, in July of last year, to the authorities controlling the Local examinations of Oxford and Cambridge Universities, setting forth the desire that "examining bodies should encourage a more rational method of teaching science" by framing the syllabuses on different lines. A committee was also appointed to consider the subject, and this committee, consisting of men possessed of considerable experience in science teaching in secondary schools, has now presented its report. They agree with all scientific educationists in saying that a large proportion of the time given to science in schools should be occupied by the pupils in performing actual measurements themselves, and that the object should be to impart not only information but chiefly the knowledge of method, and with this object in view, that the instruction should be given in strictly logical order. To serve as a basis of discussion with the University authorities, the committee has put forth an admirable syllabus, which includes the more fundamental portions of physics and chemistry, and (an important point) which indicates what experiments can easily be performed by beginners. The syllabus represents a practical scheme of elementary science which will be appreciated by teachers, and which cannot be too widely adopted. It indicates the manner in which the study of science in schools may be made of true educational value, and in the interests of science it is to be hoped that examining bodies will give it full consideration. Examinations at present dominate our educational system, and it is almost hopeless to attempt to introduce into schools a scheme of instruction that does follow the lines laid down by examiners. But if a syllabus is rational, the teaching which follows it will possess good features. If, therefore, the logical syllabus drawn up by the Committee of the Headmasters' Association be adopted by the Delegacy for Local examinations of Oxford and Cambridge, an important step will have been taken in the advance of scientific education in this country.

SCIENTIFIC SERIALS.

American Journal of Science, December 1895.—How to find the key-note of auditoriums, by E. Cutter. If a speaker uses the key-note of his auditorium, the audience shows by attitude and attention that it hears what is said. The speaker speaks with ease, and feels his voice impinge upon the farthest walls. The key-note may be found by means of a siren, or by singing, and observing which note resounds most powerfully. The paper contains practical hints of some value to public speakers, but is unscientific in tone and substance.—Stratigraphy of the Kansas coal-measures, by Erasmus Haworth. The different formations lie one above the other in regular order, similar to the order found in other parts of the world. The general character of the shales throughout the whole of the coal-measures is such that they must have been deposited, in the main, in shallow water, probably ocean-water, as evidenced by the frequency of ripple-marks and other physical properties. The coastal area must have progressed westward as geological time advanced. The thickness of the Kansas coal-measures cannot be much less than 2500 feet.—Igneous rocks of Yogo Peak, Montana, by W. H. Weed and L. V. Pirsson. Yogo Peak is composed of a core or stock of massive, granular, igneous rock, composed chiefly of augite and orthoclase. The mass shows a progressive differentiation along its east and west axis, with a continual increase in the ferromagnesian elements over the felspathic ones.—A new alkali mineral, by Warren M. Foote. This mineral, named Northupite, after its discoverer, crystallises in regular octahedra, whose diameters rarely reach 1 centimetre. It is brittle, shows uneven fracture, and a hardness of 3·5 to 4. In powdering the mineral a fœtid odour is distinctly perceptible. It is easily fusible before the blowpipe, and its analysis indicates it to be a double chloride and carbonate of sodium and magnesium, with traces of phosphoric acid, silica, iron, calcium, and organic matter. It was found in the neighbourhood of the Borax Lake, California.—On the affinities and classification of the Dinosaurian reptiles, by O. C. Marsh. Twelve restorations of Dinosaurs are given, and a relation is traced between them and the Crocodilians.

Wiedemann's Annalen der Physik und Chemie, No. 12.—On the origin of frictional electricity, by C. Christiansen. Differences of potential created by contact between two metals were investigated by means of "drop electrodes," one terminal of the electrometer being connected with the upper reservoir of mercury, and the other with the lower, in which plates of a different metal were immersed. The gas through which the drops fall is of considerable influence. Platinum becomes more positive in hydrogen, and more negative in oxygen. Other metals become more negative in hydrogen.—Dielectric constants of mixtures and solutions, by Ludwig Silberstein. Given two perfect insulators, like benzol and phenylethylacetate, which mix in all proportions and do not contract in the process, the specific inductive capacity of the mixture may be found by taking the sum of the products of the two separate volumes into their specific inductive capacities and dividing by the total volume. This proposition was experimentally proved by Nernst's method, with induction coil and telephone.—On the passage of electricity through gases, by A. Paalzon and F. Neesen. This is the continuation of a highly-interesting paper on various obscure phenomena connected with discharge tubes. The medium in which the discharge tubes were immersed had a decided influence upon them. Immersion in water or alcohol extinguished the glow. This was not due to condensation, since the total current was diminished, and extinction took some time to set in. Electrification of the outer surface of the tube, or discharge of it by a flame or other means, or the approach of a charged piece of sealing-wax—in short, any motion of electricity in the neighbourhood, favoured the internal discharge. —Movable light phenomena in rarefied gases, caused by electric oscillations, by J. Ebster and H. Geitel. In a discharge tube surrounded by a conducting ring put to earth, and touching another conductor connected with a strong induction coil, a pencil of bluish light is formed at a vacuum of 0·01 to 0·001 mm. of mercury, ending in an intense green phosphorescent patch next the conductor, tapering as it passes through the ring, and ending somewhere in the gas space. The approach of a conductor or a magnet makes the pencil assume various shapes and positions.

SOCIETIES AND ACADEMIES.

London.

Royal Society, November 21, 1895.—"On the Variable Stars of the δ Cephei Class." By J. Norman Lockyer, C.B., F.R.S.

Prof. E. C. Pickering, in his classification of the variable stars, which is based on a study of the light curves (*Amer. Acad. Proc.*, vol. xvi. p. 17), recognises two classes of variables having short periods. His Class IV. includes those variables, exemplified by δ Cephei and β Lyræ, in which the light changes are not of very great range, and continue throughout the period. Class V. comprises those like Algol in which there is a temporary reduction of light at minimum, produced by the eclipse of the bright star by a relatively dark companion; this explanation has since been established by spectroscopic investigations, which have shown that there is no change in the spectrum at minimum, and that there is an orbital movement of corresponding period.

Excluding β Lyræ, which, as shown in the paper, is spectroscopically different from the others so far examined, it will be convenient to refer to the remaining variables of Pickering's Class IV. as those of the δ Cephei class, and it is with some of these that the present paper is concerned.

The available spectroscopic data with regard to the δ Cephei class were very meagre, and I therefore determined to investigate the spectra photographically, so far as the means at my disposal would permit. Five stars were studied, namely, η Aquilæ, ζ Geminorum, δ Cephei, T Vulpeculæ, and S Sagittæ.

Five very definite results have been arrived at:—

(1) The spectra of the five variables of this class which have been photographed are practically identical.

(2) The five variables in question are stars of increasing temperature.

(3) There is a general weakening of the continuous spectrum as the light of the star decreases.

(4) There are no indications of bright-line radiation at the positions occupied by the lines of hydrogen or helium at any part of the period in the case of these variables.

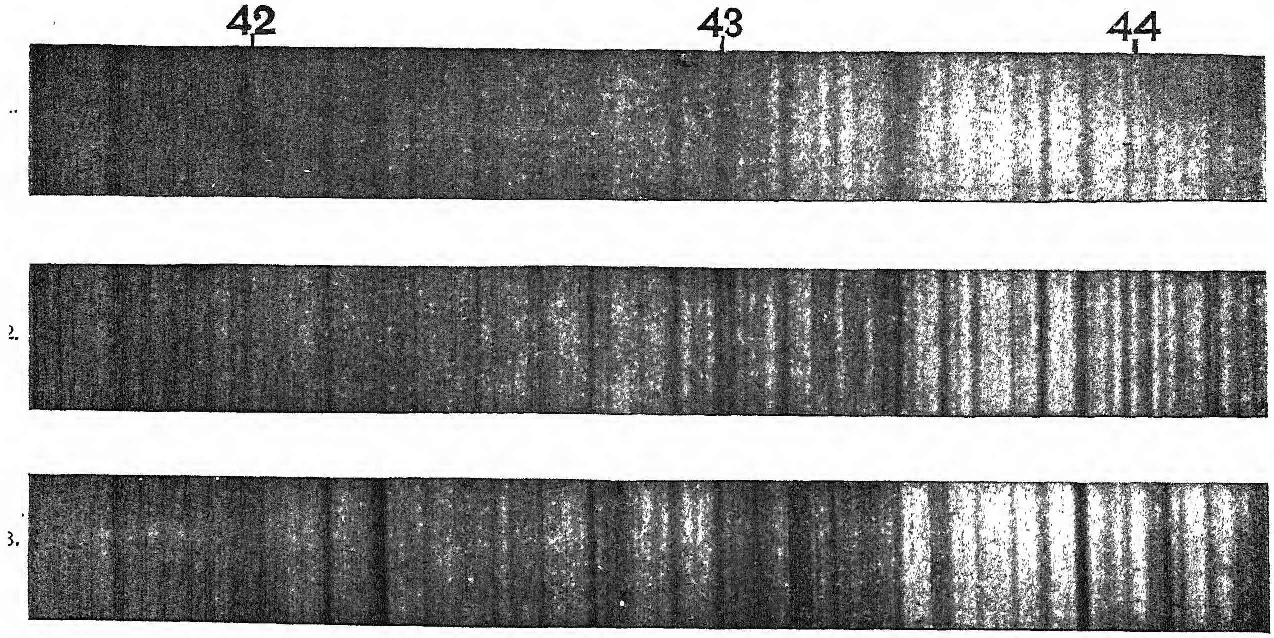
(5) There is no visible doubling of the lines in any of the photographs.

A portion of the spectrum of δ Cephei, at the time of maximum, is compared with the spectra of γ Cygni and Arcturus in the accompanying diagram. These have been enlarged about ten times from the original negatives taken at Kensington.

Taking Arcturus as a representative star of the solar type (*Phil. Trans.*, 1893, vol. 184, A, p. 699), it will be seen that although the spectra of γ Cygni and δ Cephei resemble it in showing a large number of dark lines, they differ considerably from it in point of detail.

Since the greater part of the foregoing was written, the results of a photographic study of the spectrum of δ Cephei, with special reference to its movement in the line of sight, have been published by Belopolsky (Imp. Acad. Sc., *St. Petersburg Bull.*, November 1894). Belopolsky differs from me in classing the star as a solar one, although he draws attention to numerous differences between the spectrum of the star and that of the sun.

He also finds, as I have found, that there is probably no change of spectrum corresponding to the light changes, except a general change of intensity.



1. δ CEPHEI 2. γ CYGNI 3. ARCTURUS

Linnean Society, December 19, 1895.—Mr. W. P. Sladen, Vice-President, in the chair.—Mr. William Scott was elected, and the Rev. T. R. Stebbing, Rev. H. P. Fitzgerald, and Mr. A. W. Geffcken were admitted Fellows of the Society.—Mr. W. B. Hemsley exhibited specimens and photographs of *Cacteæ* from the Galapagos Islands, and gave an account of some of the more remarkable species.—Mr. George Brebner exhibited and described, with the aid of microscope and lantern slides, several new and rare Algæ.—Mr. J. E. Harting exhibited a living specimen of the Snow Bunting (*Emberizu nivalis*), which had been captured, with several others, off Cape Race on board the s.s. *Ottoman* in October last, during the voyage from Boston to Liverpool, as mentioned at a former meeting (November 7).—Mr. R. A. Rolfe gave an abstract of a paper entitled "A Revision of the Genus *Vanilla*," in which some fifty species were enumerated, seventeen of which were new, though five of them had been previously confused with older forms. The plants in this genus were described as tall forest climbers, some of them leafless, found almost throughout the tropics, though generally somewhat local in their distribution. Of the species described, 29 were American, 11 Asiatic, and 10 African.—Mr. E. S. Goodrich communicated a report on the collection of Cephalopoda in the Calcutta Museum. He explained that this collection had been forwarded from Calcutta to Prof. Ray Lankester, at whose request he had undertaken to examine and report upon the species. It contained 162 specimens, almost all of which were collected in the Indian Seas, from the Persian Gulf to the coast of Australia, during the cruise of H.M.S. *Investigator*. Fifteen genera were represented, and several new species were described belonging to the genera *Chairotenthis*, *Histiopsis*, *Abralia*, *Loliolus* and *Faonius*. The paper was illustrated by original drawings.

PARIS.

Academy of Sciences, January 6.—M. A. Cornu in the chair.—M Chatin was elected Vice-President for 1896.—The retiring President (M. Marey) announced to the Academy how the vacancies arising in 1895 amongst the members and corresponding members had been filled up.—Note on the works of Mr. John Russell Hind, late correspondent of the Astronomical Section, by M. F. Tisserand.—An aneurism of the neck, face, and mouth treated by the sclerogenous method, by M. Lannelongue. An account of the successful treatment of a widespread aneurism by injections of zinc chloride solution (10 per cent.).—On the Calendar, by M. Flamant. A criticism of an alteration of the Gregorian rule for finding leap-year, suggested by M. Auric. The alternative proposed by the author, not to consider as leap-years the dates $(32)^n \times 100$, that is, 3200, 6400, &c., has the advantage of postponing any departure from the Gregorian rule for 1200 years. The length of the mean solar year deduced from this is only two-millionths of a mean solar day in excess of the truth.—On integral invariants, by M. G. Kœnigs.—On a method of splitting up some definite integrals into simple elements, by M. M. Petrovitch.—On the absolute values of the magnetic elements on January 1, 1896, by M. T. Moureaux. The absolute values and secular variation during 1895 of declination, inclination, horizonal and vertical intensity, and total force are given for the two observatories of Parc Saint-Maur and Perpignan.—The action of nitrogen peroxide on the halogen salts of tin, by M. V. Thomas. The reaction was studied in chloroform solution. Tin tetrachloride gave a crystalline substance of the empirical composition $Sn_4Cl_{14}.N_2.O_6$. This is hygroscopic, and is decomposed on heating. Tin tetrabromide gave $Sn_4.Br_6.N_2O_{10}$ as a white powder. The product obtained from the tetraiodide contained no iodine, and had the composition $Sn_5O_{11}(NO_3)_2 + 5H_2O$.—On a mode of decomposition of some amides and amido-compounds, by M. Œchsner de Coninck. An account of the results obtained on treating some aromatic amides and amido-

derivatives with an alkaline solution of sodium hypochlorite.—The *rôle* of the fever in the evolution of an infectious disease, by M. Cheinisse.—On serotherapy of tuberculosis, by MM. V. Babes and G. Proca. In the case of the animals used, chiefly dogs, immunity to virulent tuberculous injections was effected by treatment with tuberculin in increasing doses for several months, followed by subcutaneous injection in increasing doses of the dead bacilli that had already served for the preparation of the tuberculin.—On the embryonic membranes of the *Molgulæ*, by M. A. Pizon.—On the gills of the *Tetraclita porosa*, by M. A. Gruvel. The oxygenising surface of the gills is enlarged in a peculiar manner; instead of only one lamella, there are from eight to ten, of different sizes, according as they are at the ends or the middle of the gill, each of which is folded on itself in the most irregular fashion.—Note on *Mucor* and *Trichoderma*, by M. J. Ray. A description of a new species of mucor, to which the name of *Mucor crustaceus* is given, and of a parasite much resembling *Trichoderma viride*. This case of parasitism is accompanied by important modifications, both of the host and of the parasite: in the former, the mineral coating being largely increased, and its spores reduced in number; in the latter, appearance of a continuous structure, and reduction of the fructiferous apparatus.—On the yield of flour from wheat, and on whole-meal bread, by M. Balland.—On some French lakes, by M. A. Delebecque.—On the abyss of Gaping Ghyll, by M. E. A. Martel.

THURSDAY, JANUARY 23, 1896.

SOME RECENT WORKS ON BUTTERFLIES AND MOTHS.

A Handbook of British Lepidoptera. By Edward Meyrick, B.A., F.Z.S., F.L.S., F.E.S., Assistant Master at Marlborough College. (London: Macmillan and Co., 1895.)

British and European Butterflies and Moths (Macro-Lepidoptera). By A. W. Kappel, F.L.S., F.E.S. (Assistant Librarian, Linnean Society), and W. Egmont Kirby, L.S.A. With thirty coloured plates by H. Deuchert and S. Slocombe. (London: Ernest Nister, 1895.)

Die Artbildung und Verwandschaft bei den Schmetterlingen. II. Theil. Eine systematische Darstellung der Abänderungen, Abarten, und Arten der Schwalbenschwanz-ähnlichen Formen der Gattung Papilio. Von Dr. G. H. Theodor Eimer, Professor der Zoologie und vergleichenden Anatomie zu Tübingen. Unter Mitwirkung von Dr. K. Fickert, I. Assistent an der Zoologischen Anstalt daselbst. Mit 4 Tafeln in Farbendruck und 7 Abbildungen im Texte. (Jena: Gustav Fischer, 1895.)

LAST year was remarkable for the unusual number of publications on *Lepidoptera* which were issued from the press, especially in England. In addition to serial works and reprints, many independent works appeared, several of which have already been noticed in the columns of NATURE; and the three new books to which the present article refers, shows that the activity of entomologists in this direction is still as great as ever.

It is singular that, notwithstanding the great increase of interest taken in the British *Lepidoptera* of late years, Mr. Meyrick's is really the first serious attempt at a student's manual of the order which has yet appeared. We have any amount of popular illustrated books; but nothing beyond, except Stainton's "Manual of British Butterflies and Moths," a book nearly forty years old (though still of great value and much used, especially as it gave the only available synopsis of the *Micro-Lepidoptera*, which are generally neglected in popular works), and written rather for beginners than for students. Mr. Meyrick now offers us, in a compact volume of nearly 850 pages, a series of carefully drawn up descriptions of genera and species, with notices of localities, range, transformations, &c., and numerous systematic and phylogenetic tables; but there is not a trace of popular padding, and no illustrations, except occasional woodcuts of neuration.

As is known to all who have examined Mr. Meyrick's previous entomological writings (which have chiefly been devoted to the *Lepidoptera* of Australia and New Zealand), he attaches great importance to the neuration of the wings of the insects; and in the present volume he has adopted a new classification of his own, based mainly on the wing-neuration, which will appear to most of his readers little short of revolutionary. Suffice it to say that he divides the *Lepidoptera* into nine main groups, as follows: (1) *Caradrinina*, including the bulk of the species generally classed under *Arctiidæ*, *Liparidæ*, and part of *Noctuæ*; (2) *Notodontina*, including, in addition to the *Notodontidæ*, the *Saturniadæ*, *Sphingidæ*, *Geometræ*, and part of *Noctuæ*; (3) *Lasiocampina*, including also the *Drepanulidæ* and *Endromididæ*; (4) *Papilionina*, including the butterflies; (5) *Pyralidina* (from which group Mr. Meyrick believes the butterflies have branched), including also the Crambi and Plume moths; (6) *Psychina*, with which are included the *Zeuzeridæ*, *Zygænidæ*, and *Heterogenidæ*; (7) *Tortricina*, with which is included *Trypanus cossus*, L.; (8) *Tineina*, including also *Ægeriadæ*; and (9) *Micropterygina*, including the *Hepialidæ* and *Micropterygidæ*. Comment is needless; every one who knows our British *Lepidoptera* will recognise the sweeping character of the changes proposed; and how far they will ultimately be accepted, no one can venture to predict at present.

We will now turn to the second book on our list, which is a complete contrast to the last in design and execution. It is a handsomely got-up book intended for popular use, and illustrated with a series of excellent coloured plates, representing a considerable number of the more interesting and conspicuous butterflies and larger moths of Great Britain and the adjacent parts of Europe. All, or nearly all, the species not figured, but which fall within the limits of the book, are described in the text. No innovations of arrangement or nomenclature are attempted; and English as well as Latin names are used throughout. The book extends to the *Geometræ* inclusive; but it is more fully illustrated in the earlier groups than in the later. Useful information on technical terms, collecting and preserving, and other general matters connected with *Lepidoptera*, will be found in the introduction. This book may be safely recommended as a desirable addition to school libraries, or public institutions, or as a present to a young friend interested in natural history.

The last book on our list is one of a very different kind to the others. It is an elaborate philosophical study of the various forms presented by three groups of swallow-tailed butterflies, represented by *Papilio Turnus*, *Machaon*, and *Asterias*, in various parts of their range. These are mainly Palæarctic and Nearctic in their range. In the first volume of his work, published in 1889, Dr Eimer discussed the groups represented by *Papilio Podalirius*, *Antiphates*, *Anticrates*, *Ajax*, and *Policenes*, which are chiefly East Indian or African, though *P. Ajax* and its allies are American.

Dr. Eimer has come to the conclusion that natural selection will not account for the origin of species, though it may largely contribute to their preservation when already formed. This he expresses in a rather polemical preface, in which he claims to have practically demolished natural selection in the former sense. Perhaps it will be most fair to him to quote a paragraph, especially as it contains most of the technical terms which he uses in his work.

"In complete contrast to the teachings of Darwin, my butterflies everywhere display the origin of new peculiarities through orderly development in a few definite directions (Orthogenesis) on the basis of physiological causes, by organic increase (Organophysis). They show that it is really Genepistasis, or arrest of development at definite stages, which necessitates the separation into species of the organic chain which has

thus originated, and which is, in fact, the cause of the origin of species, independently of, and apart from other causes, discussed in the following pages, such as impediments to fertilisation (Kyesamechanism), and sudden development (Halmatogenesis)."

It is probable that various causes, acting unequally in different groups of animals and plants, have contributed to the origin and differentiation of species; and there is certainly much to be said in favour of the view that evolution proceeds along definite lines, and also that it is liable to be arrested at certain definite points. With respect to the latter phenomenon, we may refer to Dr. Leuthner's monograph of the *Odontolobidæ*, a family of East Indian stagbeetles, published in the *Transactions* of the Zoological Society for 1886, which illustrates this very clearly. It may also be observed in the common earwig.

Besides the discussion of the various points noted in the above-quoted paragraph, this work contains incidental remarks on the influence of heat and cold on butterflies reared artificially; and on mimicry, &c., as well as a reply to some criticisms by the late Dr. Haase on the first volume of the work.

While the philosophical part of the book will be read with interest by students of evolution, the special part, with its excellent illustrations of closely allied species and varieties, will be useful to collectors of foreign butterflies generally.

RECENT WORKS ON PHYSIOLOGY.

A Manual of Physiology. By G. N. Stewart, M.A., D.Sc., M.D.Edin. (London: Ballière, Tindall, and Cox, 1895.)

Physiology. By A. Macalister, LL.D., M.D., F.R.S. "Manuals of Science Series." (London: Society for Promoting Christian Knowledge, 1895.)

Elementary Physiology. By J. R. Ainsworth Davis, B.A. (London: Blackie and Son, 1895.)

WE have at the present time several very excellent text-books of physiology in English, adapted for the various needs of different classes of students. And to prevent these being inconveniently increased, it is a matter of tacit agreement amongst teachers of physiology that it is undesirable to afford a welcome to any new text-book, unless it has itself the highest claims to recognition. These claims may be based either upon some novel method of treatment of the subject, or upon the impression on the work of an author's high personal authority.

Adopting such a standard of criticism as the above, we first proceed to consider Dr. Stewart's manual. The fact of the author possessing so brilliant a reputation in the application of physics to physiology, is sufficient to make a work at his hands of the utmost value in certain branches of the subject. There are other influences to which Dr. Stewart has been exposed, which also tend to enhance the value of his work. The teaching methods of the Edinburgh school involve both conciseness and dogmatism, and these are as desirable in elementary instruction as they are pernicious in more advanced.

The manual which Dr. Stewart has written is to be regarded as an elementary *text-book*, for it is really something more than a mere *manual*. The methods throughout involve a concise expression of varying views, and the author's personal preference for any particular view is clearly indicated. Such a method we consider very desirable in a book of this character. As regards the facts incorporated, they include in general the very latest work that the time of publication permitted, and indicate an acquaintance with the progress of physiology as is possible only with a specialist in that branch of science. Interwoven with the academic exposition are detailed instructions for practical work. We have not very much faith in the success of this innovation. It is extremely inconvenient for a student to have to carry from his home to his laboratory a somewhat bulky volume, and the instructions are of no value except in the laboratory. We certainly think that it would have been much better to have omitted from such a book as this all practical instruction. We would like to offer some criticism also upon this practical instruction. It is to a considerable extent of such a character as to be impossible even to an American student, though Dr. Stewart dwells on the greater opportunities existing on the other side of the Atlantic for practical investigation. We have some doubts, also, concerning the advisability of introducing the so-called electro-physiology to the extent that has been done. It is not that too many pages have been allotted to it; on the contrary, if introduced at all, it requires many more than the author saw his way to give. The result is that, though so much has been referred to, it has been treated so briefly that the fault of brevity, vagueness, is only too apparent. We think that few students will derive the proper amount of information from this section unless it be largely supplemented by the personal instruction of a teacher.

For certain classes of students, however, the book will be of special service, and we think that it will undoubtedly be regarded as a valuable addition to our present text-books of physiology.

For Prof. Macalister's little manual we have nothing but praise. So much of elementary physiology as it is generally understood is identical with elementary anatomy that the physiologist is not at more advantage than the anatomist in describing the more elementary facts. A somewhat novel arrangement of the different points treated upon has been adopted. The author has commenced by describing the nature of food and digestion. This is already a matter of some slight acquaintance to one who has not studied physiology, and he is thus led on through partially familiar paths.

Sections then follow, treating of the blood, the circulatory system, respiration, the skeleton, joints, the nervous system, and the organs of the senses. A small amount of histology has also been introduced. The author throughout the book teaches valuable hygienic lessons from the explained phenomena. In a later edition a few corrections might be introduced; and when that is done, the book will be an excellent guide to the explanation of elementary physiological principles.

Mr. J. R. Ainsworth Davis's work is intended by the author (1) for elementary students in general; (2) for students of general biology who wish to supplement the subject on the physiological side; (3) students of psychology; (4) students of agriculture and dairying.

The necessities of these different classes of students had carefully to be borne in mind in writing the book, and consequently a work of somewhat peculiar character has been compiled. We think it undesirable that the aim of an author should be quite so far-reaching. The extensiveness is bound to detract from the value of the work for any particular class. As regards the matter actually in the volume, it is more elementary in character than that of Prof. Macalister's little book, though occupying about double the space. A redeeming feature of the work is the illustrations, which are judiciously chosen and very well executed. J. S. EDKINS.

OUR BOOK SHELF.

Practical Plane and Solid Geometry. By Joseph Harrison, M.I.M.E., A.M.I.C.E., and G. A. Baxandall. Pp. vi + 183. (London: Macmillan and Co., 1895.)

PRACTICAL geometry is taught primarily as an aid to systematic, accurate and rapid delineation of concrete objects, and, in most cases, it forms part of the student's work very early in his scientific or technical training.

In the organised science school the subject is taken contemporaneously with the first or first two books of Euclid; while the student in a technical school almost invariably goes through his elementary course of practical geometry before he arrives on the other side of the *pons asinorum.* This seems to be hardly logical, for the more important problems in practical plane geometry to be found in elementary text-books depend on propositions in Euclid's third and sixth books; and the early problems in solid geometry are based on theorems in the eleventh book; but in the majority of technical classes it is in the nature of things that practical geometry must be taught where Euclid's sixth and eleventh books are practically sealed. It is imperative that every student should be satisfied with the foundation upon which his future work is to be built; and the truth of theorems, which have such general application as that of similar triangles, must be made apparent at the outset; and with beginners, this can best be done experimentally. It is rarely that the author of a text-book is bold enough to advocate the experimental demonstration of the truth of a law in geometry, though that is almost the only method in many other branches of science.

In the little work before us, Messrs. Harrison and Baxandall have so far deviated from the beaten track as to get through a good deal of their work without some of the usual cumbrous and, to beginners, unintelligible definitions; and have added, in the form of an appendix, some theorems and definitions that may be found useful in a second reading. Some new problems have been introduced in the first and second chapters, which are devoted to plane geometry and graphic arithmetic respectively. The authors have wisely condensed the whole of the former into one chapter; and though one may be considered pedantic for saying so, there are still left in some problems that can hardly be called by the first word of the title-page. It is with great satisfaction that we notice the absence of any attempt to introduce statics with the graphic arithmetic. Too much can hardly be said in favour of graphic statics in its proper place; but when taught without any reference to the laws of equilibrium, it is not only useless but harmful.

The student is gradually led on to the study of solid geometry by a series of well-chosen diagrams and figures, and becomes well-grounded in the orthogonal projection of solids before he approaches the usual oblique line and plane problems. The figures in the text are bold, clear, plentiful and well-lettered; and this is a feature which, if lost sight of, causes much inconvenience and annoyance.

Altogether this is a work which is very carefully compiled, and from which a student can extract for himself a great deal of information without outside assistance.

A Treatise on Hydraulics. By Prof. Henry T. Bovey. Pp. viii + 336. (New York: John Wiley and Sons. London: Chapman and Hall, 1895.)

THE contents of this book formed the subject-matter of a series of lectures on hydraulics, delivered by the author at McGill University, Montreal; and though chiefly intended for students, it will doubtless prove valuable for reference to hydraulic engineers. The book deals with the experimental theory of the motion of water, its flow in pipes and open channels, and its practical application to hydraulic motors. The subject is divided into seven chapters, treating successively of flow through orifices and over weirs, fluid friction, flow in pipes, flow of water in open channels, methods of gauging, impact, and hydraulic motors and centrifugal pumps. The matter is, for the most part, treated mathematically; and the book will be mainly useful to persons who have studied mathematics; whilst numerous examples are appended at the end of most of the chapters, together with their answers, which will give students facility in working out hydraulic problems, and enable them to acquire a more thorough grasp of the principles enunciated. One hundred and ninety-six simple diagrams and drawings serve to illustrate and elucidate the text; and the book, being clearly and concisely written, will enable the intelligent reader, with some knowledge of mathematics, to obtain a deeper insight into the theory of hydraulics, and the principles of its application to practical purposes. The short chapter on gauging the velocity of flow in open channels, describes briefly and practically the different instruments used for the purpose; whilst the long final chapter, on hydraulic motors, explains, with the aid of formulæ, the principles involved in the hydraulic ram, pressure-engines, the accumulator, hydraulic brakes, the various forms of water-wheels and turbines, and centrifugal pumps.

The Scientific Foundations of Analytical Chemistry. By Wilhelm Ostwald, Ph.D. Translated by George McGowan, Ph.D. (London: Macmillan, 1895.)

THE peculiarly interesting character of this book has already been pointed out in the review of the German edition (see NATURE, vol. li. p. 482), and Dr. McGowan's translation now places its doctrines within the reach of English readers.

The only alteration made by the author upon the original edition, is the introduction of a portion of a chapter on the theory of electrolytic methods of analysis. This includes an account of the mode in which the processes of oxidation and reduction occurring in voltaic cells, and the order in which metals separate from a mixture of electrolytes under the influence of a definite external electromotive force, can be correlated with the potential differences given by the metals and the electrolytes used. J. W. R.

Elementary Algebra. By J. W. Welsford, M.A., and C. H. P. Mayo, M.A. Pp. xiii + 407. (London: Longmans, Green, and Co., 1895.)

SINCE, in its early stages, algebra is a generalisation of arithmetic, the authors give a short account of some of the processes of arithmetic, as an introduction to their subject. The book differs in character and arrangement from most text-books on algebra: for instance, the radical sign is explained at the same time as the positive integral index; factors are freely used; a table of logarithms is introduced; and oral exercises are given. There are about four thousand examples to test the student's knowledge, and impress the book-work upon his memory.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On Röntgen's Rays.

PROF. RÖNTGEN'S remarkable discovery will materially affect our views concerning the relation between the ether and matter; but further experimental evidence is required before any opinion can be expressed as to the character of the rays, which behave in so straightforward a manner that they seem to upset all one's notions of the laws of nature. Prof. Röntgen, on the strength of his carefully-conducted experiments, has arrived at a conclusion adverse to the idea that the rays only differ from light rays by the smallness of wave-length. Perhaps the following considerations may show that the evidence is not conclusive in this respect.

Röntgen's rays are not kathode rays—there can be no doubt on that point—but they are generated at the point of impact between the kathode ray and solid substances.

The discoverer has not been able to obtain any interference effects, possibly, as he says, owing to the weakness of the radiation. An absence of interference would not, however, be sufficient to show that the radiation is not of the nature of ordinary light, but only that it does not possess sufficient regularity, or, in other words, that the disturbance is not sufficiently homogeneous. That this is the case is not at all improbable, for the radiation is produced by an impact, which in the first instance may be an impulsive motion propagated outwards, and after passing through the screen, would only possess such regularity as is impressed on it by the absorption of the longer waves.

The great argument against the supposition of waves of very small length lies in the absence of refraction; but is this conclusive?

When we speak of the size of the atoms, we mean their distance in the solid and liquid state. The properties of the ether may remain unaltered within the greater part of the sphere of action of a molecule. The number of molecules lying within a wave-length of ordinary light is not greater than the number of motes which lie within a sound-wave, but, as far as I know, the velocity of sound is not materially affected by the presence of dust in the air. Hence there seems nothing impossible in the supposition that light-waves, smaller than those we know of, may traverse solids with the same velocity as a vacuum. We know that absorption bands greatly affect the refractive index in neighbouring regions; and as probably the whole question of refraction resolves itself into one of resonance effects, the rate of propagation of waves of very small lengths does not seem to me to be pre-judged by our present knowledge. If Röntgen's rays contain waves of very small length, the vibrations in the molecule which respond to them would seem to be of a different order of magnitude from those so far known. Possibly we have here the vibration of the electron within the molecule, instead of that of the molecule carrying with it that of the electron.

I should like, further, to express a certain sense of satisfaction that Röntgen's rays are not deflected in a magnetic field. They are thus clearly separated from kathode rays. The idea that kathode rays are due to vibrations has become fashionable; yet the fact that the magnet deflects them just as it would an electrified molecule, has always seemed to me to be conclusive against this view. No one has, so far, given any plausible reason why a ray of *invisible* light should be able to run round in a spiral, while a ray of *visible* light goes straight; and, so far, Röntgen's rays behave as we should expect well-conducted vibrations to do.

It is not my intention to argue in favour of any particular theory, or against Röntgen's suggestion that we have at last found the formerly missed longitudinal wave. I only desire to put those points forward which at first sight seem to go against the supposition of ordinary light vibrations, and to raise the question whether they constitute an insuperable difficulty.

ARTHUR SCHUSTER.

IN connection with the wonderful discovery by Prof. Röntgen of photographic rays, apparently hitherto unknown, and in connection with the speculation which concludes Prof. Röntgen's most interesting paper, that these rays may perhaps be longitudinal vibrations of the luminiferous ether, the following extracts will probably be found of interest to the readers of NATURE. They are taken, by permission of Lord Kelvin, from his Baltimore Lectures, delivered at the Johns Hopkins University in 1884.

The first extract is from the reprint (now in progress) of Lecture IV. Referring to mathematical work immediately preceding, Lord Kelvin says:—". . . We can do that [obtain certain forms of solutions of equations] for the purpose of illustrating different problems in sound, and in order to familiarise you with the wave that may exist along with the wave of distortion in any true elastic solid which is not incompressible. We ignore this condensational wave in the theory of light. We are sure that its energy, at all events, if it is not null, is very small in comparison with the energy of the luminiferous vibrations we are dealing with. But to say that it is absolutely null, would be an assumption that we have no right to make. When we look through the little universe that we know, and think of the transmission of electrical force, and of the transmission of magnetic force and of the transmission of light, we have no right to assume that there may not be something else that our philosophy does not dream of. We have no right to assume that there may not be condensational waves in the luminiferous ether. We only do know that any vibrations of this kind, which are excited by the reflection and refraction of light, are certainly of very small energy compared with the energy of the light from which they proceed. The fact of the case as regards reflection and refraction is this, that unless the luminiferous ether is absolutely incompressible, the reflection and refraction of light must generally give rise to waves of condensation. Waves of distortion may exist without waves of condensation, but waves of distortion cannot be reflected at the bounding surface between two mediums without exciting in each medium a wave of condensation. When we come to the subject of reflection and refraction, we shall see how to deal with these condensational waves, and find how easy it is to get quit of them by supposing the medium to be incompressible. But it is always to be kept in mind as to be examined into, are there or are there not very small amounts of condensational waves generated in reflection and refraction, and may, after all, the propagation of electric force be by these waves of condensation?

"Suppose that we have at any place in air, or in luminiferous ether (I cannot distinguish now between the two ideas) a body that, through some action we need not describe, but which is conceivable, is alternatively positively and negatively electrified; may it not be that this will give rise to condensational waves? Suppose, for example, that we have two spherical conductors united by a fine wire, and that an alternating electromotive force is produced in that fine wire, for instance by an 'alternate current' dynamo-electric machine; and suppose that sort of thing goes on away from all other disturbance—at a great distance up in the air, for example. The result of the action of the dynamo-electric machine will be that one conductor will be alternately positively and negatively electrified, and the other conductor negatively and positively electrified. It is perfectly certain, if we turn the machine slowly, that in the air in the neighbourhood of the conductors we shall have alternately positively and negatively directed electric force with reversals of, for example, two or three hundred per second of time with a gradual transition from negative through zero to positive, and so on; and the same thing all through space; and we can tell exactly what the potential and what the electric force is at each instant at any point. Now, does any one believe that, if that revolution were made fast enough, the electro-static law of force, pure and simple, would apply to the air at different distances from each globe? Every one believes that if that process be conducted fast enough, several million times, or millions of million times per second, we should have large deviations from the electro-static law in the distribution of electric force through the air in the neighbourhood. It seems absolutely certain that such an action as that going on would give rise to electrical waves. Now it does seem to me probable that those electrical waves are condensational waves in luminiferous ether; and probably it would be that the propagation of these waves would be enormously faster than the propagation of ordinary light waves.

"I am quite conscious, when speaking of this, of what has been done in the so-called electro-magnetic theory of light. I know the propagation of electric impulse along an insulated wire surrounded by gutta-percha, which I worked out

myself about the year 1854, and in which I found a velocity comparable with the velocity of light. We did not then know the relation between electro-static and electro-magnetic units. If we work that out for the case of air instead of gutta-percha we get simply v (that is, the number of electro-static units in the electro-magnetic unit of quantity) for the velocity of propagation of the impulse. That is a very different case from this very rapidly varying electrification I have ideally put before you, and I have waited in vain to see how we can get any justification of the way of putting the idea of electric and magnetic waves in the so-called electro-magnetic theory of light.

"I may refer to a little article of mine in which I gave a sort of mechanical representation of electric, magnetic, and galvanic forces—galvanic force I called it then, a very badly-chosen name. It is published in the first volume of the reprint of my papers. It is shown in that paper that the static displacement of an elastic solid follows exactly the laws of the electro-static force, and that rotatory displacement of the medium follows exactly the laws of magnetic force. It seems to me that an incorporation of the theory of the propagation of electric and magnetic disturbances with the wave theory of light is most probably to be arrived at by trying to see clearly the view that I am now indicating. In the wave theory of light, however, we shall simply suppose the resistance to compression of the luminiferous ether, and the velocity of propagation of the condensational wave in it, to be infinite. We shall sometimes use the words 'practically infinite' to guard against supposing these quantities to be absolutely infinite."

The second extract which I give is from p. 143 of the Papyrograph edition of the "Baltimore Lectures"—a portion not yet reprinted.

"The want of indication of any such actions is sufficient to prove that if there are any in nature, they must be exceedingly small. But that there are such waves, I believe, and I believe that the velocity of propagation of electro-static force is the unknown condensational velocity that we are speaking of.

"I say 'believe' here in a somewhat modified manner. I do not mean that I believe this as a matter of religious faith, but rather as a matter of strong scientific probability."

13 University Gardens, Glasgow, January 16.

The Astronomical Theory of the Ice Age.

MAY I first acknowledge the gentle kindliness with which my early teacher and friend, Sir Robert Ball, has pointed out my error in quoting from the old edition of his work. I much regret that I did not make further inquiries, but I was satisfied when the library clerks at Trinity College, Dublin, told me that if there had been any alteration in the text, they would have received a copy of the second edition. It appeared from Sir H. Howorth's letter that the mistake originated with the publishers, who erroneously informed the library agent that the second edition was a mere reprint, and therefore refused to supply a copy.

Both Sir Robert Ball and Dr. Wallace, in their letters in NATURE of January 9, have misunderstood the way in which I present my argument. If Dr. Wallace would read my papers again, I think he will see that, so far as I am concerned, the whole of his letter is founded on a complete misapprehension; and Sir Robert Ball will, I hope, also agree that he has somewhat altered the form in which I have stated my conclusions, and that I have fully recognised the difference which he thinks I have ignored. But as the matter really at issue is the present position of the astronomical theory, I may be excused from discussing this misunderstanding further, for even if every word of their criticisms on my conclusions were valid, the astronomical theory, *as it issued from the labours of Croll and Ball*, would be in no better position than before. Whether I am right or wrong in my belief that the astronomical factor cannot have been the principal one, I venture to think there can be no doubt that the existing exposition of that theory must be given up.

The foundation of the astronomical theory is the fall in temperature *directly* due to diminished sun-heat. Croll and Ball accordingly give calculations which indicate a large fall. Croll gets 45·3° F. for the lowering of mid-winter temperature in Great Britain during the long excentric winter, and Ball's modification of Croll's method gives about 25° F. as the lowering of the winter temperature. The first five pages of my article in the *Phil. Mag.* for December 1894 are devoted to showing that there is no justification for the principle on which this calculation is made, and that the fall must be a mere fraction of that postulated in either exposition of the astronomical theory. The chief flaw in the calculation is, curiously enough, that which Sir Robert and Dr. Wallace erroneously attribute to me, viz. that of considering that changes in terrestrial temperature are directly proportional to the changes in sun-heat, and ignoring the important element of storage and transference by ocean and air currents. How unsafe this is may be judged from the fact that if the method used to calculate the temperature in the Glacial Age from that in the present day were applied to find the summer temperature from the winter temperature, we should find for the British Isles a summer temperature of above 300° F. if we take Ball's hypothesis, and some thousands of degrees Fahrenheit if we take Croll's. If we calculate the winter temperature from the summer one, we should get − 125° F. for our winter temperature. A method which gives results in such striking contrast to the truth can hardly be accepted as a basis for a scientific theory.

If, therefore, this first portion of my criticism be correct (and hitherto no attempt has been made to refute it) the astronomical hypothesis is in just the position it would occupy if neither Croll's nor Ball's book had been written. So far, *the hypothesis itself* may be true or false; it is only the *reasoning* which has been put forward in its support that has to be abandoned or modified. The theory is, as all will admit, a tempting one, and accordingly I sought for some other means of establishing it. After several fruitless efforts to hit on a fairly satisfactory method of estimating the *direct* effect of an altered distribution of sun-heat on terrestrial temperatures, the method which Prof. Darwin has described occurred to me, and from it, *combined with a discussion on the transference of heat by the Gulf Stream* (see *Phil. Mag.* December 1894, p. 548 and p. 551), I was led to infer that for the British Isles at least the glaciation could not with any degree of probability be attributed to the long winter of great excentricity.

Sir Robert Ball's views, as presented in his letter, seems to involve a return to Croll's point of view, at least to the extent that the purely astronomical reason requires to be supplemented by a discussion of the oceanic and atmospheric currents. This view appears to me a true one; the only hope for the astronomical theory would be to show that the adjustment of terrestrial temperatures by the interaction of ocean and air currents with direct sun-heat is such that a very slight alteration of sun-heat produces a very great alteration of temperature; so that if the sun-heat which falls on Cornwall in winter were to be reduced to that which falls on Yorkshire, with corresponding changes for the temperate latitudes, and somewhat greater ones for the tropical belt, the ultimate result would be an Ice Age. But how can we hope to establish such a theory when we remember what a comparatively small change of temperature is due to the far greater changes of sun-heat from equator to pole as summer gives way to winter? EDWD. P. CULVERWELL.

Trinity College, Dublin, January 14.

Changes of Length in Bars and Wires of Magnetic Material due to Magnetisation.

THE appearance of a paper, by Dr. L. T. More, on the changes in length produced in iron wires by magnetisation (*Phil. Mag.*, October 1895, p. 345, and *Physical Review*, vol. iii. p. 210), has drawn my attention to a curious divergence of opinion on a fundamental point in magnetism. Dr. More has attempted to analyse the change of length accompanying magnetisation into a "*direct action*" which "may possibly be due to the orienting of the magnetised particles," and to "indirect actions." He adds (p. 224): "These indirect actions are the mechanical stresses created in the rod by the magnetism. The first of these . . . is the tractive force of the magnet and is measured by $B^2/8\pi$. That this force exists, tending always to *contract* the rod (italics mine), is seen from the fact that if the magnet is cut in two, the ends are held together. . . . This effect for high intensities of magnetisation is a large one, and becomes one of the most important factors in the observed changes in length." The stress referred to by Dr. More is that usually associated with the name of Maxwell ("Electricity and Magnetism," vol. ii. Arts. 641 *et seq.* *Cf.* Ewing, "Magnetic Induction in Iron and other Metals," § 147).

The first to propound the view adopted by Dr. More—that the mechanical force tends to *shorten* the rod—would seem to be

Mr. Shelford Bidwell (*Phil. Trans.*, 1888, pp. 216–7). He has been followed by Prof. Ewing, on pp. 242–3 of his "Magnetic Induction."

On the other hand, Maxwell, *l.c.*, speaks of a *tension* along the lines of force, and even more explicit statements to the same effect are due to Kirchhoff (*Wied. Ann.*, Bd. 24, p. 52, and Bd. 25, p. 601) and Prof. J. J. Thomson ("Applications of Dynamics to Physics and Chemistry," p. 52). The latter says: ". . . there are the strains arising from Maxwell's distribution of stress. Kirchhoff has investigated the effect of this on a small soft iron sphere placed in a uniform magnetic field and has shown that it would produce an *elongation* . . . along the lines of force and a contraction at right angles to them. We may therefore assume that in general this distribution of stress causes an *expansion* . . . in the direction of the lines of force . . ." (italics mine).

Prof. Thomson's view was accepted and restated by myself in discussing the phenomena in cobalt (*Phil. Trans.*, 1890, p. 339). The fact that my views escaped Dr. More's notice is not surprising, but it is strange that he overlooked Prof. Thomson's statement, and that I overlooked Mr. Shelford Bidwell's. My belief now, as before, is that the view of Kirchhoff and J. J. Thomson is the correct one.

Let us take the case of a long iron bar magnet suspended vertically. Suppose it cut in two transversely at a section A; then, supposing the magnetism sufficiently intense, the lower portion will, we know, adhere to the upper until a considerable weight, W, is hung from the lower end, B. If w be the weight of AB, the magnetic force over A must balance $W + w$, acting downwards, and so must itself act upwards, or away from AB. In other words, the magnetic force across A acts precisely like the elastic stress across a section of a rope fastened at one end and pulled at the other. The rope, as every one will realise, is under tension not pressure, and so clearly is the iron bar.

A more general way of looking at the matter is as follows:

A′ A B B′

$-m$ | $+m$ $-m$ | $+m$

Take imaginary sections A and B of a long uniformly magnetised straight or bent bar, and regard coterminous surfaces AA′ and BB′ as separated by distances small compared to AB. Taking the usual elementary theory, we see the force acting on the distribution $+m$ over A is $F - F' + F''$ to the *left*, where F arises from $-m$ over A′, $-F'$ from $-m$ over B, and F'' from $+m$ over B′. Now clearly F' and F'' are approximately equal, and each is small compared to F, so that A is obviously pulled to the left. Similarly B is pulled to the right, or AB is under tension.

Of course if the bar, when supported horizontally on a frictionless table, were actually cut through at A, foreign material—a finger, for instance—inserted between the naturally coterminous surfaces A and A′ would experience compression. I cannot avoid the conclusion that Mr. Shelford Bidwell and Dr. More have fallen into confusion through regarding the problem from this point of view, forgetting that the surfaces supposed to attract one another have nothing between them to squeeze.

That the question is of vital importance to a true understanding of the phenomena in iron is unquestionable if Dr. More's experiments—which seem carefully designed—gave anything like the true results. A reversal of the sign in his correction $B^2\delta l/8\pi l$ in his tables I. to IV.—necessitated by the view I advocate—would completely alter the character of the physical deductions to be made. The occasion for the correction, I may add, is as clearly indicated by Mr. Shelford Bidwell as by Dr. More, but the experimental data obtained by the former led him to attach less importance to it.

It is not my intention to discuss the actual magnitude of the magnetic stress or of the consequent alteration in length. An interesting experimental paper on the former subject by Mr. E. Taylor Jones, with references to recent conflicting authorities, appeared in the *Phil. Mag.*, March 1895, pp. 254–267. I may say, however, that the theoretical importance of investigations such as those of Prof. J. J. Thomson into the mutual relationships of magnetism and elasticity renders it all the more desirable that any doubt as to the true nature of the experimental results should be removed. To be altogether satisfactory, these investigations require trustworthy magnetic and elastic data for one and the same specimen.

C. CHREE.

January 11.

The Metric System.

MR. BROOK-FOX does not state accurately, in his letter to NATURE of January 9, what passed in relation to legislation on the subject of Weights and Measures in British India in the years 1870–1871.

It is true that an Act was passed in April 1870, enabling the Governor-General in Council to require the use of the Metrical Weights and Measures by Government departments, railway or other companies, registered under the law relating to such companies, and persons exercising specified occupations or trades; but only after certain preliminary steps had been gone through.

This Act was disallowed by the then Secretary of State for India, the Duke of Argyll, who had at first authorised legislation on the subject, in the general direction given to this Act, but considered that the actual form in which the measure was passed went beyond his original instructions, as it might have been extended to the dealings of persons engaged in business or trade, and was otherwise considered to be too drastic. Objection was also taken to the inclusion of the metre as the standard of length, the original authority to legislate having been limited to the adoption of the kilogramme as the unit of weight.

Immediately on the receipt of the Secretary of State's disallowance of the Act of 1870, a new permissive Bill was prepared, extending only to the standard of weight, which was again stated to be the kilogramme, and of measures of capacity which are subsidiary to those of weight; and limited, as to the power of applying it, to the case of Government departments, municipal bodies, and railway companies.

This measure became law as Act xxxi. of 1871, and is still in force. But it has never been put into operation. This, however, was not the result of the Duke of Argyll's action, but of the change of policy that followed on Lord Mayo's most unfortunate murder. Had Lord Mayo lived, he would certainly have given effect to the Act, the importance of which he thoroughly recognised. His successor was of a different opinion, and the combination of circumstances that for the moment appeared to have rendered possible the introduction of a rational system of weights and measures into our Indian Empire, passed away, and has not yet returned.

As having had charge of the Bill of 1870, in the Council of the Governor-General, I may be permitted, in conclusion, to quote the words that I wrote twenty-five years ago with reference to the fears expressed by the Secretary of State as to the danger of precipitate action in such a matter as this.

"The history of this very Act regarding weights and measures, which has been under consideration in one form or other for not less than fourteen years, which in its last stage has taken seven or eight years in coming to maturity, and to carry out the provisions of which no measures have yet been taken, or can be taken in all probability for another year at least, seems to me to teach that the one thing perfectly certain in the future is that the progress made in giving effect to any change in the present case will be slow in a degree most painful to all who are concerned in it; and that what with active opposition, and what with indifference, this Act is far more likely to remain a dead letter on the statute book for an indefinite period, than to be brought into operation with improper haste."

January 13. RICHARD STRACHEY.

Marsupial with an Allantoic Placenta.

I HAVE just received from my friend and former pupil Mr. J. P. Hill, Demonstrator of Biology in the Sydney University, an advanced copy of the *Abstract of Proceedings* of the Linnean Society of New South Wales for November 27, in which he announces the discovery of a true allantoic and highly vascular placenta, of a discoidal and most probably deciduous type, in the Bandicoot (*Perameles obesula*).

In the second part of his magnificent "Forschungsreisen im Australien und dem malayischen Archipel," Prof. R. Semon has substantiated the discovery of apposition between the allantois and sub-zonal membrane in *Phascolarctus*, and shown that a fusion is effected. He points out that the fœtal appendages of that animal are of a type involving certain Marsupialia in a position intermediate between the Placentalia on one hand, and the Monotremata and Sauropsida on the other, and regards the earlier recognised Marsupial condition, in which the allantois is remote from the serous membrane, as secondary and associated with the loss of a respiratory function by that organ.

The condition described by Mr. Hill in *Perameles* is one of natural advance upon the Phascolarctus type, and the facts in proof of the intimacy of relationship between the Placentalia and Lower Mammalia now overlap, like those bearing on birds and reptiles—*i.e.* just as *Archæopteryx* may be regarded as an avian reptile, and the Odontorinthes as reptilian birds—so the *Phascolarctus* may be regarded as a Placental Marsupial, and those placentalia which develop a provisionally vascular yolk-sac extending to the serous-membrane as Marsupial if not Monotrematous Placentalia. Mr. Hill's discovery, coming close upon that of Woodward that the young of the Diprotodontia are found to develop at fewest five pairs of upper incisors, and of Thomas that a representative of the Epanorthidæ survives in South America, and at a time when the tooth-genesis of both Marsupialia and Placentalia is receiving exceptional attention, is as welcome as important, in assisting us to form a clearer conception of the inter-relationships between these mammals.

Mr. Hill's observation would appear to lend not a little support to the conclusion which has for years been steadily gaining ground (*cf.* NATURE, vol. xl. p. 420), that the allantoic placenta was primitively discoidal. In an accompanying letter, he informs me that he has more recently come into possession of a uterus containing an unattached blastodermic vesicle; and it is sincerely to be hoped that he will be able to furnish observations bearing directly upon the important question of the supposed primitively chorionic nature of the Mammalian placenta.

G. B. HOWES.

Royal College of Science, London, January 14.

The Origin of Plant Structures.

MAY I call attention to a serious omission, and reply to one or two points, in Mr. Barber's review of my book? He says: "Of the *inheritance* of such acquired characters there is no proof at all. We are offered instead the 'argument of coincidences' and the 'cumulative evidence of probabilities, which amounts to a moral conviction.' Clearly, before rejecting a well-established and widely applicable hypothesis, something more tangible is required" (NATURE, December 19, 1895, p. 145).

First, with regard to inheritance. Mr. Wallace also asked for some proof of this; and I reply again that nature herself supplies it; for plant structures *are* reproduced by seed every year. It is the previous question, "How have they arisen?" with which I am concerned. But I *have*, in fact, given plenty of cases: as in my experiment with *Ononis*, Buckman's parsnip, Flahoult's with alpine plants, &c.

Moreover, the objector should state whether he means that any altered features in a plant should be reproduced by seed irrespective of the environment, or not. If a plant changes under new conditions—as ample experience shows it may—of course all its offspring will follow suit, under the same environment, irrespective of heredity; and if the conditions be maintained long enough, *then* the new features will tend to become relatively fixed, as all cultivators know. As long, however, as a natural environment is constant, no varieties are, as a rule, to be expected. Under cultivation, this rule does not hold good. Thus, *e.g. Brassica oleracea* gives rise to no varieties in nature; but there are very many fixed and hereditary races in artificial soils.

Secondly, the truth of an hypothesis or deduction cannot be more surely established than by "verification by experiment." Thus, with desert, aquatic, alpine, maritime, and other plants, I not only established the truth of my contention by *induction*, but have given the experimental verifications both of others and myself. For *this* fact Mr. Barber gives me no credit. It is in these two lines of proof, viz. by *induction* and *experiment*, that the theory of "the origin of species by means of natural selection" is wanting. It is, as Mr. Barber says, based on an "assumption," and is an *à priori* deduction that, because plants can vary indefinitely under cultivation, therefore they do so also in nature. *This has never been verified.*

Mr. Barber adds: "It is usually agreed that, from the nature of the case, a definite proof of the action of natural selection is difficult, if not impossible, in the present state of our knowledge." Is not this a most damaging admission? If the word "present" has to cover the thirty-six years since the "Origin" appeared, it would seem to be about time to abandon the theory even as a working hypothesis. The "wideness of its application" is no test of the truth of a deduction; for though natural selection may account for all organic structures, it can only do so because it is *assumed* that it can account for them. Herein it agrees precisely with the theory of special creations; which is equally assumed to be capable of accounting for every organic structure.

Mr. Barber tells me that I show a want of good taste in "narrowing" Darwin's field of observation. I much regret that anything I have written should be regarded as uncourteous; but it is Darwin himself who admits the "imputation," for he wrote: "I will give in detail all the facts which I have been able to collect," *i.e.* of "definite action" in plants, and mentions about thirty instances which he had heard of. He did not believe in definite variation being the rule in nature.

Lastly, I make no claim "to reconstruct the theory of evolution." All I have done is to take the following passage of Mr. Herbert Spencer's Essay on "The Development Hypothesis" (published in 1852, seven years before Darwin's "Origin" appeared) as my subject; and I have simply verified its profound truth in its application to plants. "The supporters of the developmental hypothesis can show . . . that any existing species—animal or vegetable—when placed under conditions different from its previous ones, immediately begins to undergo certain changes of structure fitting it for the new conditions . . . that in successive generations these changes continue until ultimately the new conditions become the natural ones. . . . They can show that throughout all organic nature there is at work a modifying influence of the kind they assign, as the causes of . . . specific differences; an influence which, though slow in its action, does in time, if the circumstances demand it, produce marked changes."

GEORGE HENSLOW.

I AM sorry I cannot agree with Prof. Henslow as to the nature of the proof required of him.

The fact that "plant structures *are* reproduced by seed every year" in nature is surely no proof of the inheritance of acquired characters!

Plants are, it is true, exceedingly plastic structures, and, as all allow, are both temporarily and permanently affected by their surroundings. This, if we needed further proof, Prof. Henslow has repeatedly demonstrated by his interesting series of facts. There seems to be danger, however, of confusing these *changes in the individual* with *changes in the race*. Prof. Henslow makes the former the prelude to the latter; and the first question to be settled is, What connection is there between these two classes of changes? In other words, Are acquired characters hereditary?

The issue is the same if we seek for the *causes of variation*. Darwinism, realising that there is a gradual adaptation of plants to altered surroundings, explains the fact by the *indirect* influence of the environment acting through natural selection. Among plants, which are stimulated to vary in all directions under change of conditions, those are preserved which vary so as to place themselves in adaptation to their new surroundings. Prof. Henslow substitutes the *direct* influence of the environment upon the *individual* plant, and asserts that the changes thus induced "become relatively fixed if the conditions are maintained long enough." Here is an assumption that the *change in the race* is the outcome of the *direct effect of the environment upon the individual*, or, again, that acquired characters are hereditary. I have carefully re-examined the cases mentioned of *Ononis*, parsnips and alpine plants, but cannot trace any proof of this assumption.

As to the *indefinite variation* of plants and animals in nature, it is difficult to conceive of doubt upon the subject. It is a common saying that "no two blades of grass are alike," although conditions could hardly be imagined more uniform than those in one and the same field. Moreover, the fact of indefinite variation has been fully proved by Prof. Wallace in his work on Darwinism. In chapter iii., on "Variability of Species in a State of Nature," the whole subject has been exhaustively dealt with, and I cannot do better than refer Prof. Henslow to that chapter, where numerous cases are given, both in animals and plants. I would especially refer to the extracts from Darwin's note-books there published for the first time.

I do not quite follow Prof. Henslow in rejecting evidence drawn from cultivated plants. Placing wild forms under cultivation is a severe change of environment, and any such change induces, of itself, a great tendency to vary. The influences which work slowly in nature are intensified; and the substitution

of artificial instead of natural selection further increases the rapidity of the results.

It must be borne in mind, too, that plants under cultivation are not necessarily grown for successive generations under the same conditions. While the change from the wild state to cultivation is as slight in some cases as it is profound in others, plants under continued cultivation are frequently subject to a succession of changes of environment as to soil, locality, water, manure, &c.: and we should therefore, according to well-known laws, expect to obtain a greatly increased number of variations in them. And these variations, as elsewhere, are coupled with a strong hereditary tendency, thus producing many new varieties.

Lastly, as regards the quotation from Mr. Herbert Spencer's essay, its terms are not at all inimical to natural selection, but apply to it equally well—a remark which, I cannot but feel, also applies to the bulk of Prof. Henslow's work. C. A. B.

A Remarkable Discharge of Lightning.

[THE following letter was sent to the Royal Society, and has been forwarded to us by the Secretary.—ED. NATURE.]

I THINK it may interest you to know that an extraordinary flash of lightning was witnessed from this place, this evening, at 7.38 p.m. It has been raining in torrents nearly all day long; the heavens seem heavy and saturated with rain, but we have had no thunder at all.

Now the undersigned were seated round a table in a room in Fife Street, and only one of us had his eyes turned in the direction of the door, which was open. Suddenly he exclaimed, "Good heavens! just look at that lightning; it's standing still!"

All of us promptly went to the door, whence we witnessed a truly extraordinary sight in the shape of three ribbons of a greenish white lightning, which hung in the sky, motionless, for what must have been fifteen to twenty seconds. It seemed to be a long way off (in a north-westerly direction), as we heard no report of thunder whatever. We put some questions to our Makalaka boy, who said that he had never seen anything like it in all his life.

There could be no mistake about it—it was as distinct as possible; and it must have lasted fifteen seconds *at least* (I should say twenty myself). I can refer you (should you desire to know more of me) to John Chumley, Esq., Manager of the Standard Bank of South Africa, Limited, 10 Clement's Lane, London, E.C.; Major W. E. Gilbert, Warleigh Lodge, Upper Tulse Hill; or John Heal, Esq., Hertford Lodge, Church End Finchley, London, N. ROB. GODLONTON.

The undersigned were witnesses of the stroke of forked lightning described in the letter to you, written by Mr. Godlonton, and consider his description accurate in every detail.

Lecture Experiments on the Nodes of a Bell.

I WAS much interested in the communication from Mr. Osborn on the above subject (see NATURE, January 9). For some years I have been in the habit of showing these nodes in the following way. An ordinary glass bell-jar, eight or ten inches high, with a moderately broad, flat, ground edge, is held with the edge upright, and fine sand scattered all over the flat edge. It is comparatively easy to excite the edge with a bow in such a way that the sand will be driven off everywhere except at the four nodes. I have never been able, however, to obtain more than four nodes in this way.

I have also employed a similar method for showing the nodes of a tuning-fork. If the fork is a moderately large one, it is held horizontally in the hand, and the upper prong is covered with sand. By bowing sharply near the middle and near the root of the prongs, two overtones can usually be obtained, the nodes of which are clearly marked by the sand.

Central School, Manchester. R. L. TAYLOR.

THE STATUS OF LONDON UNIVERSITY.

PROF. S. P. THOMPSON'S lecture to the Society of Arts on the 15th inst. will greatly assist the scheme for the reform of the University of London. The statistics brought forward by him show how hopelessly inadequate the equipment of the present University appears when compared with that of almost any other University in the world. It can hardly be believed that while Strassburg receives State aid to the extent of £44 per annum for each student, the University of London actually *pays the State* ten shillings for each student. As the lecturer remarked, a University which has no professors, no museums, no laboratories for research, whose library is practically unused and unusable, and whose sole function is to examine, cannot be called a *great* University, if, indeed, it be rightly entitled to be called a University at all. Limits of space prevent us from reprinting Prof. Thompson's paper, but we give, on the following page, a table prepared by him to exhibit the material and financial aspects of different Universities. This information, and Lord Reay's remarks upon the paper, should do much to controvert dialectic denunciations, and to show the true position of London University among the Universities of the world.

Prof. Thompson considered in succession the points upon which information is given in the different columns of his tabulated statement. He showed that not only is the educational position of the existing University entirely anomalous, but the financial position is still more extraordinary.

In closing the discussion which followed the reading of Prof. Thompson's paper, the Chairman, Lord Reay, remarked that the statistics which it included could not be too much impressed on the public mind, as an indictment against the country for leaving waste resources unparalleled in the civilised world. He was quite convinced that, if there were in any other country the treasures we had in London, both in the way of museums and libraries, and of men who were prepared to teach, it would not take ten, twelve, or twenty years to bring about the result required: but that whoever was the director of public instruction in that country would at once say to the Minister that it was his duty to lay on the table of the Legislature a Bill for the establishment of a teaching university. Among the many extraordinary symptoms which this controversy had brought to the surface, there was one of a very curious nature. Whenever they read an argument against the creation of such a university they found, either outspoken or in a latent form, this accusation: "Such a scheme will hand us over to the tender mercies of the London teachers." Now to the tender mercies of the teachers higher education was left in all the countries of Europe. He was not yet acquainted with the constitution of the University of Tokio, but he should be much surprised if they found there the slightest jealousy of leaving to the teachers the management of that which they must understand better than others. As a member of the Cowper Commission, he had been agreeably surprised to find that amongst all those on whose opinion the Commission set most store, there had been hardly a dissentient voice. In the case of every former report or scheme, those who would have had to put it in operation, and on whose labours its success depended, were in doubt, not about details, but about some leading feature; but this last scheme had been accepted not only by the teachers in London, but by the staffs of those very provincial schools whose students, they were told, in some questions had not been sufficiently considered. The best answer to the difficulty about external students was that given by Prof. Thompson when he said that learning, not teaching or examining, was the primary essential. That meant that, in a teaching university, the individuality of the teacher should be allowed its full scope, and also that each individual student should be allowed to work for the sake of learning, not for the sake of the examination. There might be as much difference between two internal students as between an internal student and an external, and in the examination the individual character of each student would be allowed for. The external students would not only have the same guarantees of a fair examination as at present, but perhaps even better; but if further guarantees were wanted, by all means let them be given. The great point was that internal students of London should, at least, have that to which they had a right—a teaching university of their own. It was nothing less than a scandal that London, with a greater population than Scotland, or than many of the countries of Europe, which had two or three universitie, should not have a university of its own.

With regard to the question of the boundary line, every one who had had any experience in such questions knew that controversy was endless, but that was a matter for the Statutory Commission, and the subjects to be included in the curriculum were also open; but agriculture was expressly included, because it was found that at most universities the science of agriculture, apart from its practical aspect, was deemed essential. He thought it was not only the duty, but the privilege of any Government of this country to at least give to the metropolis and to the empire a worthy university.

VOTE OF CONVOCATION ON THE COWPER COMMISSION SCHEME.

ANOTHER step has been taken in the long controversy with respect to the equipment of the University of London with teaching functions. While the other bodies represented on the recent deputation to the Duke of Devonshire had passed resolutions asking the Government to introduce a Bill similar to Lord Playfair's "London University Commission Bill, 1895," but with an added clause giving a right of appeal to the Privy Council (NATURE, December 5, 1895), Convocation had not expressed any opinion either on the Bill or on the proposed appeal, owing to Lord Playfair's Bill being introduced into the House of Lords too late to allow of a resolution approving its terms to be moved at the last meeting in May. On Tuesday last, the Annual Committee recommended Convocation to adopt the following resolution: "That this House desires the early introduction into Parliament of a Bill for the reconstitution of the University similar to that introduced last year by Lord Playfair, but with an inserted clause securing to the Senate, to Convocation, and to other bodies affected, the right of appeal to the Privy Council on any of the provisions which may hereafter be settled by the Statutory Commission." This resolution was carried by 470 votes against 244, and thus for the third time Convocation, in the only legal way, has pronounced decisively in favour of the Cowper Commission scheme. The progressive rise in the majorities is not the least satisfactory feature of the struggle in Convocation—a majority of 24 in a house of 290 in January of last year rose to 122 in a house of 354 in May, and has now become 226 in a house of 714. The next step rests with the Government, but in view of the remarkable unanimity existing among the bodies affected by the scheme, and the universally favourable attitude of the metropolitan press towards it, we can be in no doubt as to what the final settlement must be.

ON A NEW KIND OF RAYS.[1]

(1) A DISCHARGE from a large induction coil is passed through a Hittorf's vacuum tube, or through a well-exhausted Crookes' or Lenard's tube. The tube is surrounded by a fairly close-fitting shield of black paper; it is then possible to see, in a completely darkened room, that paper covered on one side with barium platinocyanide lights up with brilliant fluorescence when brought into the neighbourhood of the tube, whether the painted side or the other be turned towards the tube. The fluorescence is still visible at two metres distance. It is easy to show that the origin of the fluorescence lies within the vacuum tube.

(2) It is seen, therefore, that some agent is capable of penetrating black cardboard which is quite opaque to ultra-violet light, sunlight, or arc-light. It is therefore of interest to investigate how far other bodies can be penetrated by the same agent. It is readily shown that all bodies possess this same transparency, but in very varying degrees. For example, paper is very transparent; the fluorescent screen will light up when placed behind a book of a thousand pages; printer's ink offers no marked resistance. Similarly the fluorescence shows behind two packs of cards; a single card does not visibly diminish the brilliancy of the light. So, again, a single thickness of tinfoil hardly casts a shadow on the screen; several have to be superposed to produce a marked effect. Thick blocks of wood are still transparent. Boards of pine two or three centimetres thick absorb only very little. A piece of sheet aluminium, 15 mm. thick, still allowed the X-rays (as I will call the rays, for the sake of brevity) to pass, but greatly reduced the fluorescence. Glass plates of similar thickness behave similarly; lead glass is, however, much more opaque than glass free from lead. Ebonite several centimetres thick is transparent. If the hand be held before the fluorescent screen, the shadow shows the bones darkly, with only faint outlines of the surrounding tissues.

Water and several other fluids are very transparent. Hydrogen is not markedly more permeable than air. Plates of copper, silver, lead, gold, and platinum also allow the rays to pass, but only when the metal is thin. Platinum ·2 mm. thick allows some rays to pass; silver and copper are more transparent. Lead 1·5 mm. thick is practically opaque. If a square rod of wood 20 mm. in the side be painted on one face with white lead, it casts little shadow when it is so turned that the painted face is parallel to the X-rays, but a strong shadow if the rays have to pass through the painted side. The salts of the metals, either solid or in solution, behave generally as the metals themselves.

(3) The preceding experiments lead to the conclusion that the density of the bodies is the property whose variation mainly affects their permeability. At least no other property seems so marked in this connection. But that the density alone does not determine the transparency is shown by an experiment wherein plates of similar thickness of Iceland spar, glass, aluminium, and quartz were employed as screens. Then the Iceland spar showed itself much less transparent than the other bodies, though of approximately the same density. I have not remarked any strong fluorescence of Iceland spar compared with glass (see below, No. 4).

(4) Increasing thickness increases the hindrance offered to the rays by all bodies. A picture has been impressed on a photographic plate of a number of superposed layers of tinfoil, like steps, presenting thus a regularly increasing thickness. This is to be submitted to photometric processes when a suitable instrument is available.

(5) Pieces of platinum, lead, zinc, and aluminium foil were so arranged as to produce the same weakening of the effect. The annexed table shows the relative thickness and density of the equivalent sheets of metal.

	Thickness.	Relative thickness.	Density
Platinum	·018 mm.	1	21·5
Lead	·050 ,,	3	11·3
Zinc	·100 ,,	6	7·1
Aluminium	3·500 ,,	200	2·6

From these values it is clear that in no case can we obtain the transparency of a body from the product of its density and thickness. The transparency increases much more rapidly than the product decreases.

(6) The fluorescence of barium platinocyanide is not the only noticeable action of the X-rays. It is to be observed that other bodies exhibit fluorescence, *e.g.* calcium sulphide, uranium glass, Iceland spar, rock-salt, &c.

Of special interest in this connection is the fact that photographic dry plates are sensitive to the X-rays. It is thus possible to exhibit the phenomena so as to exclude the danger of error. I have thus confirmed many observations originally made by eye observation with the fluorescent screen. Here the power of the X-rays to pass through wood or cardboard becomes useful. The photographic plate can be exposed to the action without removal of the shutter of the dark slide or other protecting case, so that the experiment need not be conducted in darkness. Manifestly, unexposed plates must not be left in their box near the vacuum tube.

It seems now questionable whether the impression on the plate is a direct effect of the X-rays, or a secondary result induced by the fluorescence of the material of the plate. Films can receive the impression as well as ordinary dry plates.

[1] By W. C. Röntgen. Translated by Arthur Stanton from the *Sitzungsberichte der Würzburger Physik-medic. Gesellschaft*, 1895.

I have not been able to show experimentally that the X-rays give rise to any calorific effects. These, however, may be assumed, for the phenomena of fluorescence show that the X-rays are capable of transformation. It is also certain that all the X-rays falling on a body do not leave it as such.

The retina of the eye is quite insensitive to these rays: the eye placed close to the apparatus sees nothing. It is clear from the experiments that this is not due to want of permeability on the part of the structures of the eye.

(7) After my experiments on the transparency of increasing thicknesses of different media, I proceeded to investigate whether the X-rays could be deflected by a prism. Investigations with water and carbon bisulphide in mica prisms of 30° showed no deviation either on the photographic or the fluorescent plate. For comparison, light rays were allowed to fall on the prism as the apparatus was set up for the experiment. They were deviated 10 mm. and 20 mm. respectively in the case of the two prisms.

With prisms of ebonite and aluminium, I have obtained images on the photographic plate, which point to a possible deviation. It is, however, uncertain, and at most would point to a refractive index 1·05. No deviation can be observed by means of the fluorescent screen. Investigations with the heavier metals have not as yet led to any result, because of their small transparency and the consequent enfeebling of the transmitted rays.

On account of the importance of the question it is desirable to try in other ways whether the X-rays are susceptible of refraction. Finely powdered bodies allow in thick layers but little of the incident light to pass through, in consequence of refraction and reflection. In the case of the X-rays, however, such layers of powder are for equal masses of substance equally transparent with the coherent solid itself. Hence we cannot conclude any regular reflection or refraction of the X-rays. The research was conducted by the aid of finely-powdered rock-salt, fine electrolytic silver powder, and zinc dust already many times employed in chemical work. In all these cases the result, whether by the fluorescent screen or the photographic method, indicated no difference in transparency between the powder and the coherent solid.

It is, hence, obvious that lenses cannot be looked upon as capable of concentrating the X-rays; in effect, both an ebonite and a glass lens of large size prove to be without action. The shadow photograph of a round rod is darker in the middle than at the edge; the image of a cylinder filled with a body more transparent than its walls exhibits the middle brighter than the edge.

(8) The preceding experiments, and others which I pass over, point to the rays being incapable of regular reflection. It is, however, well to detail an observation which at first sight seemed to lead to an opposite conclusion.

I exposed a plate, protected by a black paper sheath, to the X-rays. so that the glass side lay next to the vacuum tube. The sensitive film was partly covered with star-shaped pieces of platinum, lead, zinc, and aluminium. On the developed negative the star-shaped impression showed dark under platinum, lead, and, more markedly, under zinc; the aluminium gave no image. It seems, therefore, that these three metals can reflect the X-rays; as, however, another explanation is possible, I repeated the experiment with this only difference, that a film of thin aluminium foil was interposed between the sensitive film and the metal stars. Such an aluminium plate is opaque to ultra-violet rays, but transparent to X-rays. In the result the images appeared as before, this pointing still to the existence of reflection at metal surfaces.

If one considers this observation in connection with others, namely, on the transparency of powders, and on the state of the surface not being effective in altering the passage of the X-rays through a body, it leads to the probable conclusion that regular reflection does not exist, but that bodies behave to the X-rays as turbid media to light.

Since I have obtained no evidence of refraction at the surface of different media, it seems probable that the X-rays move with the same velocity in all bodies, and in a medium which penetrates everything, and in which the molecules of bodies are embedded. The molecules obstruct the X-rays, the more effectively as the density of the body concerned is greater.

(9) It seemed possible that the geometrical arrangement of the molecules might affect the action of a body upon the X-rays, so that, for example, Iceland spar might exhibit different phenomena according to the relation of the surface of the plate to the axis of the crystal. Experiments with quartz and Iceland spar on this point lead to a negative result.

(10) It is known that Lenard, in his investigations on kathode rays, has shown that they belong to the ether, and can pass through all bodies. Concerning the X-rays the same may be said.

In his latest work, Lenard has investigated the absorption coefficients of various bodies for the kathode rays, including air at atmospheric pressure, which gives 4·10, 3·40, 3·10 for 1 cm., according to the degree of exhaustion of the gas in discharge tube. To judge from the nature of the discharge, I have worked at about the same pressure, but occasionally at greater or smaller pressures. I find, using a Weber's photometer, that the intensity of the fluorescent light varies nearly as the inverse square of the distance between screen and discharge tube. This result is obtained from three very consistent sets of observations at distances of 100 and 200 mm. Hence air absorbs the X-rays much less than the kathode rays. This result is in complete agreement with the previously described result, that the fluorescence of the screen can be still observed at 2 metres from the vacuum tube. In general, other bodies behave like air; they are more transparent for the X-rays than for the kathode rays.

(11) A further distinction, and a noteworthy one, results from the action of a magnet. I have not succeeded in observing any deviation of the X-rays even in very strong magnetic fields.

The deviation of kathode rays by the magnet is one of their peculiar characteristics; it has been observed by Hertz and Lenard, that several kinds of kathode rays exist, which differ by their power of exciting phosphorescence, their susceptibility of absorption, and their deviation by the magnet; but a notable deviation has been observed in all cases which have yet been investigated, and I think that such deviation affords a characteristic not to be set aside lightly.

(12) As the result of many researches, it appears that the place of most brilliant phosphorescence of the walls of the discharge-tube is the chief seat whence the X-rays originate and spread in all directions; that is, the X-rays proceed from the front where the kathode rays strike the glass. If one deviates the kathode rays within the tube by means of a magnet, it is seen that the X-rays proceed from a new point, *i.e.* again from the end of the kathode rays.

Also for this reason the X-rays, which are not deflected by a magnet, cannot be regarded as kathode rays which have passed through the glass, for that passage cannot, according to Lenard, be the cause of the different deflection of the rays. Hence I conclude that the X-rays are not identical with the kathode rays, but are produced from the kathode rays at the glass surface of the tube.

(13) The rays are generated not only in glass. I have obtained them in an apparatus closed by an aluminium plate 2 mm. thick. I purpose later to investigate the behaviour of other substances.

(14) The justification of the term "rays," applied to the phenomena, lies partly in the regular shadow pictures produced by the interposition of a more or less permeable

body between the source and a photographic plate or fluorescent screen.

I have observed and photographed many such shadow pictures. Thus, I have an outline of part of a door covered with lead paint; the image was produced by placing the discharge-tube on one side of the door, and the sensitive plate on the other. I have also a shadow of the bones of the hand (Fig. 1), of a wire wound upon a bobbin, of a set of weights in a box, of a

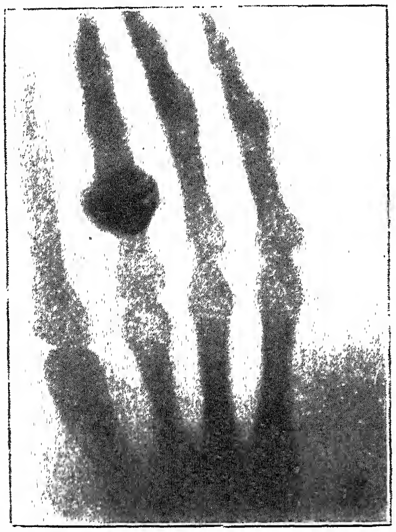

FIG. 1.—Photograph of the bones in the fingers of a living human hand. The third finger has a ring upon it.

compass card and needle completely enclosed in a metal case (Fig. 2), of a piece of metal where the X-rays show the want of homogeneity, and of other things.

For the rectilinear propagation of the rays, I have a pin-hole photograph of the discharge apparatus covered with black paper. It is faint but unmistakable.

(15) I have sought for interference effects of the X-rays,

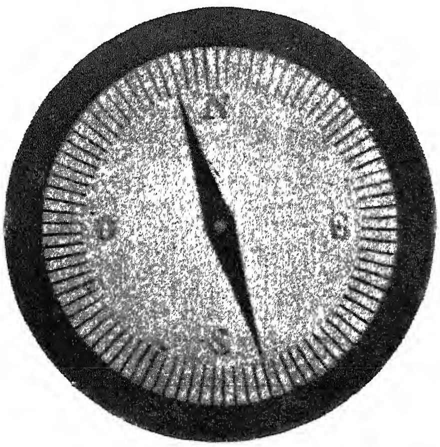

FIG. 2.—Photograph of a compass card and needle completely enclosed in a metal case.

but possibly, in consequence of their small intensity, without result.

(16) Researches to investigate whether electrostatic forces act on the X-rays are begun but not yet concluded.

(17) If one asks, what then are these X-rays; since they are not kathode rays, one might suppose, from their power of exciting fluorescence and chemical action, them to be due to ultra-violet light. In opposition to this view a weighty set of considerations presents itself. If X-rays be indeed ultra-violet light, then that light must possess the following properties.

(*a*) It is not refracted in passing from air into water, carbon bisulphide, aluminium, rock-salt, glass or zinc.

(*b*) It is incapable of regular reflection at the surfaces of the above bodies.

(*c*) It cannot be polarised by any ordinary polarising media.

(*d*) The absorption by various bodies must depend chiefly on their density.

That is to say, these ultra-violet rays must behave quite differently from the visible, infra-red, and hitherto known ultra-violet rays.

These things appear so unlikely that I have sought for another hypothesis.

A kind of relationship between the new rays and light rays appears to exist; at least the formation of shadows, fluorescence, and the production of chemical action point in this direction. Now it has been known for a long time, that besides the transverse vibrations which account for the phenomena of light, it is possible that longitudinal vibrations should exist in the ether, and, according to the view of some physicists, must exist. It is granted that their existence has not yet been made clear, and their properties are not experimentally demonstrated. Should not the new rays be ascribed to longitudinal waves in the ether?

I must confess that I have in the course of this research made myself more and more familiar with this thought, and venture to put the opinion forward, while I am quite conscious that the hypothesis advanced still requires a more solid foundation.

PROFESSOR RÖNTGEN'S DISCOVERY.

THE newspaper reports of Prof. Röntgen's experiments have, during the past few days, excited considerable interest. The discovery does not appear, however, to be entirely novel, as it was noted by Hertz that metallic films are transparent to the kathode rays from a Crookes or Hittorf tube, and in Lenard's researches, published about two years ago, it is distinctly pointed out that such rays will produce photographic impressions. Indeed, Lenard, employing a tube with an aluminium window, through which the kathode rays passed out with comparative ease, obtained photographic shadow images almost identical with those of Röntgen, through pieces of cardboard and aluminium interposed between the window and the photographic plate.

Prof. Röntgen has, however, shown that this aluminium window is unnecessary, as some portion of the kathode radiations that are photographically active will pass through the glass walls of the tube. Further, he has extended the results obtained by Lenard in a manner that has impressed the popular imagination, while, perhaps most important of all, he has discovered the exceedingly curious fact that bone is so much less transparent to these radiations than flesh and muscle, that if a living human hand be interposed between a Crookes tube and a photographic plate, a shadow photograph can be obtained which shows all the outlines and joints of the bones most distinctly.

Working upon the lines indicated in the telegrams from Vienna, recently published in the daily papers, I have, with the assistance of Mr. J. C. M. Stanton, repeated many of Prof. Röntgen's experiments with entire success. According to one of our first experiments, an ordinary gelatinous bromide dry photographic plate was placed in an ordinary camera back. The wooden shutter of the back was kept closed, and upon it were placed miscellaneous articles such as coins, pieces of wood, carbon, ebonite, vulcanised fibre, aluminium, &c., all being quite opaque to ordinary light. Above was supported a

Crookes tube, which was excited for some minutes. On development, shadows of all the articles placed on the slide were clearly visible, some being more opaque than others. Further experiments were tried with thin plates of aluminium or of black vulcanised fibre interposed between the objects to be photographed and the sensitive surface, this thin plate being used in place of the wood of the camera back. In this manner sharper shadow pictures were obtained. While most thick metal sheets appear to be entirely opaque to the radiations, aluminium appears to be relatively transparent. Ebonite, vulcanised fibre, carbon, wood, cardboard, leather and slate are all very transparent, while, on the other hand, glass is exceedingly opaque. Thin metal foils are moderately opaque, but not altogether so.

As tending to the view that the radiations are more akin to ultraviolet than to infra-red light, it may be mentioned that a solution of alum in water is distinctly more transparent to them than a solution of iodine in bisulphide of carbon.

So far as our own experiments go, it appears that, at any rate without very long exposures, a sufficiently active excitation of the Crookes tube is not obtained by direct connection to an ordinary Rhumkorff induction coil, even of a large size. So-called high frequency currents, however, appear to give good results, and our own experiments have been made with the tube excited by current obtained from the secondary circuit of a Tesla oil coil, through the primary of which were continuously discharged twelve half-gallon Leyden jars, charged by an alternating current of about 20,000 volts pressure, produced by a transformer with a spark-gap across its high-pressure terminals.

For obtaining shadow photographs of inanimate objects, and for testing the relative transparency of different substances, the particular form of Crookes tube employed does not appear to greatly signify, though some forms are, we find, better than others. When, however, the human hand is to be photographed, and it is important to obtain sharp shadows of the bones, the particular form of tube used and its position relative to the hand and sensitive plate appear to be of great importance. So far, owing to the frequent destruction of the tubes, due to overheating of the terminals, we have not been able to ascertain exactly the best form and arrangement for this purpose, except that it appears desirable that the electrodes in the tube should consist of flat and not curved plates, and that these plates should be of small dimensions.

The accompanying photograph of a living human hand (Fig. 1) was exposed for twenty minutes through an aluminium sheet ·0075 in thickness, the Crookes tube, which was one of the kind containing some white phosphorescent material (probably sulphide of barium), being held vertically upside down, with its lowest point about two inches above the centre of the hand.

By substituting a thin sheet of black vulcanised fibre for the aluminium plate, we have since been able to reduce the exposure required to four minutes. Indeed with the aluminium plate, the twenty minutes' exposure appears to have been longer than was necessary. Further, having regard to the great opacity of glass, it seems probable that where ordinary Crookes tubes are employed, a large proportion of the active radiations must be absorbed by the glass of the tube itself. If this is so, by the employment of a tube partly constructed of aluminium, as used by Lenard, the necessary length of exposure could be much reduced.

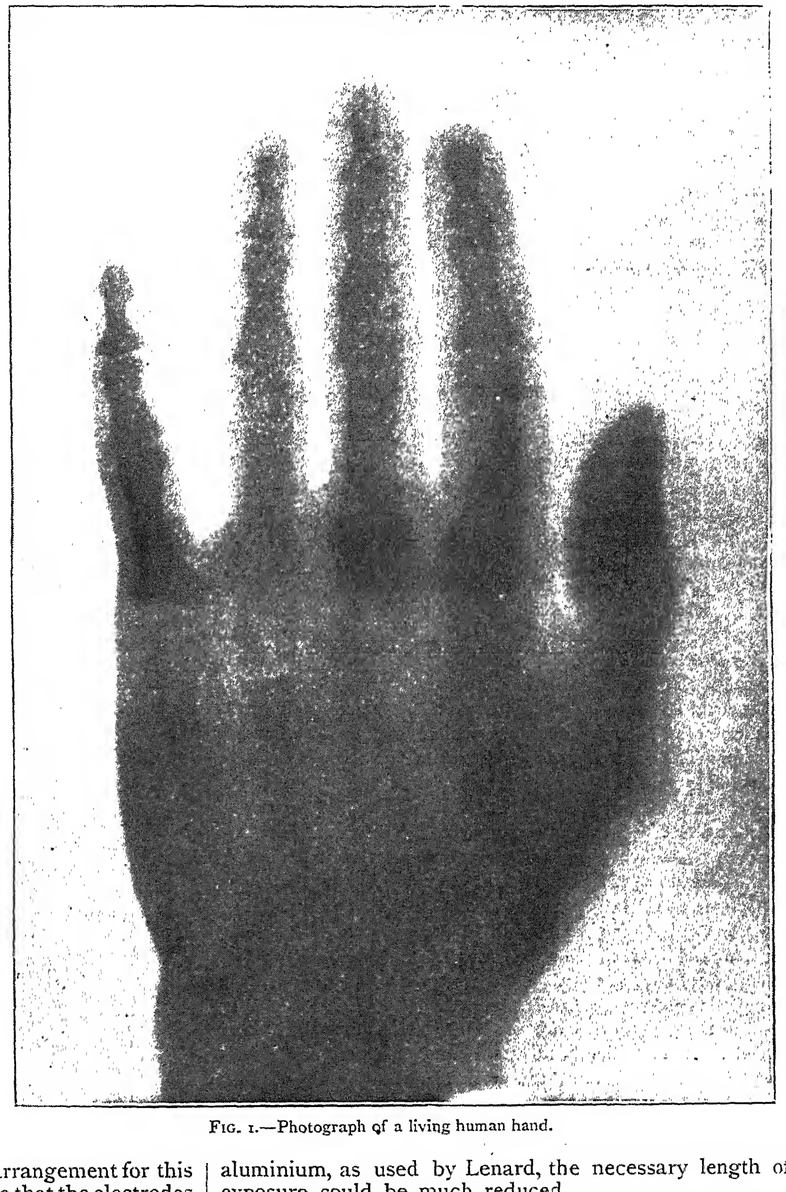

FIG. 1.—Photograph of a living human hand.

A. A. C. SWINTON.

NOTES.

AT their scientific meeting on March 3, the Zoological Society propose to discuss the much-vexed question of zoological nomenclature. This subject will be introduced by Mr. Sclater, the Secretary of the Society, who will read a paper on the "Rules for naming Animals," lately adopted by the German

Zoological Society, and point out the divergences between them and what is called the Stricklandian Code of Nomenclature, recognised by the British Association, and usually followed in this country.

THE question of technical and commercial attachés to British Embassies was referred to by the Right Hon. George Curzon, M.P., Under Secretary for Foreign Affairs, in the course of some remarks to the Wolverhampton Chamber of Commerce last week. He acknowledged that it is desirable, in many of those countries where our commercial connection is large, to have representatives whose attention is exclusively directed to our commercial interests. He also remarked that it appeared to his Department that the existing arrangement of the areas of our commercial attachés in Europe, of which there are three, is unscientific and imperfect. A technical attaché should be appointed in Germany, and our forces in other directions ought to be increased. But while he agreed that attachés with technical knowledge could be of great assistance in the development of British trade, and hoped that the Foreign Office would soon be able to do something to extend the Consular service in the desired direction, he thought that Chambers of Commerce should do more than they seem to do at present in furtherance of their own trades, by sending out commissions to distant parts to ascertain on the spot what are the particular points with which they have to contend, and the lines of possible development. This is typical of the kind of advice usually given by the British Government. It amounts to an acknowledgment of defects, but leaves private enterprise to supply the remedy. In this respect our Government differs in policy from those of France and Germany—two of our chief competitors in trade—for in those countries the State takes an active interest in the development of industries; and the knowledge which makes for such advancement, as well as the men who are competent to form an opinion upon industrial processes, are fully utilised. The Foreign Office exists for the promotion and fostering of British trade, as well as for the handling of our relations with foreign Powers. It certainly does something to supply the commercial world with trade statistics received through its Consuls, but it could do much more for the real advancement of industry if it were advised and guided in technical matters by scientific opinion. The collection of facts useful in the improvement of industrial methods and processes should form a very important part of the work carried on at our Consulates. To leave this valuable work to men sent out by traders, is to court defeat by the countries which recognise the value of attachés possessing technical and scientific knowledge. We agree that our Chambers of Commerce might adopt with advantage the forward policy of some of the French Chambers of Commerce, but, at the same time, we hold that the comparison of the Chambers of the two nations does not show British traders to extreme disadvantage as regards enterprise, whereas the work of the British Government in the same direction is not comparable with that of other nations. As in trade, so in science and education, individuals have done their share in the work of advancement; it is the Government which lags behind.

As an example of what private associations do to discover in what way industrial practices and processes on the continent differ from those in Great Britain, we may mention the delegation recently organised by the British Iron Trade Association for the purpose of inquiring into the conditions of competition in the iron and steel industries of the continent. The report of the delegates has just been finally adopted by the Association, and one or two points in it furnish instructive reading. It is admitted that both Belgium and Germany are well to the front in regard to mechanical appliances. The general arrangement of the blast furnace plants was modern and excellent, and they appeared to be worked to secure a large output with a minimum of capital and labour expenditure. In the finished iron and steel works visited, the practice adopted was excellent, and in some respects in advance of England. But of more especial interest to us is the fact that attention is called to the greater importance attached in Germany than in England to technical education, and the facilities given for its acquisition. This is regarded as one of the reasons why Germany has been able to quickly acquire, and make rapid advances in, iron and steel manufacture. On account of the attention given to scientific and technical education, the masters, as a rule, thoroughly understand the principles of their industrial processes, and are therefore able to economise in matters of detail; and moreover, they recognise the value of scientific advice and guidance upon all questions of improved methods.

THE appointment of Scientific Adviser to the Trinity House, which has been in abeyance since the resignation of Dr. Tyndall, and which was formerly held by Prof. Faraday, has been revived, and has been accepted by Lord Rayleigh.

THE engineer to the scheme for bringing sea-water from Lancing to London has prepared, for the information of Parliament, an estimate of the entire cost of this scheme. He states that the works contained in the Bill can be carried out for £450,000, which includes the acquisition of all the necessary lands for the distribution of sea-water throughout London.

A REUTER telegram from Christiania announces that Lieut. Ewind Astrup, the well-known Polar explorer, who took part in both Lieut. Peary's Greenland expeditions, was found dead on Tuesday in the Lille-Elvedal. Lieut. Astrup left Jerkin, at the foot of Sneehätta, in the Hovre Fjeld, shortly before Christmas, but since then nothing had been heard of him. A few days ago twenty-five men on snow-shoes started out to search for the explorer, with the result that they found his remains in the valley.

THE Committee of the Œuvre de la Tuberculose, founded by the late Prof. Verneuil, have (says the *British Medical Journal*) elected Prof. Bouchard to succeed that distinguished surgeon in the office of President. Prof. Lannelongue was at the same time elected Vice-President, and Dr. L. Henri Petit, General Secretary. The next Congress on Tuberculosis, which had been fixed for July 1896, has been postponed to 1897.

WE are informed that the Geological Society will this year award the following medals and funds:—The Wollaston medal to Prof. E. Suess, the Murchison medal to Mr. T. Mellard Reade, the Lyell medal to Mr. A. Smith Woodward, the proceeds of the Wollaston fund and part of the Barlow-Jameson fund to Mr. Alfred Harker, the proceeds of the Murchison fund to Mr. Philip Lake, the proceeds of the Lyell fund to Dr. W. F. Hume and Mr. W. C. Andrews, the proceeds of the Barlow-Jameson fund to Mr. Joseph Wright and Mr. John Storrie.

AN International Exhibition is to be held at Brussels in 1897. The exhibition will comprise fourteen sections: 1. Fine arts. 2. Social economy. 3. Hygiene. 4. Life saving. 5. Industrial and decorative arts. 6. Lighting and heating. 7. Electricity—traction. 8. Military art. 9. Industrial manufactures—materials, methods, and products. 10. Sporting material. 11. Exercises—popular games. 12. Temporary competitions in agriculture and horticulture. 13. Practical teaching, and the industries and handiwork of women. 14. Trade. Colonies.

A PRELIMINARY account of the Florentine earthquake of last May 18, the strongest felt in the district during the present century, has been written by Dr. M. Baratta. The chief damage

to buildings occurred within a nearly circular area about 35 km. in diameter, the centre of which is close to Florence. The disturbed area contains about 27,000 sq. km. Under the form of microseismic movements, the earthquake was recorded at several Italian observatories, and also at Grenoble (France), which is 460 km. from Florence, the mean velocity to the latter place being 1·75 km. per second.

ACCORDING to a Reuter telegram from Christiania, the estate of Hafslund, near the great waterfall known as the Sarpsfos, between there and Göteborg, has been acquired by a syndicate, consisting chiefly of German and American capitalists, for the sum of 800,000 kroner. The purchasers intend to form a large company with a capital of three to five million kroner, in order to utilise the water power of the falls for electrical power, and establishing aluminium works on the same principle as planned at the Falls of Foyers in Scotland. The Sarpsfos is one of the finest falls in south-eastern Norway, being 74 feet in height and 116 feet in width.

THE ancestral history of the horse, long familiar as a most striking instance of the possibility of tracing a pedigree by the aid of palæontology, is now being worked out still more minutely. In a paper just published (*Bull. Amer. Mus. Nat. Hist.*, December 23, 1895) on the Perissodactyls of the White River beds (Oligocene and Lower Miocene), Messrs. Osborn and Wortman announce the discovery of so complete a series of intermediate forms between *Mesohippus Bairdi* and *Anchitherium præstans*, that a strict definition of generic and specific names becomes impossible. These two and the intermediate types "form a closely-connected phylogenetic series of animals, slowly specialising and constantly increasing in size. So far as we know," the authors add, "there is not a single character missing in the structural chain."

AMONG the many points of interest which they possess, the Ratite birds of the southern hemisphere have presented no feature more curious and more inexplicable than the opercular fold which covers the transitory gill-slits in the neck of the embryo. The fold was first discovered five years ago by Prof. T. J. Parker, who described its occurrence in embryos of the New Zealand *Apteryx;* but its recent discovery by Prof. Nassonow in embryos of the ostrich also (*Zool. Anzeiger*, No. 492) shows that it is a feature which probably characterises the development of all the Ratite birds. A branchial operculum has not, however, been observed in the early stages either of reptiles or of Carinate birds, and the retention of so obviously amphibian a character in Ratite birds alone among Sauropsida provides a puzzle for ornithologists and embryologists alike.

IT is interesting to note, with reference to the observation of of the meteor seen at Cahirciveen on the 6th inst. (NATURE, p. 253), notice of which was sent to us by Mr. R. H. Scott, that according to a letter received at the Meteorological Office from Dr. A. Riggenbach, of Basle, a similar phenomenon was seen at Hochwald, about seven miles to the south of the former place, at 6 p.m. on the same evening. The observer noticed over the mountains of Nunningen what appeared to be a star of unusual magnitude. After looking at it for some time he was surprised to find it moving and leaving a long trail after it. The light increased in splendour, being first of a yellowish colour, which, upon the bursting of the meteor into three or four pieces, assumed a bluish-green colour. The movement continued in a south-westerly direction for about 1½ seconds, when the phenomenon disappeared below the horizon.

THE history of the introduction of the first hermetically-sealed thermometer into France is contained in *Cosmos* of the 4th inst., with extracts from the correspondence of Pierre des Noyers, Secretary of the Queen of Poland. In 1657 he sent a description of a Florentine thermometer to M. Boulliau, of Paris, with a drawing of it, which is reproduced in *Cosmos*, and in 1658 a specimen of the instrument was sent to Paris, and was apparently used by M. Boulliau on June 25 of that year. This thermometer was graduated by means of small black enamelled knobs on the outside of the tube, and was subsequently improved by the Accademia del Cimento. A full description of the instrument is contained in Prof. Hellmann's "Anfänge der meteorologischen Beobachtungen und Instrumente" in *Himmel und Erde*, vol. ii. p. 175 (see NATURE, vol. xlii. p. 207). We are indebted to M. G. Maze for the publication of extracts from the interesting original documents which are contained in the National Library in Paris.

AN account of some ingenious experiments on wind pressure is reported in *Engineering* of December 27 last, made by Messrs. H. C. Vogt and I. Irminger, of Copenhagen, to prove that "the greater part of the lifting power of an aeroplane, or the thrust of a close-hauled sail, was to be attributed to the rarefaction on the leeward side of the same, and not to the direct pressure." The experiments seem to show that even when a pressure-plate was perpendicular to the wind, the direct pressure was equal to only about one-third of the vacuum behind, and that when the vane was placed parallel to the wind, a negative pressure was indicated. For the purpose of the experiments, a current of air was produced by inserting in the side of a high chimney connected with the Gas Works one end of a rectangular conduit, the interior sectional area of which was $4\frac{1}{2} \times 9$ inches, and the length 40 inches. In this conduit was placed a hollow vane which reached from side to side, but the width of which was only $1\frac{5}{8}$ inches. The interior of the hollow vane was connected through its axis with a water-gauge, and the arrangement was such that the vane could be turned to any desired angle. Three holes were bored in both faces of the vane, but only one of these holes was used at a time, the others being stopped when not in use. We think that the results arrived at should be accepted with caution. The second leg of the pressure-gauge was connected with the inside of the conduit by an opening just above the vane, and there seems to be little doubt that the disturbance of the air current must, in such a small passage, have been considerable, and would probably affect the pressure upon the hole connected with the second leg of the gauge. This may possibly account for some of the rather improbable results obtained.

The Scalpel—a monthly journal of medicine and surgery—has just made its bow to a medical public. The new journal is edited by Dr. T. M. Dolan, and it will be conducted upon much the same lines as the late *Provincial Medical Journal.*

THE January *Journal* of the Sanitary Institute (vol xvi. part iv.) contains a paper on infectious diseases and methods of disinfection, by Dr. E. Seaton; and among the articles is one on the Hermite process for sanitation of towns, by Mr. E. J. Paterson.

THE careers of few men inspire such international admiration as the life of Huxley. His sterling qualities stand out so boldly that they command the attention of the entire intellectual world. The latest biographical notice that we have seen has appeared in the last two numbers of the *Revue Scientifique*, the author being Dr. H. de Varigny. We commend Dr. Varigny's appreciative notice to the attention of those who would be interested to learn of the high regard in which Huxley's works are held among men of science in France.

WE have received from Prof. G. Klebs, of Basel, an interesting paper entitled *Ueber einige Probleme der Physiologie der Fortpflanzung.* He deals with all the most recent observations on the phenomena of non-sexual propagation and of sexual reproduction, especially in the vegetable kingdom, and sums up

in favour of the view that the non-sexual was the original universal mode of multiplication. He supports this view largely by the phenomena of parthenogenesis, and by the fact that it is possible, by preventing the conjugation of the two gametes in *Spirogyra*, to cause each of them to develop into a "spore" fully capable of germination.

THE additions to the Zoological Society's Gardens during the past week include a Mozambique Monkey (*Cercopithecus pygerythrus*, ♂) from East Africa, presented by Miss Louisa Hutt: a Pig-tailed Monkey (*Macacus nemestrinus*, ♂) from Java, presented by Mr. W. Englehardt; a Puff Adder (*Vipera arietans*) from South Africa, presented by Mr. J. E. Matcham: two Golden-crowned Conures (*Conurus aureus*) from South-east Brazil, deposited; two Black-headed Caiques (*Caica melanocephala*) from Guiana, a Green-cheeked Amazon (*Chrysotis viridigenalis*), from Columbia, purchased.

OUR ASTRONOMICAL COLUMN.

A NEW AUSTRALIAN OBSERVATORY.—The site for the new observatory, which the Government of West Australia are about to erect, has been selected at Perth. The cost of the buildings and instruments is estimated at about £5000. The latter will have such improvements on ordinary construction as have been suggested by experience with the instruments used at the Adelaide Observatory. The equipment will include an equatorial having an object-glass of 8 inches aperture. This instrument will be furnished with a spectroscope, and with photographic appliances. There will also be a transit circle 6 inches in diameter. The post of Astronomer has been filled by the appointment of Mr. W. Ernest Cooke, the Assistant Astronomer of South Australia. Mr. Cooke is an Australian by birth, and has been trained under Sir Charles Todd in observatory work.

THE SUN'S PATH IN SPACE.—The question as to a possible orbital movement of the solar system is revived by Mr. G. C. Bompas in the current number of the *Observatory*. Determinations of the position of the apex of the sun's way have been variously based on groupings of selected stars according to number, magnitude, or proper motion, the latter being now acknowledged the best test of distance. When arranged according to the distances of the stars on which they are based, the results seem to indicate that the position deduced from the nearer stars moves south-west along the plane of the Milky Way, as compared with the apex derived from stars supposed to be more distant. If the sun's path were rectilinear and the stars at rest, the "radiant point" would be the same for near and distant stars, but if curvilinear it would be shifted in accordance with the varying direction of the tangent, and the displacement would be in proportion to the apparent velocity. From existing data, Mr. Bompas considers it probable that the sun moves in a retrograde orbit from east to west in a plane inclined a few degrees to the Milky Way, and the conclusion is independent of any further consideration as to the presence or absence of a systematic movement of the stars round a common centre. "The relation of the solar system to the galaxy would thus resemble that of Uranus and his moons to the ecliptic, the solar system being inclined about 70° to the plane of the galaxy and the planets revolving round the sun in a reverse direction to the orbit attributed to the sun."

EQUATORIAL VELOCITY OF JUPITER.—A spectroscopic determination of the equatorial velocity of rotation of Jupiter has been made by Dr. Belopolsky, the resulting value being 11·4 kilometres per second (*Ast. Nach.* 3326). Taking the rotation period to be 9h. 50m., the calculated velocity varies from 12·1 to 12·8 kilometres per second, according to the angular diameter which is accepted. Although the difference between the observed and computed velocity is possibly within the limits of error in measurement, it is not considered improbable that the apparent discrepancy may have its origin in the increase of the angular diameter of the planet due to refraction in its atmosphere, and the consequent apparent increase of the calculated linear velocity. A similar result has been observed in the case of Saturn, the measured velocity being smaller than that which the known rotation period and angular diameter require.

PERRINE'S COMET.—The comet discovered by Mr. Perrine on November 16, 1895, was well observed in the northern hemisphere up to December 7, when it was seen at Greenwich, and stated to be very bright with a conspicuous tail. It was thought that it might possibly be subsequently observed in daylight in the southern hemisphere, but no observations have been published so far as we are aware. Towards the end of January it will be sufficiently removed from the sun to be seen as a morning comet, but with greatly diminished brightness. The following ephemeris, for Berlin midnight, is by Dr. E. Lamp:—

	R.A. h. m. s.	Decl. ° ′	Brightness.
Jan. 24	19 37 27	−7 3·4	0·43
28	39 13	5 51·2	0·35
Feb. 1	40 50	4 41·6	0·29
5	42 17	3 33·7	0·25
9	43 34	2 27·0	0·21
13	44 40	1 21·0	0·18
17	45 33	−0 15·5	0·16
21	46 13	+0 49·8	0·15
25	46 38	1 55·1	0·13
29	46 48	+3 0·7	0·12

The unit of brightness is that on November 18.

OYSTERS AND TYPHOID.

THE fourth meeting of the tenth session of the Liverpool Biological Society was held on January 10, at University College, Liverpool. During the evening an interesting report on "Green Oysters, and the connection between Oysters and Disease" was presented by Prof. Herdman, who explained that a year ago he and Prof. Boyce commenced to investigate the conditions under which oysters lived healthily. Among other matters they directed their particular attention to the possibility of the oyster being infected by sewage in sea-water with the typhoid organism, and of so transmitting the disease to the consumer. At the meeting of the British Association at Ipswich, last September, they communicated the results they had obtained up to that point, and then they were appointed (with the addition of Prof. Sherrington and Mr. G. C. Bourne) as a committee to investigate the matter further. At present they were really in the midst of their observations; and the present communication could only be regarded in the nature of an interim report, as their conclusions would not be drawn up for publication until the meeting of the British Association in September next. In the meantime a most alarming and widespread scare, following upon incidents connected with a ball at Stirling, on October 1, had arisen, it being assumed that there was some connection between oysters and an outbreak of typhoid. This had considerably affected the important oyster trade of the country, and had probably thrown a great deal of quite undeserved suspicion upon perfectly wholesome oysters. Under these circumstances they had felt it their duty to take an early opportunity of stating their results and impressions as they stood at present. Their work, so far as it had gone, was of a reassuring character, and demanded from the public at the very least a suspension of judgment, whilst it indicated that the adoption of some simple sanitary precautions would, if properly carried into effect, go far to remove suspicion from the oyster. Prof. Herdman then proceeded to describe, with the aid of lantern slides, specimens and microscopic preparations, the different descriptions of oysters which are supplied in North-west Europe, and the methods of treatment they are subjected to prior to being placed on the market. He dealt with the cultivation of the French green oyster, and discussed the cause of the green colour, both in that oyster and in Americans relaid on the Lancashire coast. He pointed out that the most important precaution to take in oyster culture was to choose perfectly healthy grounds for the fattening process, it being necessary, in the first place, to ascertain that the purity from sewage of the water was beyond question. Further it was advisable to submit the oysters for a short time to disgorging basins or tanks, a method which was adopted with success by the French, before sending them to the market. Prof. Boyce then followed with an account of the experiments on the infection of oysters with typhoid, and showed, by means of tables, the rate at which the typhoid bacillus disappeared in sea-water. There was no evidence of increase in numbers of the bacillus when grown in sea-waters, either when incubated or at ordinary temperatures.

THE SMITHSONIAN INSTITUTION.[1]

II.

The System of Administration.

THE Smithsonian Institution was formally established by the Act of Congress approved August 10, 1846. As defined in the fundamental Act the "Establishment," a body which is in fact "the Institution," is composed of the President of the United States, who is presiding officer *ex officio*, the Vice-President, the Chief Justice, and the members of the Cabinet; and the body thus constituted is made responsible for the duty of "the increase and diffusion of knowledge among men."

In addition to the "Establishment," the Act provides for a "Board of Regents," by whom the business of the Institution is administered, composed of the Vice-President of the United States, the Chief Justice of the Supreme Courts, three members of the Senate, three members of the House of Representatives, and six citizens, no two of whom may be from the same State, though two must be residents of the District of Columbia.

The presiding officer of the Regents is the Chancellor, whom they may elect from their own number. This position has, however, customarily been held by the Vice-President or by the Chief Justice. The executive officer is the Secretary of the Institution, who is elected by the Regents, and is also the Secretary of that Board. The duties and responsibilities of the Secretary are, as has already been explained, such as in other institutions usually belong to the office of Director. He presents to the Regents an annual report upon the operations, expenditures, and condition of the establishment, which is transmitted by the Board to Congress for publication. By special Act of Congress of 1884 an acting-Secretary is provided, in case of the absence or disability of the Secretary, the designation being left with the Chancellor of the Institution. There is at present but one assistant-Secretary, who is in charge of the National Museum.

The annual meeting of the Regents is held in January; their executive committee of three members meet quarterly.

The building occupied by the Institution, and bearing its name, is an ornate structure of Seneca brown stone, occupying a prominent position in the "Mall," which extends from the Capitol to the Washington Monument, in the square known as the Smithsonian Park. This edifice, planned by James Renwick, was begun in 1847 and completed in 1855. Features from different periods of Romanesque styles are combined in its architecture; but its exterior, owing chiefly to the irregular skyline, is very picturesque and pleasing.

The eastern wing of the building, for so many years the hospitable home of Prof. Henry, has been reconstructed internally, and the offices of the Institution are all established within its walls. The remainder of the building is occupied by the laboratories and exhibition halls of the National Museum.

Another building of brick, 325 feet square, was built east of the Smithsonian in 1881, for the reception of a portion of the Museum collections.

The Objects of the Institution.

The objects of the Institution, as defined by Henry, are, first, to increase knowledge by original investigations and study either in science or literature; and, second, to diffuse knowledge, not only through the United States, but everywhere, especially by promoting an interchange of thought among those prominent in all nations. No restriction is made in favour of any one branch of knowledge.

The leading features of the plan of Prof. Henry were, in his own words, "to assist men of science in making original researches, to publish them in a series of volumes, and to give a copy of them to every first-class library on the face of the earth." There are not many scientific investigators in the United States to whom a helping hand has not at some time been extended by the Institution, and the hand has often reached across the Atlantic. Books, apparatus, and laboratory accommodation have been supplied to thousands, and each year a certain number of money grants have been made. Not less important has been the personal encouragement afforded, and the advice given in the tens of thousands of letters of information written in response to inquiries.

It is not, as some persons suppose, a teaching institution, nor does it receive students. It constantly aids, however, in the improvement of the educational system of the country.[1]

An important feature in the educational work of the Institution has been its participation in the various International Expositions. It was represented at Philadelphia in 1876; Berlin, 1880; London, 1883; New Orleans, 1885; Cincinnati, 1889; Madrid, 1892; Chicago, 1893; Atlanta, 1895; and has received many medals and diplomas of commendatory nature upon these occasions.

The Publications.

The publications are numerous, and include many important and authoritative works. There is no restriction as to subject, and they consist of memoirs upon archæology, ethnology, botany, zoology, geology, palæontology, meteorology, magnetics, physics, physiology, and philology, and many other branches of investigation.

These books are practically given away, for although there is a provision for their sale at cost price, only a few hundred dollars worth are sold each year. They are regularly distributed to about 4000 institutions in all parts of the world, and are supplied also to numerous private investigators. There are several series, the aspect of which must be familiar to every observing person who has ever spent a day among the shelves in any American library of respectable standing.

(1) The Annual Report of the Regents to Congress, of which the forty-ninth, that for 1894, is now in press. Since 1884 the report of the Museum has been printed in a separate volume (Part II.).[2]

(2) The Smithsonian Contributions to Knowledge, thirty-two volumes in quarto, containing over 7000 pages and many fine plates.[3]

(3) The Smithsonian Miscellaneous Collections, in thirty-five octavo volumes, aggregating about 22,000 pages.[4]

(4) The Bulletins of the National Museum, fifty in number, beginning in 1875.[5]

(5) The Proceedings of the National Museum, including already 1100 separate papers, embraced in seventeen annual volumes, beginning in 1878.[6]

(6) The Annual Reports of the Bureau of Ethnology, beginning in 1879, and forming a series of twelve illustrated volumes in royal octavo.[7]

(7) The Bulletin of the Bureau of Ethnology, of which twenty-six numbers have appeared.[8]

The value of the books distributed since the Institution was opened has been nearly 1,000,000 dollars, or nearly twice the original bequest of Smithson.[9] Many of the publications in each of these series are now out of print.

The Library.

One of the most important features of the Institution is the library which has grown up under its fostering care. For nearly fifty years its publications have been distributed throughout the world to almost every scientific and literary establishment of good repute. In return for these, and by purchase, it has received the great collection of books which forms its library, and which is one of the richest in the world in the publications of learned societies, and therefore of inestimable value, containing as it does the record of actual progress in all that pertains to the mental and physical development of the human family, and affording the means of tracing the history of every branch of

1 By Dr. G. Brown Goode. (Continued from page 261.)

1 The Institution supports a table at the International Zoological Station in Naples for the benefit of naturalists. There is an assembly hall in the Museum building, in which meetings of scientific bodies of national scope are held. Here the National Academy of Sciences holds its annual meeting every April, and the American Historical Association (which is by law affiliated with the Institution) its December meeting. Here also each year a course of popular scientific lectures is delivered under the direction of the scientific societies of Washington.

2 "Public Documents" printed by order of Congress, and distributed in large editions.

3 Published at the cost of the Smithsonian Fund, and not "Public Documents."

4 *Ibid.*

5 Published in a limited edition from a special appropriation, and not "Congressional Documents."

6 *Ibid.*

7 "Public Documents" printed by order of Congress, and distributed in large editions.

8 The Bureau also supervises a series of quarto volumes, bearing the title "Contributions to North American Ethnology," begun in 1877 by the U.S. Geographical and Geological Survey, of which nine have been issued.

9 This estimate is based upon the prices which are charged for the books by second-hand dealers, as shown in their sale catalogue.

positive science since the days of the revival of letters until the present time.

This library was, in 1865, deposited at the Capitol, as a portion of the Congressional Library.

The Smithsonian Collection, which includes more than three hundred thousand volumes and parts of volumes, constituting perhaps one-fourth of the National Library, is to be installed in a special stack-room of its own upon the main floor of the new Library Building, with a commodious reading-room adjacent for the use of special students. The rapidity with which it is increasing is indicated by the fact that in 1894, 37,952 titles were added.[1]

The Institution has probably done more towards building up a great library in Washington than would have been possible had all its income been devoted strictly to library work, as was at one time seriously proposed.

THE NATIONAL MUSEUM.

The Smithsonian Institution is the custodian of the National Museum, which is the only lawful place of deposit of "all objects of art and of foreign and curious research, and all objects of natural history, plants, and geological and mineralogical specimens, belonging to the United States." The nucleus of the collections consists of the specimens brought home by the Wilkes and other exploring expeditions, but for many years the Museum was supported entirely at the expense of the Smithson Fund, and a considerable portion of the collections is the property of the Institution. Since 1881, the entire expenses of administration have been met by Congressional appropriations. The appropriations from 1858 to 1880 were only sufficient to meet these expenses in part.

FIG. 6.—The New Museum Building.

Prof. Huxley defines a museum as "a consultative library of objects." The National Museum is such a consultative library, and it is a great deal more. It is an agency for the instruction of the people of the whole country, and it keeps in mind the needs of persons whose lives are not occupied in the study of science as well as those of the professional investigator and teacher.

Its benefits are extended without cost or reserve to hundreds of thousands of visitors from all parts of the United States who pass through its doors each year, as is shown in the following table:

Number of Visitors since 1881.

Year.	New Building.	Old Building.	Total.
1881	150,000 ...	100,000 ...	250,000
1882	167,455 ...	152,744 ...	320,199
1883	202,188 ...	104,823 ...	307,011
1884 (half-year)	97,661 ...	41,565 ...	139,226
1884-85 ...	*205,026 ...	102,093 ...	307,119
1885-86 ...	174,225 ...	88,960 ...	263,185
1886-87 ...	216,562 ...	98,552 ...	315,114
1887-88 ...	249,665 ...	102,863 ...	352,528
1888-89 ...	*374,843 ...	149,618 ...	524,461

* Years of Presidential inaugurations.

And also through the distribution of the duplicate specimens in the Museum, which are made up into sets, accurately named, and given to public institutions in all parts of the country.

The history of the Museum is divided into three periods: First, that from the foundation of the Smithsonian Institution to 1857, during which time specimens were collected purely and solely to serve as materials for research, no special effort having been made to publicly exhibit them or to utilise them, except as a foundation for scientific description and theory. Second, the period from 1857, when the Institution assumed the custody of the "National Cabinet of Curiosities," to 1876. During this period the Museum became a place of deposit for scientific material which had already been studied; this material, so far as practicable, being exhibited to the public, and thus made to serve an educational purpose. Third, the present period, beginning in the year 1876, during which the Museum has entered upon a career of active work in gathering collections and exhibiting them on account of their educational value.

During the first period, the main object of the Museum was scientific research; in the second, the establishment became a museum of record as well as of research; while in the third period there is growing up also the idea of public education.

The three ideas, *Record*, *Research* and *Education*, co-operative and mutually helpful as they are, are essential to the development of every great museum. The National Museum endeavours to promote them all.

It is a *Museum of Record*, in which are preserved the material foundations of an enormous amount of scientific knowledge—the types of numerous past investigations. This is especially the case with those materials that have served as a foundation for the reports upon the resources of the United States.

It is a *Museum of Research*, which aims to make its contents serve in the highest degree as a stimulus to inquiry and a foundation for scientific investigation. Research is necessary in order to identify and group the objects in the most philosophical and instructive relations, and its officers are therefore selected for their ability as investigators, as well as their trustworthiness as custodians.

It is an *Educational Museum*, through its policy of illustrating by specimens every kind of natural object and every manifestation of human thought and activity, of displaying descriptive labels adapted to the popular mind, and of distributing its publications and its named series of duplicates.

The collections are installed, in part, in the Smithsonian

[1] The working libraries of the National Museum and the Bureau of Ethnology are distinct from the general Smithsonian Library, and are separately administered. All of these are placed at the service of advanced students and specialists.

building and, in part, in the large building adjacent, covering three and a half acres of ground, which was erected in 1881 to afford temporary accommodation for the overflow until such time as an adequate new building could be constructed.

The number of specimens in the various departments of the Museum, in 1894, is shown in the following table:

STATISTICS OF THE NATIONAL COLLECTIONS.

Arts and Industries.	
Historical collections, coins, medals, &c.	29,998
Musical instruments	1,219
Modern pottery, porcelain, bronzes, &c.	3,583
Graphic arts	1,704
Physical apparatus	366
Transportation and engineering	1,793
Naval architecture	802
Fisheries	10,080
Animal products	3,028
Domestic animals	162
Chemical products	1,309
Materia medica	6,317
Foods	1,111
Textiles	3,306
Forestry	726
Ethnology	423,000
Oriental antiquities and religious ceremonial	4,145
Prehistoric anthropology	153,424
American aboriginal pottery	33,293
Mammals	12,948
Birds	73,325
Birds' eggs and nests	58,041
Reptiles and batrachians	34,215
Fishes	125,000
Vertebrate fossils[1]	1,595
Mollusks (including Cenozoic fossils)	510,256
Insects	610,000
Marine invertebrates	520,000
Comparative anatomy	14,828
Palæozoic fossils	95,631
Mesozoic fossils	89,493
Fossil plants	113,685
Recent plants	252,111
Minerals	25,431
Geology	63,606
Total	3,279,531

The importance of these collections is greatly enhanced by this fact, that they include many thousands of types of the original descriptions of the pioneers of American natural history—Audubon, Baird, Agassiz, Girard, Cope, Marsh, Gray, Young, Dana, Gill, Jordan, and many more, and as such constitutes an important part of the foundation of our systematic zoology and botany.

The intrinsic value of such material as this cannot well be expressed in figures. There are single specimens worth hundreds, others worth thousands of dollars, and still others which are unique and priceless. Many series of specimens, which owe their value to their completeness and to the labour which has been expended on them, are priceless. The collections at a forced sale would realise more than has been expended on them, and a fair appraisal of their value would amount to several millions of dollars.

In the direct purchase of specimens but little money has been spent, less perhaps in fifty years than either France, England, Germany, or Austria expends in a single year on similar objects. The entire Museum is the outgrowth of Government expeditions and expositions, and of the gifts prompted by the generosity of the American people.

THE BUREAU OF EXCHANGES.

The Smithsonian system of international exchanges, begun in 1852, had for its object the free interchange of scientific material between scientific institutions and investigators in the United States and those in foreign lands. For this purpose it established correspondence with scientific societies, literary and learned men all over the world, until there is no civilised country or people, however remote, upon the surface of the planet, so far as is known, where the Institution is not represented. The list of correspondents has lengthened until those external to the country alone number nearly 17,000, while the total number is about 24,000.

Many of the principal steamship companies gave generous aid in recognition of this disinterested work by granting important concessions of free freight. The United States and foreign Governments permitted the entrance through their Customs services of Smithsonian exchange boxes, and the Institution was enabled to distribute its exchange packages in this country, without expense to its funds, under the franking privilege.

In recent years the Smithsonian has been recognised by the United States Government as being in charge of its official Exchange Bureau, through which the publications of Congress are exchanged for those of foreign Governments, and by a formal treaty it acts in an official capacity as intermediary between the learned bodies and literary and scientific societies, &c., of the contracting States for the reception and transmission of their publications.

The Exchange Service has become a most valuable adjunct to educational interests, and there are few important libraries or workers in science, either at home or abroad, who have not had direct experience of its benefits.

The rules established for its control provide for the distribution to any accessible point abroad of books, pamphlets, charts, and other printed matter sent as *donations or exchanges*, and without expense to the sender beyond that of the delivery of the packages to the Smithsonian Institution in Washington, and also without expense to the receiver, except in some instances the small cost of delivery from the Smithsonian agent or correspondent nearest at hand. Similar material sent from abroad to this country is forwarded to the recipient without expense to him, the packages having been delivered free of freight charges to a foreign agent or correspondent of the Institution.

A scientific society or individual in the United States desiring to take advantage of the Exchange Service should have each of the packages transmitted strongly wrapped and separately and legibly addressed, being careful to give the full local address, and should send them in bulk, carriage prepaid, to the Institution in Washington. The separate packages should not exceed one-half of one cubic foot in bulk, and they should not contain letters or written matter.

Transmissions from abroad are received by freight in large boxes, and are distributed in the United States under frank by registered mail, a record first having been made of the name of the sender and of the address of each package. A receipt card, returnable by mail without postage, is sent with each of these packages, and should be forwarded at once by the recipient in acknowledgment of the package.

The Institution and its agents will not knowingly receive for any address purchased books, nor apparatus and instruments, philosophical, medical, &c. (including microscopes), whether purchased or presented; nor specimens of natural history, except where special permission from the Institution has been obtained.

The operations of this Bureau have affected most beneficially the libraries of all learned institutions in America. In 1867 Congress assigned to the Institution the duty of exchanging fifty copies of all public documents for similar works published in foreign countries. Finally in 1889 a definite treaty, made previously at Brussels, was formally proclaimed by the President of the United States, wherein the United States Government, with a number of others, undertook the continuation of the exchange service on a more extensive basis. Out of this has grown the Bureau of International Exchanges, for the maintenance of which Congress partially provides by annual appropriation. From 1852 to 1895 the Smithsonian exchange service handled 1,459,448 packages, and for three years past the weight of books passing through this office has been considerably over one hundred tons annually.

SPECIAL GIFTS AND TRUSTS.

The authority of the Institution to undertake the administration of financial trusts for any purpose within the scope of its general plan, preserving in connection with each fund the name of the person by whom it was established, has been recognised by Congress.

There is no institution in the world which is more favourably

[1] Only that portion of the Collection which is in Washington is included.

situated for the administration of trusts of this character, and this privilege has, within the past few years, been accepted by several benefactors.

Dr. Jerome H. Kidder, of Washington City, bequeathed, in 1889, 5000 dols. for the purpose of an astro-physical observatory.

Dr. Alexander Graham Bell, in 1889, gave 5000 dols. to the Secretary for his personal use in physical investigation, which has been transferred by him to the credit of the Institution, and devoted to physical work.

Mr. Thomas G. Hodgkins, of Setauket, N.Y., gave, in 1891, nearly 250,000 dols., a portion of the income from which is to be applied to the investigation of atmospheric air.[1]

Robert Stanton Avery, of Washington City, who died in 1894, left property then estimated to be worth at least 50,000 dols. to provide for special investigations.

There have also been many valuable gifts to the Museum, such as that of Dr. Isaac Lea, of Philadelphia, who gave his great collections of mollusks, and of gems and precious stones; that of Mr. Joseph Harrison, of Philadelphia, consisting of the collection of Indian portraits painted by George Catlin; that of Mr. R. D. Lacoe, of Pittston, Pa., the largest existing collection of American fossil plants; and the collections of American birds' eggs given by Major Charles Bendire, U.S.A., and Dr. William H. Ralph, of Utica, N.Y.

THE ASTRO-PHYSICAL OBSERVATORY.

The Astro-physical Observatory was established in 1891, under the immediate direction of the present Secretary. The expense of maintenance has since been provided for by a small appropriation from Congress. Here is carried on work corresponding to that of similar institutions maintained by the principal European Governments, and on a much less expensive scale, though not less effectively.

Since astro-physics is almost the newest of sciences, it may not be amiss to give here a brief description of the purposes of this observatory:

"Within the past generation," we are told, "and almost coincidentally with the discovery of the spectroscope, a new branch of astronomy has arisen, which is sometimes called astro-physics, and whose purpose is distinctly different from that of finding the places of the stars, or the moon, or the sun; which is the principal end in view at such an observatory as that, for instance, at Greenwich.

"The distinct object of astro-physics is, in the case of the sun, for example, not to mark its exact place in the sky, but to find out how it affects the earth and the wants of man on it; how its heat is distributed, and how it in fact affects not only the seasons and the farmer's crops, but the whole system of living things on the earth, for it has lately been proven that in a physical sense it, and almost it alone, literally first creates and then modifies them in almost every possible way.

"We have, however, arrived at a knowledge that it does so, without yet knowing in most cases how it does so, and we are sure of the great importance of this last acquisition, while still largely in ignorance how to obtain it. We are, for example, sure that the latter knowledge would form, among other things, a scientific basis for meteorology, and enable us to predict the years of good or bad harvests, so far as these depend on natural causes, independent of man, and yet we are still very far from being able to make such a prediction, and we cannot do so till we have learned more by such studies as those in question. Knowledge of the nature of the certain, but still imperfectly understood dependence of terrestrial events on solar causes is, then, of the greatest practical consequence.

"It has been observed that this recent science itself was almost coeval with the discovery of the spectroscope, and that instrument has everywhere been largely employed in most of its work. Of the heat which the sun sends, however, and which, in its terrestrial manifestations, is the principal object of our study, it has long been well known that the ordinary spectroscope could recognise only about one-quarter, three-quarters of all this solar heat being in a form which the ordinary spectroscope cannot see nor analyse, lying as it does in the, till lately, almost unknown 'infra-red' end of the spectrum, where neither the eye nor the photograph can examine it."

This Observatory in Washington has been continuing the famous researches in regard to that invisible portion of the solar spectrum which lies beyond the limit of the red, which had been begun by Mr. Langley while director of the Allegheny Observatory. The exploration of "this great unknown region," which was first rendered possible by the invention of the bolometer, is now being carried still further by means of a new method, much perfected during the last four years, which has rendered it possible to produce a complete map by an automatic and absolutely trustworthy process, which shows the lines which resemble the so-called Fraunhofer lines in the upper spectrum. The results already attained are believed to be the most important which have ever been reached in regard to that region of the spectrum of which so little is known, and which includes the greater portion of all those energies of the sun which, through its heat, affect climate and the crops, and are thus related not only to questions of abstract interest, but to utilities of national importance.

THE NATIONAL ZOOLOGICAL PARK.

The National Zoological Park was established by Congress in 1890, as a result of the desire to secure the preservation of such American animals as are upon the verge of extinction and will soon vanish for ever if something is not done to protect them, and occupies a tract nearly twice as extensive as that of any zoological garden in the world; this includes one hundred and sixty-seven acres upon Rock Creek, only two miles north of the Executive Mansion, at the centre of the city. The site has admirable natural advantages, and much has already been done in the opening of drives and the construction of buildings.

When Congress was asked to appropriate funds for this Park, it was in view of the fact that many North American animals, constituting a part of the national wealth, and formerly occupying a large portion of its domain, are threatened with speedy extinction.

The buffalo, the beaver, the wapiti, the moose, and many other species, which until lately were abundant east of the Mississippi, are each year becoming rarer. On the Pacific Coast the sea-elephant is gone, and the walrus practically so, and the sea-otter, the fur-seal, and the sea-lion rapidly disappearing. The passenger-pigeon and the Carolina parrakeet are almost gone. It was urged upon Congress that unless steps were speedily taken, these races must perish.

The reservation of the Yellowstone National Park as a great game preserve was an important start in this direction, but the very immensity of the reservation seems to threaten the defeat of the plan, for the animals cannot be protected from marauders, and are being rapidly destroyed. To retard their extinction and to provide opportunities for their study, was the intention of those who first advocated the establishment of a preserve near Washington large enough to keep the animals as close to natural conditions as is possible, and the project seems to have been even more important than was at first supposed.

A small representative collection of native American animals has already been formed, including about five hundred individuals, among them a fine herd of young elk and a small herd of buffaloes; but the annual appropriations have not been sufficient to permit satisfactory progress.

THE BUREAU OF AMERICAN ETHNOLOGY.

The Bureau of Ethnology is an outgrowth of activities beginning early in the history of the Institution, which has from the very outset devoted much attention to the native American races.

The special work of the Bureau in its present form was begun in 1872, in response to a request from the Commissioner of Indian Affairs, who desired trustworthy information concerning the affinities of the Indian tribes, to serve as a guide in grouping them on the reservations. The question was referred by the Secretary of the Smithsonian Institution to Major J. W. Powell, then engaged, under the direction of the Institution, in explorations in the south-west. Combining the vocabularies and other manuscipts already in possession of the Institution, he prepared a report showing the character and extent of existing information, and the manner in which it was possible to utilise this in the segregation of the Indian tribes, at the same time suggesting plans for the completion of the work of classification.

This was the beginning of the Bureau, which since 1879 has been supported by special appropriations from Congress, with the understanding that the research should be so extended as to

[1] A prize of 10,000 dols., derived from this fund, was awarded August 6, 1895, to Lord Rayleigh and Prof. William Ramsay, of London, for the discovery of Argon, a hitherto unknown element in the atmosphere.

embrace the habits and customs of the American Indians, their tribal organisations and government, and their myths and ceremonials.

Major Powell was made director, and no one could have been better fitted for the task. For more than thirty years he had been a student of the native races of this continent. He and his associates in the Bureau have succeeded in placing on record, before it was too late, a vast number of facts in regard to the Indians. The Annual Reports of the Bureau, twelve in number, and nine volumes of Contributions to North American Ethnology, with the Bulletin of the Bureau, form a considerable library in themselves. The archives still contain much unpublished material, including hundreds of vocabularies.

A complete linguistic classification of the native languages of the United States has been prepared by the director, and an effective classification of the tribes on the reservation, reducing materially the danger of warlike outbreaks, has already been accomplished.

EXPLORATIONS.

The promotion of exploration has, from the beginning, been an important feature in the work of the Institution, and grants of money and loans of apparatus have been made to many hundreds of explorers, who have thus been enabled to contribute to the knowledge of the zoology, botany and ethnology of the American continent. Much has also been done in supplying scientific apparatus to the officers of the various Government surveys, which, in early days, were very often equipped only for geographical work. The Naval Astronomical Expedition to Chili was supplied by the Institution with a telescope and other apparatus, which was afterwards bought by the Government of Chili for the National Observatory at Santiago. The medical officers of the numerous surveys preliminary to the building of the transcontinental railroads, and those of the several boundary surveys, thus equipped for natural history work, made vast collections.

Members of the Smithsonian staff have frequently been detailed to serve as tidal or meteorological observers, under other departments of the Government, in remote localities, for the purposes of exploration. The important early explorations of John Xantus on the extremity of the Lower Californian Peninsula, and of Turner, Nelson, Murdoch, Kumlien, and others in the Arctic regions, were effected in this manner, as well as the earlier and more important work of Kennicott, Dall and Bannister, in Alaska, in connection with the Russian Telegraph Expedition.

On the staff of the Bureau of Ethnology important explorations of the western portion of the continent have been made, especially those of the Stevensons, Cushing, Fewkes, and the Mindeliffs, among the Pueblo people and the ruins of the southwest: those of Holmes among the prehistoric quarry sites and villages of the eastern part of the continent; those of Thomas among the mounds of the Mississippi Valley, and of McGee among the Papago and Seri Indians of the Mexican boundary; and the notable explorations of Major J. W. Powell among the tribes of Utah, California, Arizona and New Mexico.

The expeditions of Rockhill in Tibet, of Jouy in Korea, of Abbot and Chanler in Eastern Africa and Kashmir, Madagascar and the islands of the Indian Ocean, have been indirectly under the auspices of the Institution, and allusion should also be made to the visit of Major Dutton to the Hawaiian Islands for the study of volcanic phenomena, which was carried on directly at the expense of the Smithsonian Fund.

The Institution participated also in fitting out the Arctic Expedition of Kane, Hayes and Hall.

THE PROMISE OF THE FUTURE.

At the time of the Smithson bequest, the endowment of research had scarcely been attempted in America. There were schools and colleges in which science was taught, and certain of the teachers employed in these institutions were engaged in original investigation. There were a few young and struggling scientific societies, very limited in extent and influence, but at that time the chief outcome of American scientific work. Science in America was an infant in swaddling clothes. Fifty years have passed, and American science now stands by the side of the science of Great Britain, of Germany, of France, a fellow worker competing in nearly every field of research.

The Smithsonian Institution did what was, at the time of its organisation, absolutely indispensable to the rapid and symmetrical development of American scientific institutions, and but for it, science in America would no doubt have advanced with much less rapidity. It is also certain that the progress of American science has had an immense influence upon the welfare of America in every department of intellectual and industrial activity, and also a reflex action upon the scientific and industrial progress of the entire world.

This year the Smithsonian Institution will celebrate the end of its first half-century. A special volume will be published to commemorate the event, and two memorial tablets will be erected in honour of the founder in the city of Genoa, where he died, June 26, 1829; one in the English church, and one upon his tomb in the beautiful little English cemetery on the cypress-clad heights of San Benigno.

It is interesting to remember that in September next will occur not only the semi-centenary anniversary of the birth of the Institution founded in the City of Washington by Smithson, but also the centenary of the delivery of that immortal address in which Washington so forcibly recommended to his countrymen "to promote as an object of the highest importance INSTITUTIONS FOR THE INCREASE AND DIFFUSION OF KNOWLEDGE."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Council of the Royal Geographical Society offer in the present academical year a Studentship of £100, to be used in the geographical investigation (physical or historical) of some district approved by the Council. Candidates must be members of the University of not more than eight years' standing from matriculation, who have attended the courses of lectures given in Cambridge by the University Lecturer in Geography. Applications should be addressed to the Vice-Chancellor not later than the last day of the full Lent Term, March 13, 1896.

LORD HALSBURY has been elected Chairman of the Council of the City and Guilds of London Institution for the Advancement of Technical Education.

THE *Technical World* has extended its sphere of usefulness. Henceforth it will be the newspaper for secondary and technical education broadly defined. It has been accepted as the official organ of the Association of Headmasters, and of the Association of Organising Secretaries and Directors. The general policy of our contemporary will be to support the conclusions of the Royal Commission on Secondary Education, by which we understand that it will exert its influence in co-ordinating the work of secondary education. With one paragraph in the announcement of the enlargement of the journal we are in entire agreement; it is this: "That the organising secretaries and directors should have an official organ will serve to remind them (a fact which a few are prone to forget) that they have duties not only to their own counties and committees, but to each other and to higher education generally. The more they co-operate, and within limits agree, the better will be the individual work of each."

WISE words were spoken by Sir Henry Fowler last week, while commenting upon the report of the Wolverhampton Chamber of Commerce. Referring to the necessity for technical education, he remarked: "In this respect foreigners are ahead of England, and Chambers of Commerce might attach more importance to the point. In foreign countries they make greater sacrifices for it and do not grumble at the expense. In England we are now waking up to the importance of it, but we want technical education on a very much larger scale than we have as yet got it. We want it very much on the lines which the Committee of the Chamber of Commerce in their report point out, namely, technical instruction for foremen and better-class artisans. In a competition between two manufacturing countries, the country where the manufacturing population has the better technical education is more favourably placed in connection with its operations, and has a distinct advantage in the markets of the world." We are doing a little, it is true, to advance technical and scientific knowledge, but much of the money allocated to local authorities for technical education is being frittered away. Many Technical Instruction Committees are incapable of organising a scheme of instruction which will prove of permanent benefit to industry. Instead of concentrating their attention upon a few subjects, and supplying effective education in them, they devote £10 or £20 to each of a multiplicity

of little efforts. We find that technical education has been made to include all sorts of subjects, even music. Several Councils give grants to classes formed for the exclusive study of music, either instrumental or vocal. The following selection of subjects taught will give some idea of the variegated nature of "technical" work: farriery, straw-plaiting, basket-making, ploughing, draining and dyking, clicking, cabinet-making, thatching, sheep-shearing, fishing, sail-making, china-painting, hat-manufacture, type-writing, political economy, life-saving, and house-decoration. So long as such subjects absorb the attention of Committees, little national advancement is possible. Instruction in the dodges of the workshop may produce a more dexterous and quicker workman, but it does nothing to educate him in those broad principles which enable him to assist intelligently in the real improvement of industry.

THE spirit of rivalry which regulates the conduct of educational institutions in some of our large towns is to be deplored, for its effects are detrimental to the advance of education. Reports, received from time to time, show that, in many districts, local institutions compete with one another instead of forming distinct steps in the educational ladder. So common is this kind of competition that it is refreshing to learn that the City Council and the School Board of Manchester have agreed between themselves that the Technical School shall discontinue its more elementary classes, and begin its curriculum at the points where the Board schools leave off. An effort is to be made to secure a corresponding gradation between the Technical School and Owens College. Manchester has thus taken important steps towards the solution of a difficult problem in public education, and it would be well if those provincial towns that have not already considered the correlation of their technical and scientific institutions would do so without delay. It is a question, indeed, whether a central authority ought not to be able to give a definite place in the educational ladder to the various institutions in a town, and to insist upon the absence of competition with one another. With each part of the engine doing its proper work, progress will be made; but if there is a confusion of functions, advance is impossible. The establishment, in recent years, of numerous technical institutions in many of our large provincial towns, and the extension of the work of old-established Mechanics' Institutes and Trade Schools, make it very necessary that something should be done to define the place of these institutions in our educational system. The University Colleges are especially affected by such institutions. Bristol, for instance, possesses one of the best University Colleges in the country; it has done excellent work, and will certainly do more. But during the past few years the Merchant Venturers' School has largely developed, and it is now a rival establishment situated only a few hundred yards from University College, with which it competes. This competition is no doubt responsible, to some extent, for the adverse balance of £950 in the accounts of University College, Bristol, for the year 1895; the total indebtedness of the College is now more than £6000. There is ample room for both institutions in Bristol, but the work of one should supplement, and not clash with, the work of the other. What is happening in Bristol is happening elsewhere, and is retarding educational advancement. In fact, we have no hesitation in saying that one of the most important points which needs to be settled at the present time is that which refers to the status of various institutions in the scheme of education.

SCIENTIFIC SERIALS.

American Journal of Science, January.—The quarries in the lava beds at Meriden, Conn., by W. M. Davies. The present condition of the quarries in the Triassic (Newark) formation near Meriden shows the vesicular upper surface of one lava bed under the dense basal portion of a later flow, and a number of fractures dislocating the double flow.—The form of isolated submarine peaks, by G. W. Littlehales. Theoretically the form of an isolated submarine peak would be that of a solid of revolution in which the crushing strength of any section is equal to the combined weight of the portion of the formation above that section and of the superincumbent body of water. The author derives a general equation for the slope of submarine peaks, and finds that the average slopes of Dacia Bank, Seine Bank, The Salvages, and Enderbury Island are fairly in accordance with the formula. This investigation has an important bearing upon the intervals at which deep-sea soundings should be taken in searching for probable shoals in the open ocean and in developing the character of the sea-bottom. The minimum radius at the bottom which a dangerous shoal can have, must vary directly with the depth, but on the average, in the deep sea, it may be stated as ten miles. An interval of ten miles, coupled with an interval of two miles, would be sufficient for general development, and would prove with certainty the existence or absence of any formation rising close to the surface.—On the epidote from Huntingdon, Mass., and the optical properties of epidote. This epidote is almost identical with that of Zillerthal, in Tyrol, but has the lowest percentage of iron oxides (6·2) and the lowest double refraction of any epidote recorded.—The iodometric determination of selenious and selenic acids, by F. A. Gooch and A. W. Peirce. The principle previously applied to the estimation of chlorates is equally advantageous for the determination of selenious and selenic acids. The selenious acid is treated with potassium iodide, di-hydrogen potassium arseniate, and half-strength sulphuric acid. The liquid is concentrated by boiling, the residue is cooled and the acid nearly neutralised with potassium hydroxide, acid potassium carbonate is added in excess of neutralisation, and, after the addition of starch, standard iodide is introduced until the starch-blue appears. The iodine introduced measures the arsenious acid, and the difference between it and the iodine, originally present in the form of the iodide, represents the amount set free by the selenious acid. Selenic acid, on the other hand, may be determined iodometrically with accuracy by first reducing it to the condition of selenious acid by treatment with potassium bromide in the presence of sulphuric acid, and then completing the reduction to the elementary condition by the treatment with potassium iodide and potassium arseniate.

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, December 18, 1895.—Dr. Henry Woodward, F.R.S., President, in the Chair.—Prof. G. K. Gilbert, Washington, D.C., was elected a Foreign Member, and Dr. A. Penck, Vienna, was elected a Foreign Correspondent of the Society.—The tertiary basalt-plateaux of North-western Europe, by Sir Archibald Geikie, F.R.S. The author in this paper gave the results obtained by him in the continued study of Tertiary volcanic geology during the seven years which have elapsed since the publication of his memoir on "The History of Volcanic Action during the Tertiary Period in the British Isles." His researches have embraced the Western Islands of Scotland, St. Kilda, and the Faröe Islands. In an account of the rocks of the basalt-plateaux, attention was particularly directed in this paper to a type of banded basic lavas which played an important part in the structure of the volcanic districts both of the Inner Hebrides and of the Faröes. A number of examples were adduced of the volcanic vents which form a characteristic feature of the basalt-plateaux. The paper described in some detail the evidence for the flow of a large river across the lava-fields during the time when volcanic activity was still vigorous. Many additional details were given to illustrate the structure and behaviour of the basic sills which are so abundantly developed, especially at the base of the plateaux. The author added some additional particulars, more especially from Skye and St. Kilda, to his published account of the dykes which had taken so important a place in the origin and structure of the plateaux. Further observations were narrated regarding the great bosses of gabbro in the Inner Hebrides. The author, having been able to visit St. Kilda, described the junction of the granophyre of that remote island with the basalts and gabbros. He brought away a series of specimens and photographs which demonstrated that the acid rock had been injected into the basic masses, traversing them in veins and enclosing angular pieces of them. The granophyre was precisely like that of Skye and Mull, and was traversed by veins of finer material, as in these islands. By way of illustrating the probable history of the basaltic plateaux of North-western Europe, the author gave a short summary of the results of recent investigations of the modern volcanic eruptions of Iceland, especially of Th. Thoroddsen and A. Helland. Reference was made to the evidence of considerable terrestrial movement since the Tertiary volcanic period, as shown by the tilting of large sections of the plateaux in different directions, and also by the existence of actual faults. The con-

cluding section of the paper dealt with the effects of denudation on the plateaux. The author remarked that there was certainly no other area in Europe where the study of the combined influence of atmospheric and marine denudation could be so admirably prosecuted, and where the imagination, kindled to enthusiasm by the contemplation of such scenery, could be so constantly and imperiously controlled by the accurate observation of ascertainable fact.—The British Silurian species of *Acidaspis*, by Mr. Philip Lake. Descriptions were given of those species of *Acidaspis* in the Silurian of Britain which have hitherto been incompletely described. The British forms were compared with those from the same system in Sweden and Bohemia. Five, out of nine, were represented by the same or very closely allied species in Sweden; two in Bohemia. All the Swedish forms except one were represented in Britain, and one in Bohemia as well as in Britain.

Royal Microscopical Society, December 18, 1895.—Mr. A. D. Michael, President, in the chair.—Mr. E. M. Nelson exhibited and described a portable microscope in which the stage had been enlarged to $4\frac{1}{2}'' \times 5''$, and the body fitted with three draw-tubes giving a range of length from $4\frac{3}{4}''$ to $12\frac{3}{4}''$.—A discussion on tube-length ensued, in which Mr. C. Beck, Mr. Nelson, and Mr. J. E. Ingpen took part.—Dr. H. C. Sorby gave an interesting account of his methods for preserving some of the more delicate marine organisms.—Mr. T. D. Ersser exhibited a new method for showing the multiplied images formed by the compound eyes of insects.—The President having reminded the Fellows that the meeting on January 15 would be their annual meeting, the list of Fellows recommended as officers and Council for the ensuing year was then read.

Mathematical Society, January 9.—Major Macmahon, R.A., F.R.S., President, in the chair.—Prof. Elliott, F.R.S., by a method used in connection with seminvariants, showed how to obtain a criterion as to whether or not a rational integral homogeneous function of y, a function of x, and its derivatives, is an exact differential, and further showed that if it is its integral can be found by differential operations only.—The President announced the title of a paper by Prof. Tanner, viz. on a certain ternary cubic. The paper, in the absence of the author, was taken as read. The notes chiefly relate to the automorphs and units of the form, and include a short geometrical discussion.—Mr. S. H. Burbury, F.R.S., made a further communication on Boltzmann's minimum function. Lieut.-Colonel Cunningham, R.E., and Dr. Larmor, F.R.S., joined in a discussion on the paper.—Mr. Love, F.R.S. (Hon. Sec.), communicated some examples illustrating Lord Rayleigh's theory of the stability and instability of certain fluid motions, and subsequently answered questions, bearing on the subject, by Dr. Larmor.

Entomological Society, January 15.—The sixty-third annual meeting, Prof. Raphael Meldola, F.R.S., President, in the chair.—After the balance-sheet had been read by one of the auditors, Mr. Goss read the report of the Council. It was announced that the following gentlemen had been elected as officers and Council for 1896: President, Prof. R. Meldola, F.R.S.; Treasurer, Mr. Robert McLachlan, F.R.S.; Secretaries, Mr. Herbert Goss and the Rev. Canon Fowler; Librarian, Mr. Geo. C. Champion; and as other members of the Council, Mr. Walter F. H. Blandford, Mr. Geo. F. Hampson, Prof. Edwd. B. Poulton, F.R.S., Mr. Osbert Salvin, F.R.S., Dr. D. Sharp, F.R.S., Mr. Roland Trimen, F.R.S., the Lord Walsingham, F.R.S., and Colonel J. W. Yerbury, R.A. It was announced that the President would appoint Dr. D. Sharp, Mr. Roland Trimen, and Mr. W. F. H. Blandford Vice-Presidents for the Session 1896–1897.—Prof. Meldola then delivered an address, in which he first drew attention to the remarkable literary activity of the entomologists of this country during the past year, referring particularly to the works recently published by Miall, Meyrick, Barrett, Rye, Lucas and Buckton, and to the new volume of the "Cambridge Natural History" by Sedgwick, Sinclair and Sharp. Attention was also called to the interesting discoveries in insect physiology by Latter and Hopkins. The main portion of the address was devoted to a plea for a more liberal use in biological work of the theoretical or speculative method which had proved so fruitful in other branches, and which, in the President's opinion, might with advantage be more freely employed in connection with entomological investigation. Illustrations were taken from the work of Bates on mimicry, Wallace on the colours of insects, and Poulton's researches on variable colouring, all of which had been prompted by hypothesis, and which had led to discoveries of large bodies of facts which would never have been gleaned by haphazard observation. In conclusion, the President referred to the losses by death during 1895 of many Fellows of the Society and other entomologists, special mention being made of Prof. Charles V. Riley, Prof. C. C. Babington, F.R.S., the Right Hon. T. H. Huxley, F.R.S., M. E. L. Ragonot, Major J. N. Still, Prof. Carl E. A. Gerstäcker, M.D., M. Claudius Rey, M. Jules F. Fallou, and Mr. W. H. Tugwell.

Royal Meteorological Society, January 15.—Annual meeting.—Mr. R. Inwards, President, in the chair.—The report of the Council showed that the Society was in a satisfactory condition, thirty-four new Fellows having been elected during the year. Mr. Inwards devoted his presidential address to the subject of meteorological observatories, which he illustrated with numerous lantern slides. After describing some ancient observatories, including the Nilometers and the Tower of the Winds at Athens, he gave an account of national observatories, of which the Royal Observatory, Greenwich, was taken as a type. High-level observatories were next described, of which that on Mont Blanc was taken as a type. Special reference was also made to the observatories on the Sonnblick, the high-level observatory at Arequipa on the Andes, and that on Ben Nevis. An account was next given of tower observatories, together with some of the results obtained from the Eiffel Tower at Paris. Mr. Inwards, in concluding, said: "One can figure to oneself a tower piercing the air from any of the elevated tablelands of this country—Salisbury Plain, the Stray at Harrogate, or the Downs between Guildford and Dorking—and from which the most interesting results could not fail to accrue. It is the opinion of M. Vallot—no mean authority—that a high tower is for air-observing purposes equivalent to a mountain station of ten times the altitude: and this is plain when one considers that any mountain must act as an obstacle which thrusts upward the strata of the atmosphere into a form almost like its own, so that some of the effects are very little different from those observed below; while a tower like the Eiffel Tower thrusts itself in the air without obstructing its movements. It is the boast of the Royal Meteorological Society that it is gradually covering the country with a network of private observing stations, and is collecting together, for the enlightenment of all future time, a mass of accurate knowledge on the subject of the changes in our atmosphere, its varying moods, its beating pulses, its calms and its convulsions, so that when the philosopher is born who is destined to unravel all its mysteries, he will have the tools and instruments ready to his hand."—Mr. E. Mawley was elected President for the ensuing year.

EDINBURGH.

Royal Society, December 2, 1895.—Prof. Geikie in the chair.—Before business proper was commenced, the Chairman, in reviewing the work of the past session, congratulated the Society on the reappointment of Lord Kelvin as President. This was the third time, he remarked, that the Edinburgh Royal Society had provided the Royal Society of London with a President. In referring to the successful completion of the *Challenger* Reports, for which the Society offered its heartiest congratulations to Dr. Murray, Prof. Geikie hoped that Government would be induced, by the publication of these results, to equip a proper expedition to the Antarctic regions.—Prof. Tait read a paper, by Lord Kelvin, on the application of network to a surface, in particular to a toroidal surface. Lord Kelvin had had his consideration directed to this subject, in connection with attempts to protect the pneumatic tyres of bicycles, which were examples of a toroidal surface. Dr. Noel Paton read a communication on the relationship of the liver to fats.—Mr. James Milne, gave an account of a mass of manufactured iron, which he found in the valley of the Rhone near the Glacier de la Plaine Morte. It bore the date 1807, and Mr. Milne was of opinion that it had been left there as a mark by an expedition which did some scientific work in the Alps in that year.

December 16, 1895.—Prof. Copeland, Vice-President, in the chair.—An obituary notice of the late Dr. Benjamin Carrington, by W. H. Pearson, Esq., was read by Prof. Tait.—Dr. C. Hunter Stewart, of the Public Health Laboratory, made two communications on allied subjects: Three years' daily determinations of the amount of carbonic acid in the atmospheric air, and in the ground air of Edinburgh; and on the physical and chemical examination of the soil, and the relation of the soil to the incidence of summer diarrhœa in Scotland.—

The result of his investigations on the first subject showed that the proportion of CO_2 in the atmosphere of Edinburgh in 1893 was 3·96, in 1894, 3·72, and in 1895, so far, 3·45 per ten thousand. Dr. Stewart contended that eventually the amount of CO_2 in the air depended on the nature of the soil, as the ground air was the source and regulator of the atmospheric. The ground soil of Edinburgh being clay, produced less carbon than a "travelled" and therefore porous soil. Passing to the second part of his subject, Dr. Stewart adduced statistics to show that, in the case of summer diarrhœa, the mortality was low when the soil was clay, and high when it was sandy.—Prof. Hartley, of Dublin, read a paper on the cause and nature of chemical changes in ocean deposits, and Dr. J. L. Kerr described a new method of making plaster of Paris.

PARIS.

Academy of Sciences, January 13.—M. A. Cornu in the chair.—Observations of the minor planet CH Charlois (January 8), made at the Observatory of Paris, by M. O. Callandreau.—The expenditure of energy in muscular work, by M. A. Chauveau. In the case of a muscle which is doing positive work, such as lifting a weight, the expenditure of energy by the muscle is divided by the author into two parts; one spent in displacing the weight, the other in sustaining it during the displacement. In the experimental study, the external work done in lifting a weight is measured directly, the energy changes in the muscles indirectly, by means of analyses of the inspired and expired air.—Note from the report of M. P. Ballif on the hydraulic works carried out in Bosnia-Herzegovina, and on the meteorology of the two provinces, by M. B. de la Grye.—On the variations in the ratio of the two specific heats of gases, by M. E. H. Amagat. From calculations of the values of the ratio of the specific heats of air at 50° C. under pressures varying from 1 to 50 atmospheres, widely differing results are obtained according as the determinations of the specific heat at constant volume by Joly, or those at constant pressure by Lussana, are taken as the basis of the calculation. The results of Joly are shown to be the most probable. The expression $p(v - \epsilon)^\gamma$ = constant, where ϵ is $\frac{d(pv)}{dp}$ and p, v, and γ have their usual significations, is then developed, as giving the adiabatic expansion for fluids, including highly compressed gases. For low pressures ϵ is negligible, and the equation reduces to the ordinary form.—Observations of the minor planet CH Charlois, made at the Observatory of Toulouse, by M. F. Rossard.—On the nature of the solar prominences, by M. J. Fényi.—On the generalisation of the idea of the limit, and on the extension, to summable divergent series, of Abel's theorem on complete series, by M. E. Borel.—On the theory of cathode rays, by M. G. Jaumann. A reply to a note of M. H. Poincaré. The author thinks it is not necessary to modify his hypotheses to meet the objections of M. Poincaré.—Observations on the preceding communication, by M. H. Poincaré.—On Hall's phenomenon in liquids, by M. H. Bagard. An experimental proof of the existence of the Hall effect in a saline solution. The results for a solution of zinc sulphate are of the same order of magnitude as for metallic bismuth. The experiments contradict the conclusion previously arrived at by M. Roiti, that Hall's effect did not occur with liquids.—Acetylene as a photometric standard, by M. J. Violle. As a single chemical individual of high illuminating power now easily obtained in a state of purity, acetylene offers obvious advantages as a secondary photometric standard. A flat flame of acetylene burning under a pressure of 30 cm. of water, and used with a screen, gave perfectly satisfactory results.—On the heat of formation of some compounds of manganese, by M. H. Le Chatelier. Thermochemical data are given for the combustion in oxygen of manganese, its carbide and protoxide.—On the crystallised iodides of strontium and calcium, by M. Tassilly. A thermo-chemical paper.—On aldehydes derived from the isomeric alcohols $C_{10}H_{18}O$, by MM. Ph. Barbier and L. Bouveault.—On the multirotation of the reducing sugars and isodulcite, by M. Tanret.—Retinal oscillations resultingfrom luminous impression, by M. A. Charpentier.—On the formation of the duramen, by M. E. Mer.—On a new locality in France for *Pinus Salzmanni*, by M. G. Fabre.—Pliocene glaciers in the mountains of Aubrac, by M. G. Fabre.—On some anomalies in the temperature of subterranean springs, by M. E. A. Martel.—On the mechanical production of extreme temperatures, by M. E. Solvay. A note admitting the priority of Prof. Dewar in the use of vacuous envelopes for retarding heat radiation.—On a meteor observed at Chambéry, by M. Chabert, January 6, 5.15 p.m.; direction N.E. to S.W.

BERLIN.

Meteorological Society, December 3, 1895.—Prof. Hellmann, President, in the chair.—General von Tillo, of St. Petersburg, who was present as a guest, explained a series of charts giving the chief results of his observations on the distribution of terrestrial magnetism.—Dr. Fischer described in detail a thunderstorm which occurred over Silesia and Posen on September 30. It began at midnight in a region of low temperature, advanced very slowly, accompanied by very light or even no wind, and did not cease until the next night. The storm area was covered with dense mist, rain was slight and local, and the atmospheric pressure was maximal. This storm was therefore due to neither heat nor wind eddies.—Dr. Zenker spoke on the climate of Werchojansk, with special reference to its temperatures.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Plant-Breeding: L. H. Bailey (Macmillan).—N.S.W. Government Railways and Tramways. Annual Report of the Railway Commissioners for the Year ending June 30, 1895.—First Annual General Report upon the Mineral Industry of the United Kingdom for the Year 1894: Dr. C. Le Neve Foster (Eyre).—On the Deep and Shallow-Water Marine Fauna of the Kerguelen Region of the Great Southern Ocean: Dr. J. Murray (Edinburgh, Grant).

PAMPHLETS.—Von der Menschlichen Freiheit: Dr. H. Achter (Leipzig, Engelmann).—Review of the Mineral Production in India for 1894 (Calcutta).

SERIALS.—Quarterly Journal of Microscopical Science, January (Churchill).—American Journal of Psychology, Vol. vii. No. 2 (Worcester, Mass.).—Psychological Review, January (Macmillan).—North American Fauna, No. 10 (Washington).—Journal of the Franklin Institute, January (Philadelphia).—Journal of the Sanitary Institute, January (Stanford).—Palestine Exploration Fund Quarterly Statement, January (Watt).—Intles. Archiv für Ethnographie, Band viii. Heft 5 and 6 (Leiden, Brill).—Record of Technical and Secondary Education, January (Macmillan).—Nyt Magazine for Naturvidenskaberne. 34te Binds 3 die og 4 de Hefte, 35te Binds, 1 ste, 2 de og, 3 die Hefte (Christiania).

GROTH'S CRYSTALLOGRAPHY.

Physikalische Krystallographie und Einleitung in die krystallographische Kenntniss der wichtigeren Substanzen. Von P. Groth. Dritte, vollständig neu bearbeitete Auflage. Pp. 783. (Leipzig: Wilhelm Engelmann, 1894–5.)

NEARLY twenty years ago, in 1876, the present writer was acting as Demonstrator in Physics at the Clarendon Laboratory, Oxford, and chanced to see on Prof. Clifton's table a book just published, which differed in subject and treatment from any he had then met with. It contained in small compass (523 pages) that part of Physics which was more especially related to crystallised matter, and without delaying the reader with difficult or abstruse problems, gave in the most fascinating way a general idea of the physical and morphological symmetry of crystals. A few months later, and as a direct consequence of the interest in crystals thus aroused, the writer was advised to submit himself to Mr. Maskelyne as a candidate for the assistantship in the Mineral Department of the British Museum, just vacated owing to health-failure by Mr. Lewis, since appointed Professor of Mineralogy at Cambridge. The book was the "Physikalische Krystallographie" of Paul Groth, and the present writer is glad to have this opportunity, when giving a notice of the third edition of this useful book, to put on record his sense of gratitude to the author, a feeling which is doubtless shared by other crystallographic students in this country.

Prof. Groth was particularly well fitted for the work which he had taken in hand; he had already initiated and organised the teaching of Crystallography and Mineralogy at Strassburg (1870); gifted with great enthusiasm, he had also the rarer power of inspiring his students with the same quality; in this book he published (1876) the method which he had found to be practically useful in the course of instruction given by him as Professor of Mineralogy in that University. In the next year (1877) the *Zeitschrift für Krystallographie und Mineralogie* was started by Prof. Groth, who took upon himself the arduous duties of editor; this was the beginning of a new era for the subject. The pages of this periodical have since been at the service of crystallographic students of every country, and the twenty-four volumes already issued are a rich storehouse of the results of recent research. Succeeding von Kobell, Prof. Groth afterwards migrated to Munich, and has since completely reorganised the mineralogical collections and teaching in that University. With twenty-five years' experience as a University Professor, the editor of the many path-breaking memoirs which have appeared in the *Zeitschrift* could not fail, in the preparation of a new edition of his book, to keep his readers in touch with all that is best in the subject; and in a living subject like Crystallography, twenty years cannot pass away without the discovery of new facts and new methods, and the invention of new instruments of research.

In the case of any scientific book which is worthy of careful study, it must often be the fate of the student to react upon the author; and in this respect the present treatise is not exceptional. The treatment of the dilatation of crystals on change of temperature, as given in the first edition of the work, appeared to be out of harmony with the ideas there propounded as to crystal structure; at the suggestion of Mr. Maskelyne, the writer studied this thermal problem from a theoretical standpoint, and recorded his results in a short paper. Attracted to the subject once more, Prof. Groth had the problem practically investigated by one of his students (Dr. Beckenkamp) with the aid of the fine instrument which had then been just made for the University of Strassburg. The conclusions arrived at by Beckenkamp from his experiments, whether strictly justifiable or not is a distinct matter, were in complete agreement with those already suggested on theoretical grounds, and the variation of treatment which had been indicated was introduced by Prof. Groth in the second edition; this, indeed, was the only change of any theoretical importance at that time made. The third edition is, however, so different from those which have preceded it, that although the general aim is unaltered, the book is virtually new in its mode of treatment, and demands a more detailed notice than the new edition of a work generally calls for.

It may be remarked that the title ("Physikalische Krystallographie") suggests a more restricted survey than is actually undertaken by the author; for the morphological being regarded as likewise physical characters, geometrical crystallography falls within the scope of the book: the title is intended to be complementary to that of another treatise ("Chemische Krystallographie"), a work which Prof. Groth has long had in hand, and now looks forward to quickly completing.

A statement of the numbers of the pages allotted to the various parts of the subject will be useful as suggesting the relative degrees of importance assigned to them. The First Part begins with a discussion of the optical characters of crystals, and extends to no fewer than 163 pages; the thermal characters are allowed 24 pages; the magnetic and electrical 11 pages; the action of mechanical forces on crystals 43 pages; and the molecular structure of crystals 47 pages. The Second Part is devoted to the geometrical characters of crystals, and occupies 248 pages. The Third and last Part treats of the calculation and graphic representation of crystal forms (65 pages), of goniometers and refractometers (81 pages), and of polarising instruments (82 pages).

There are three great changes introduced in the present edition. In the first place, the optical part has been re-modelled on the basis suggested in the Tract on the "Optical Indicatrix," a work which was some time ago noticed in these columns. As stated by Prof. Groth in his preface, "the optical part is no longer based on the theory of an elastic ether, but on the purely geometrical treatment proposed by Fletcher; this method, without involving any mathematical speculations whatsoever, suffices to give even for the most complicated optical phenomena, such as conical refraction, that correct insight which is indispensable to the student in his microscopical investigations." The "Optical Indicatrix" itself, it may be here observed, was written not so much for the instruction of the ordinary student as to indicate

to the teacher a method of escape from a very awkward difficulty. Prof. Maskelyne, for whose book on Crystallography the method was devised, has the intention of presenting the method in text-book form, and of making it accessible and useful to the English student; unfortunately the many distractions of a busy public life have led to prolonged delay in the completion and issue of that part of his crystallographic treatise. Prof. Groth, however, has been quick to show that the method is one which is practically useful both to the teacher and the student; in the course of years the idea of optical elasticity will disappear from crystallographic text-books, and an unnecessary obstacle will vanish therewith from the path of the optical student. One word on a trivial matter, that of nomenclature: Prof. Groth has translated the term Indicatrix into Index-fläche, on the ground that the word Indicatrix is not acceptable in a Teutonic language. To an Englishman it is not intelligible on literary grounds why Index should be within and Indicatrix be without the limits of what is acceptable in Germany; nor were any objections to the term Indicatrix made by the German Professors (König and Ambronn), by whom the Tract itself was translated into German and rendered more accessible to the German student. In any case the constant repetition of the word "surface" in the proofs of the various geometrical propositions would make "Index-surface" unacceptable for common use in English, and it would have been a simplification of nomenclature if the term Indicatrix (*i.e.* the indicating surface) could have been adopted bodily in the other European languages.

The second great change is the total exclusion of the Naumann symbols from the text. There was much to be said for the use of the Naumann symbols in the indication of a limited number of crystallographic forms, but they are too complex in others, and are thus not generally useful: further, in the specification of particular faces and in crystal calculations, the Millerian symbol is infinitely superior, and is quite indispensable for the more advanced student. Looking to the slightness of the advantages of the Naumann symbol even in the most favourable cases, it has seemed better to Prof. Groth to now completely dispense with its consideration; this saves much valuable time to the Professor in his lectures, much space in the text-book, much unavailing toil for the student.

The third great change has involved a complete alteration of treatment of the geometrical characters of crystals. A century ago the Father of Crystallography, Romé de l'Isle, introduced the idea of a primitive form, and showed that all the crystal forms of the same kind of substance are such as could be derived from a single primitive form by similar alterations of all those parts which are geometrically similar to each other; the octahedron and the tetrahedron, for instance, were different kinds of primitive form, and were regarded as mutually independent. Later on, the idea of a primitive form was discarded by crystallographers, and that of crystalline axes, systems and symmetry, was introduced. This necessitated the recognition of symmetry as being either complete or partial in each crystalline system; and the forms presenting incomplete symmetry were treated as resulting from the suppression of half or three-fourths of the faces of forms having a complete symmetry proper to the system. Certain elements of symmetry were regarded as being then in abeyance. One educational disadvantage of this method is that the student is almost led to imagine that the axes and planes of symmetry have a physical existence anterior to that of the matter itself, and to think that the inert matter is compelled to arrange itself in a particular way through the action of these pre-existing axes and planes. Or again, he imagines that the tetrahedron was at one time an octahedron, and that it only arrived at the tetrahedral form through the excessive growth of four alternating faces of an eight-sided crystal. In the present edition Prof. Groth has followed a method suggested amongst others by Fedorow, now the Professor of Mineralogy at Moscow, and one which presents some analogy to that of Romé de l'Isle; in that, for instance, it treats the octahedral and tetrahedral symmetries as quite independent of each other. It has now been known for some decades that thirty-two, and only thirty-two, classes of symmetry are consistent with that law of whole numbers which had been discovered by Haüy to control the positions of crystal faces. This limitation of the classes of crystal symmetry was first established by Hessel in 1829, but, owing to some extent to the repellent form in which the reasoning was presented, did not then attract the attention of other crystallographers. It was re-discovered, however, by Axel Gadolin, and made known by him (1866–7) in a very lucid memoir; since that time the law has been universally recognised.

The thirty-two classes of symmetry can be grouped in various ways; and one method is that of the old so-called "systems of crystallisation." In the new mode of treatment, the six systems are merely conventional and have no structural importance; it is the thirty-two classes, not the six systems, which are fundamental, and the classes themselves are regarded as independent of each other and co-equal in importance.

In his exposition of geometrical crystallography, Prof. Groth starts from the simplest type of form, that in which there is no symmetrical repetition at all, and thence gradually advances to the most complex type, in which the existence of a single face may involve the co-existence of forty-seven others. This method, so long as it does not involve trigonometrical calculation, presents no greater difficulty than the usual mode of treatment; indeed, Prof. Groth asserts from practical experience that the student in this way makes quicker progress in the acquisition of knowledge. Each of the thirty-two classes being regarded as independent of the rest, the idea that a form may be hemimorphous, hemihedral, tetartohedral or holohedral, is completely eliminated from the science. In one respect the method actually adopted seems to the writer to fail of the desired simplicity; in the case of an ordinary crystal belonging to the Anorthic system, a crystal of albite for example, every face is accompanied by one which is parallel and opposite, and the crystal is usually regarded as having a centre, but no planes, of symmetry. For some reason not clear to the writer, Groth, following Federow, rejects the idea of a centre of symmetry, and regards such a crystal as being one in which there is no centre of symmetry at all, and every plane of the crystal, actual or crystallographically

possible, is a plane of what is termed "composite symmetry." Such an artificial and complicated method of interpreting the result of the old-fashioned centre of symmetry seems to involve its own condemnation, and to be quite unsatisfactory for the purposes of the teacher. As regards the nomenclature of the thirty-two classes, the sooner the Professors of Mineralogy can come to a decision as to the best names to be applied to them, the better for the student. Some of the names here suggested are too long to be often used: Class 28, for example, is termed the "tetraëdrisch-pentagondodekaëdrische Klasse." Though nomenclature is not of essential importance, the giving of a name is by no means a small matter; still, even a long adjective of thirty-four letters will be better than a constantly changing adjective of seventeen.

A very brief account of the researches of Bravais, Sohncke, and Schönflies, relative to the nature of crystal structure, is all that could possibly be included in a work which is to be useful to the general student; such a sketch has been given in this edition, and has had the benefit of revision by one of the great pioneers in the subject, Prof. Sohncke himself.

The above are the more important of Prof. Groth's constitutional innovations, and all that can be referred to in this brief notice. We would only add that the book is well illustrated, there being no fewer than 702 figures and three excellent coloured plates, and that it is furnished with a very complete index to its contents. By the issue of this last edition of his book, Prof. Groth has conferred one more boon on the students of Crystallography.

L. FLETCHER.

ELEMENTARY IDEAS OF MANKIND.

Ethnische Elementargedanken in der Lehre vom Menschen. By A. Bastian. 2 vols. Pp. xvi + 314; xlv + 224. (Berlin: Weidmannsche Buchhandlung, 1895.)

PROFESSOR BASTIAN has here added to his numerous works on ethnology what must be regarded as, in some sense, the crown of the edifice he has spent his life in rearing. It is an attempt to trace out the elementary ideas of mankind. For long ages every historical people, shut up within a very limited area, both physically and mentally, when inquiring through its foremost thinkers into the mental constitution of the race, had no other means of finding an answer to its questions than an analysis of the individual mind. The philosopher examined his own consciousness, forgetful that it was the consciousness of an individual in an advanced stage of civilisation, and that what might seem to him elementary, from his familiarity and the familiarity of those with whom he came into contact with it from earliest years, might really be the result of long development, or an amalgam of numerous, perhaps but slightly related, ideas. The results, therefore, of his inquiries were shifting, uncertain, in many cases absolutely untrue. And, when he came to apply those results objectively to the society in which he found himself, still greater uncertainties and divergencies of course followed. What was needed, was an external means of checking and comparing the conclusions arrived at from time to time. For want of this, the conclusions themselves remained without practical influence, or (especially, it may be added, when applied to social and political organisations) became positively disastrous. Man did not really know himself; and thinking that he did so, he often committed great and deplorable blunders.

But at last, in the gradual progress of discovery—first of geographical discovery, afterwards of scientific, and more particularly biological, discovery—the essential unity of mankind has been demonstrated. Reports of discoverers and the great ethnographical collections, formed chiefly in the capitals of Europe and at Washington, have exhibited unity, not merely physical, but mental and spiritual. It has thus become possible to set the ideas, the customs, and the organisation of the more advanced peoples over against those of the less advanced, and thus to effect that "parallelisation with equivalent corresponding existences" which gives the long-wanting means of checking the results of introspective psychology.

Starting then from the postulate of the essential unity of mankind, the veteran Professor follows the comparative method for the purpose of ascertaining in the order of conception-types, as they emerge in ethnical ideal creations, what are the elementary ideas of mankind, and thus of grasping what is involved in the totality of these conceptions, and of discerning oneself in every child of man, so far as intelligence reaches. Accordingly, although the book is addressed primarily to metaphysicians, Dr. Bastian writes not without a practical aim. A thorough comprehension of the mental and spiritual unity of mankind, a realisation of the fact that under all superficial divergencies of expression, whether in language, in myth or in custom, the same ideas, the same purposes rule in all men, and a consequent conviction that patience and tact only are required to reconcile all these divergencies by discovering their underlying identity, and tracing the devious path whereby each of them has travelled—these are qualifications not merely of the ideal anthropologist, but of the ideal statesman: qualifications more than ever necessary in these days, when discoveries and inventions have brought the foremost nations of Europe into relations of one kind or other with so many of the more backward races all over the world, making continually fresh demands on the sympathy born of knowledge to avoid difficulties and bloodshed, promote good feeling, and clear away obstacles to the progress of civilisation. Even among the civilised nations themselves, all of which have their social questions, sprung from the ferment of mutual intercourse under the influence of modern conditions, knowledge of the elementary ideas of mankind and of their expressions in social form—that is to say, in institutions—is calculated to assist materially in the solution of the problems which are now presenting themselves.

The book has, therefore, been written with these things in view; and there is no nation to which they are more important than our own: none, perhaps, to which they are so important. Yet the British Government has done less than any towards the systematic study of anthropology. The Imperial Institute might have served the purpose of a great national school of anthropology, where the rulers of our subject-peoples could be trained. It has been turned, instead, into a second-rate club. Meanwhile, those whose mission it is to direct the destinies of

tribes remote and strange alike in space and in culture, remain in total ignorance of the ideas which govern them, or are driven to acquire what little information they may ultimately obtain in the course of years by actual contact and repeated mistakes, learning their business at the expense of the unfortunate savages they are set to manage, as well as at ours, or else to seek for it in a desultory way without a trustworthy guide through that vast and tropical wilderness, the literature of travel and research.

Unhappily it cannot be said that the book before us will be of very much use to such inquirers, or to many anthropological students in this country. Addressed, as I have said, in the first instance to metaphysicians, it is written in an involved and allusive style, bristling with metaphysical technicalities; and the learned author has too little respect for his readers to assist them by dividing his work into chapters or sections, or to give them more than, at most, the bare names of the authorities for his numerous citations. What good is there in telling us vaguely, in a little aside, "see Hiekish," or "see Schwebel," or "see Swan"? We want to be able to verify the statements, and test the use that is made of them; and the scientific writer, be he professor with world-wide reputation, or obscure student, who neglects to enable us to do this, foregoes half his title to our confidence. Some of these faults, indeed (especially the last), disfigure all the author's works. To call attention to them is not a pleasant task; nor do I deny—I cordially acknowledge—Dr. Bastian's many claims on our gratitude and admiration. At the same time, a protest in favour of lucidity and exactness is all the more needful where the transgressor is so able and so justly distinguished as Dr. Bastian.

E. SIDNEY HARTLAND.

THE BIRDS OF GREEK LITERATURE.

A Glossary of Greek Birds. By D'Arcy W. Thompson, Professor of Natural History in University College, Dundee. Pp. xvi + 204. (Oxford: Clarendon Press, 1895.)

BOSWELL once told Johnson that he had a plan for collecting the poetry of the Border, a task which he fortunately left to be undertaken by a more skilful hand. Not indeed that he feared he would be unequal to it, but, as he told his master, he doubted whether it would be of much good to any one. "Sir," replied the sage, "never mind whether it is going to be any good to any one: do it." It is in the spirit of this answer, that Prof. D'Arcy Thompson has been for years accumulating the material brought together in this volume. He must have often had doubts as to the practical value of his labour, and as to the reception it would meet with from scholars on the one hand, and scientific men on the other. The region of scholarship invaded by a Professor of science, the precious time of a scientific researcher given up to laborious reading of a voluminous Greek literature! It is true enough that if called upon to explain to any ordinary man of business what the value of the work is, we should find it hard to do so; yet we feel all the more disposed to admire the indefatigable perseverance which has carried the author through his self-imposed task to its completion, dogged as he must have been by the sense that he was travelling all the time in a mist, where no certain conclusions could be drawn as to bird, or legend, or etymology.

Yet it would be by no means true to say that the book will be of no practical value. In the first place, it is compiled with such laborious thoroughness, that it will serve as a thesaurus of reference and information for all scholars who may have to deal with passages in Greek literature relating to birds; and such passages are abundant. Their difficulty often arises from the tangle of myth which grew up around certain birds, *e.g.* the Hoopoe, the Cuckoo, the Nightingale, &c.; and what a scholar needs for the elucidation of his author, is a handy book of reference to all that has been written or bears on the matter, both in ancient times and modern. Here is exactly the book for him; he will find (so far as I am able to judge) the whole available material in two or three pages. It matters little whether the guesses, combinations, conclusions are sound or not; it is the collection of material that will be really valuable. Nor is the pure scholar the only workman who may profit; the numismatist, the mythologist, the student of the ancient science of divination, may find their advantage in this volume.

The method adopted by the author makes reference to the glossary quick and easy. He begins with the identification of the species where it is at all practicable; sometimes, perhaps, stating it too definitely, and without the necessary warning-note for too precipitate readers. An etymology sometimes follows, which is, indeed, as a rule, superfluous; for no scholar will in these days listen to any one but a specialist in a science so difficult as comparative philology, and the attempts are here often obviously unscientific. But no harm is done in this way, for I have noticed hardly a case in which any serious conclusion is built upon an etymology—a form of Teutonic crime familiar to all scholars. Then follows the description of the bird, beginning with Aristotle as a rule, cited, as he should be, from the paging of the Bekker edition: and so onwards to the later Greek writers. Here a critic must point out that a list of the writers quoted, with their date and the edition used in the compilation of this work, would have been a great convenience to the student; for the Professor's reading has been so insatiable, that he sometimes quotes authors of whom even a good Greek scholar may never have heard in his life. Then come the habits of the species, *e.g.* nesting, song, migration, each point being clearly distinguished in a separate paragraph; and lastly, the myths attaching to the bird, with an attempt, instructive if not always convincing, to elucidate them. This account of the method pursued applies, it need hardly be said, only to those species which especially attracted the attention of the Greeks: *e.g.* the eagle, cock, kingfisher, crane, nightingale, swallow, &c. The great majority of glosses are naturally very brief.

Undoubtedly the most striking and interesting parts of the work are those in which the author ceases for the moment to be a compiler, and offers us a new key to the interpretation of certain myths. "I offer," he says in the preface, "a novel, and at first sight a somewhat startling explanation: to wit, that many of them (*i.e.* the fables about birds) deserve not a zoological but an

astronomical interpretation." For example, the story of the halcyon days is hypothetically explained in this way: it "originally referred to some astronomical phenomenon, probably in connection with the Pleiades, of which constellation Alcyone is the principal star" (p. 31). A criticism of any one such explanation would be impossible in a limited space, even if the present writer were qualified to undertake it. Suffice it to say, that even if it could be proved that every one of these interpretations is wrong, and that simpler methods are applicable, yet credit would be still due to the man who indicated a possible way of dealing with these difficulties, and one which would not be likely to occur to the ordinary book-scholar. We must of course be on our guard against the danger of missing our footing while we thus gaze into the heavens for a missing clue; but I venture to say that any one who will carefully study the whole of the passage from which a sentence was just now quoted, or that in which is discussed the fable of the Swan and the Eagle, will hardly avoid the conclusion that there may be an astronomical aspect of the folk-lore of some peoples, which has still to be scientifically investigated.

In conclusion, it may be asked what contribution there is in this volume to zoological science. Positively and directly, there cannot well be any; the identification of species is in most cases too doubtful to allow us to compare them with those now familiar to us in regard to distribution, migration, nesting habits, &c. But, as a contribution to the history of the science, this book will be of great value, and the future editor of Aristotle's *Historia animalium* will find himself relieved by it in many particulars from a great deal of tedious research.

The revision of the proofs has evidently been carried out with scrupulous care—no easy task, considering the innumerable proper names and Greek quotations; and the accentuation of Greek words seems to be remarkably accurate. In a few unimportant points, I should differ from the author's views; but of these I will only mention one, about which I am confident. He declines to identify Aristotle's σχοινίλος as the reed bunting, on the ground that that species (*Emberiza schœniclus*) does not flick its tail as other buntings do. But the reed bunting *does* flick its tail, as I have every reason to know, and I believe the old identification to be probably right. I may just add that I see no difficulty in identifying Aristotle's κύανος with the wall-creeper, though he says that it is κυανοῦς ὅλος; for the Greeks were weak in discriminating colours, and I can testify that it is not so easy as one might expect to catch the crimson of the wing-coverts when the bird is on a rock high above you. And it is not likely that the Greeks should have been able to procure specimens of this shy species for closer examination.

W. WARDE FOWLER.

OUR BOOK SHELF.

Polyphase Electric Currents and Alternate Current Motors. By S. P. Thompson. Pp. vi. + 261. (London: E. and F. N. Spon, 1895.)

THIS book resembles others by the same author, in being an amplification of a course of lectures. Every one who knows Prof. Thompson's later work, will expect to find evidence of a good deal of study; nor will he be disappointed. Not the least important part of the book is the list of works and articles which have been written upon this comparatively new department of electrical engineering. A chapter and many other paragraphs are of an historical nature, and if in some cases those who have been behind the scenes more than the author, may consider that he has not been quite fair in his conclusions, yet every one will admit that impartial fairness has always been aimed at by Prof. Thompson.

Here and there a little more care might have been exercised. On p. 24 the lettering on Fig. 28 is wrong. The views of M. Goerges on the comparative economy in copper when used with one, two, and three phases is not at all clearly put. The author has a liking for new terms. The "stator" and "rotor" of a dynamo or motor have an unpleasant sound, and are not so good as the French "inducteur" and "induit," but they will serve their purpose. "Star" and "mesh" groupings do not explain their meaning (referring to the connections for a three-phase system) so well as the old and appropriate symbols Y and Δ.

The mathematical theory of polyphase systems has been worked out by many writers and on different lines. The method selected by the author has the merit of being simple, and easily followed by those who do not handle mathematics easily. The parts of the book which relate to the design of machinery are not very complete, and would hardly suffice to enable the average electrical engineer to make a good polyphase dynamo or motor. But we must remember that this was a fault of the first edition of "Dynamo Electric Machinery," by the same author, which has steadily improved with each new edition, and has become one of the leading text-books of its kind. So, also, we expect that the book before us has in it at least the germ of a treatise which will be a standard work of great value as it passes through successive editions. As it stands, the book should be on the shelves of all those who are engaged in developing that most useful auxiliary of the electrician, a polyphase system for distributing electrical motive power.

G. F.

Elementary Physical Geography. By R. S. Tarr, B.S., F.G.S.A. (New York and London: Macmillan and Co., 1895.)

THE most prominent feature of this book is the wealth and excellence of its illustrations; in less than 500 pages there are close upon 300 of them, many being new, while numerous others are from official publications which are not accessible to most elementary students. The admirable photographic reproductions, illustrating a great variety of natural phenomena, are especially noteworthy, as are also the illustrative maps. The three main divisions of the book treat of the atmosphere, the ocean, and the land. Strangely enough, "the earth as a planet" falls into the first division, and meteorological instruments and methods are relegated to an appendix. "To present facts and furnish information" is the avowed object of the book, and although it is recognised that "the average mind learns unconnected facts with much less ease than those which are philosophically related," many objections to this method of teaching might be made. One of the defects of the method is the liability to employ terms without sufficient explanation, and we find the author so using the terms "waves of ether," specific heat, density, and temperature. Again, a student would be very much wiser for a demonstration that the air has weight, than for a mere statement of the fact. It is true that the introduction of laboratory and field work is strongly advocated, and some very useful suggestions for such work are made. If the facts and information furnished by the book are supplemented by laboratory and field study, the course may be made one of great educational value. Otherwise, to use the author's words

"the value of the study will be very slight indeed," as a means of mental discipline. Nevertheless, the logical sequence of subjects, and the statement of sufficient evidence to justify the conclusions drawn as to the causes of many natural phenomena, combine to provide a useful course of reading. The information is fairly up-to-date, and the descriptions are clear as well as interesting. References to the literature of the various parts of the subject, and questions for examination, will greatly increase the value of the book to teachers.

An Introduction to the Study of Seaweeds. By George Murray, F.L.S. (London: Macmillan and Co., 1895.)

IN this little volume, one of the Manuals for Students Series, we have a fairly satisfactory account of those forms of Algæ which live in salt water. We had fancied that the English name "seaweed" had by this time lost its first or original meaning, and that it had come to be considered as equivalent to Algæ, in its widest sense; but Mr. Murray has drawn the line between those forms which live in fresh and those which live in salt water, and whenever it is possible he avoids all reference to the former. This being so, there is no account of the lovely Desmids, nor of the interesting species of Bulbochæte and Œdogonium. Noting this as a fact, but one to be regretted so far as the Chlorophyceæ, which "attain their finest development in fresh waters," are concerned, we welcome this little book as a useful and pleasantly written introduction to an ever-fascinating group of plants, which are easily, for the most part, preserved and are equally easy of observation. Their life-history, despite that many of them are so common, has still many a secret, which it will take long and patient research to find out. The introductory chapter condenses a great deal of valuable information into a few pages, and is accompanied by a useful list of books and memoirs on seaweeds.

Beginning with the Phæophyceæ, and with their more specialised forms, the Chlorophyceæ come next in order, then the Diatomaceæ, followed by the Rhodophyceæ, and ending with the Cyanophyceæ. Eight well-drawn and neatly-coloured plates illustrate the volume, which also abounds with numerous woodcuts; most of these latter are satisfactory, and all of them are selected from modern and authentic sources.

We trust that this help to a study of these "seaweeds" will be successful in attracting many to their study. When the late Dr. Harvey was writing his well-known "Phycologia Britannica," he had a very numerous set of correspondents, living on all parts of our coasts; some of them, like Mrs. Griffiths and Miss Hutchinson, were excellent botanists, but most of them were excellent observers. Is it too much to expect that others may arise to take their long-left places?

Public Health in European Capitals. By Thomas Morison Legge, M.A., M.D. (Oxon), D.P.H. (Cantab.). Pp. vi + 202. (London: Swan Sonnenschein and Co., 1896.)

THE author points out in the preface that the work is a record of his own observations during many visits to "some of the most important capitals on the continent"; and a very interesting and instructive record it is.

The cities dealt with are Paris, Berlin, Brussels, Christiania, Stockholm, and Copenhagen. It will be noted that several important capitals (Vienna, St. Petersburg, Rome), and many others the sanitation of which would be interesting, if not edifying, are omitted. It is to be hoped that Dr. Legge will be able to include these in a subsequent edition, for he has shown in the present volume that he can interest while he instructs.

A comparison is set forth of the methods employed in different countries for coping with the great problems of sewage disposal, water-supply, the spread of preventible disease, and the housing of the poor; and it is a work that can be read by all who take an interest in these vital subjects, for the information it conveys is not set in abstruse technical language. The book presents many instances of the experts of different countries differing in their methods and views, but the differences are mainly those of detail in the application of great principles of sanitation that are equally recognised by all.

The writer is perhaps at his best when treating of Paris. In that city, during the past two years, some much-needed sanitary improvements have been inaugurated; but it is only fair to our neighbours to concede that their appreciation of the principles of sanitation have for many years been in advance of that of a certain French judge, who, as Dr. Legge tells us, declared, as recently as 1885, that for a landlord to be compelled to lay on water to his house for the use of the tenants was an interference with the liberty of the subject, and that a water-supply was not an indispensable necessity for maintaining the healthiness of a dwelling.

It is a source of satisfaction, while reading of the various capitals, to find that, in matters relating to the public health, London is certainly *facile princeps.* In one particular, however, we fall far behind some other capitals, and that is in the matter of meat inspection. The sooner we adopt the Berlin system of skilled inspection of the live animals in public abattoirs, and the detailed examination of the carcases, the sooner shall we remove what is a very great reproach upon the thoroughness with which our methods of disease prevention are carried out in this country.

History of the Cholera Controversy. By Sir George Johnson, M.D., F.R.C.P., F.R.S. Pp. 78. (London: J. and A. Churchill, 1896.)

SIR GEORGE JOHNSON has held for years, as is well known, very strong views as to the treatment of cholera, and the above little volume, with its seventy-eight pages, is devoted to an elaborate exposition of these views, together with an account of their reception by the medical world. The so-called "Cholera Controversy" gathers, we are told, round the support given respectively to the "evacuant" and "astringent" treatment of this disease; or, in other words, the use of castor-oil *versus* opium in the handling of cholera cases. It is not possible here to enter into the various medical arguments and discussions which occupy these pages; but we cannot help regretting that in the treatment of this subject, the author has allowed the personal element to play so conspicuous a part, as it detracts from the value of its discussion and tends, necessarily, to restrict the area of observation. Thus it would have been of interest to have had some reference to the latest official document published last year in Germany on cholera, from which we should have learnt that calomel is frequently referred to as of great therapeutic value. The "historical" side of the question would thus not only have gained in interest, but the arguments, from a layman's point of view, would have been more convincing.

Mechanics. Part iii. *Hydrostatics.* By R. T. Glazebrook, M.A., F.R.S. Pp. x + 213. (Cambridge: University Press, 1895.)

A CLEARLY-PRINTED and well-arranged text-book of hydrostatics for colleges and schools. The subjects and order of the eight chapters are: states of matter, fluid pressure, propositions of fluid pressure, fluid-thrust centre of pressure, floating bodies, measurement of specific gravities, pressure of the atmosphere, hydrostatic machines. The descriptions are clearly written, and the exercises are numerous. Moreover, the treatment is experimental; so that altogether the book is calculated to give a good grasp of the fundamental principles of hydrostatics.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Prints of Scars.

THE accompanying print is sent with a two-fold object. First, for its intrinsic interest in showing how thoroughly and definitely a grafted slice of skin and flesh has established itself under its new conditions, retaining its original characteristics unchanged during thirty years. Secondly, because of its probable interest to surgeons in illustrating the ease and completeness with which a record can be kept of the process and results of the cicatrisation of wounds.

Prints are more clear, more cheap, and more trustworthy than photographs. They are not distorted through perspective, nor blurred owing to differences of focus; they can be taken in any light, and their scale is absolutely correct. They are made by rolling the scarred part on a porcelain pallet or metal slab, that has been covered evenly and very thinly with printer's ink; or, conversely, the pallet and paper are rolled upon the scar. As many duplicate prints can be taken as desired. I have written at so much length about these and alternative methods of printing in my book, "Finger Prints," and elsewhere, that I need say no more about them now. The print sent herewith is a photographic

Enlarged print of a misplaced graft of flesh on the side of a thumb, thirty years after it was made.

enlargement, being more suitable for rough process-printing than the somewhat minute originals; but one of these is also enclosed. The history of the graft is as follows: J. R. H., who is a solicitor in large practice, when he was twenty-five years old, sliced a piece clean off the thumb of his left hand. He was cutting cardboard with a sharp knife guided by a rule, upon which the thumb pressed, and which it slightly overlapped. The piece that was cut off fell on the table; it was at once picked up, clapped upon the wound, and the thumb was tightly bandaged. After a few days reunion had taken place, and the wound was healed. It then proved that the graft had not been replaced in its original position, but crossways to it, as seen by the papillary ridges in the accompanying print, taken in 1895, thirty years after the accident. FRANCIS GALTON.

The Cause of an Ice Age.

SIR ROBERT S. BALL appears to admit the correctness of Mr. Culverwell's argument against Croll's astronomical theory of an Ice Age so far as, that "the direct sun-heat received on any parallel at the time of greatest eccentricity is the same as that now received on the parallel not more than three or four degrees north"; and then proceeds to explain, with perfect truth, that "the actual temperature in a region depends, not merely upon the sun-heat there received, but also upon the transference of heat across the boundaries of that region."

Now the causes upon which the transference of heat depend, viz., the prevailing winds and the ocean currents, rest ultimately upon the sun-heat received over the whole globe. The soundness of Mr. Culverwell's argument therefore seems to hinge upon whether the general shift of the isotherms of *sun-heat* three or four degrees southward would be incapable of greatly altering the winds and currents. If this were so, it might be admissible to reason upon the sum total of the local climatal effects at a period of great eccentricity, with the winter in aphelion, from the conditions of temperature as they now exist. If a shift three or four degrees southward would not appreciably alter these currents, I think Mr. Culverwell's argument against Croll's theory a strong one; and to reply effectually to it, it ought to be explained that such a slight shifting of the isotherms of sun-heat would be likely to affect those currents to so great an extent that the then conditions of local temperature would not bear comparison with the present—as, for instance, of Cornwall then with Yorkshire now. O. FISHER.

Harlton, Cambridge, January 17.

Barisal Guns and Similar Sounds.

IN Colonel Godwin-Austen's interesting letter on the Barisal guns (page 247 *ante*), he mentions as suggested sources of these remarkable sounds fireworks (*i.e.*, bombs, cannon), bursting bamboos in jungle-fires, thunder-claps, landslips, the falling of river-banks or sand-banks, and seismic disturbances; but he does not add what seems to me to be a more probable source of the sounds, namely, ball or globular lightning, known to the French as *éclairs en boule*.

It is true, as I stated in my letter to the *Times* in August last, that Faraday, so late as 1838, said:—"That phenomena of balls of fire may appear in the atmosphere I do not deny, but that they have anything to do with the discharge of ordinary electricity, or are at all related to lightning or atmospheric electricity, is much more than doubtful." ("Researches," sec. 1641.)

Snow Harris, however, in his book on "Thunderstorms," 1843, recognises the phenomenon as a case of glow discharge, often terminating in disruptive discharge, as in the case of H.M.S. *Montague*. After this, the reported cases of ball-lightning and the damage caused by their violent explosion are numerous, and some remarkable ones have been described lately in NATURE. When of lower tension, these fire-balls, as they were called by the older physicists, may envelop the person without doing any harm, a striking example of which is given in Shakespeare's *Julius Cæsar*, Act i. Scene iii.

The explosive sounds heard by the Rev. W. S. Smith, while skating on Lough Neagh, may still be due to globular lightning. The dry atmosphere occasioned by frost is highly favourable to the development of atmospheric electricity; and we have still to learn whether these electrical globes will not account for the observed phenomena. C. TOMLINSON.

Highgate, N., January 20.

IN connection with the correspondence on mysterious atmospheric sounds, which originated with Prof. Darwin's communication in the issue of NATURE for October 31 last, I have official sanction for forwarding the following extracts from the meteorological logs of vessels visiting high latitudes.

S.s. *Resolute*, Captain W. Deuchars; 8 p.m., July 30, 1883, in 71° 9′ N., 12° 28′ W.—"Six reports like those of guns heard to the westward, supposed to be caused by electricity, as no ships are thought to be in the vicinity." Wind during the day calm to very light easterly airs; weather foggy; sea smooth, with a very slight south-easterly swell; pressure and temperature as follows:

	Barometer.	Air temperature. Dry bulb.	Damp bulb.	Sea temperature.
	In.	°	°	°
Noon	30·08	50·0	48·8	41·5
4 p.m.	30·09	42·0	41·8	37·0
8 p.m.	30·10	40·8	40·5	37·0
Midnight	30·11	46·5	46·5	35·0

S.s. *Windward*, Captain A. Murray; 4 a.m. June 12, 1883, in 71° N., 7½° W.—"There is a distinct murmur as of a waterfall from the island" [of Jan Mayen]. Calm; weather foggy;

sea very smooth; barometer 29·83 in., rising; temperature of air 33°, of sea 34°.

S.s. *Labrador*, Captain A. Gray; July 14, 1882, about 56° N., 60° W.—"Saw an iceberg, which collapsed with a thundering squash." Next day, "icebergs all over the place, with an occasional collapsing roar."

It may be thought, perhaps, that the thundering roars of collapsing bergs would be the explanation of the six reports heard by Captain Deuchars; but as he had many years' experience whaling and seal fishing in the ice on both sides of Greenland, he would be well acquainted with the sounds from bergs breaking up, and there must have been, therefore, something peculiar about the "guns" to lead him to suggest an electrical origin.

With reference to M. Van den Broeck's explanation of the expression *mist-poeffers* as *fog-belchings*, not *fog-dissipators*, it may be interesting to add another extract from Captain Deuchars's log: June 15, 1883, in 71° N., 11° W.—"Weather dense fog, with a white bow to south-east, known generally as a *fog-scaffer* or *demolisher*." HY. HARRIES.

Meteorological Office, January 17.

WITH reference to the letters on this subject which have recently appeared in your pages, and more especially to the communication of my friend Rev. W. S. Smith, relative to Lough Neagh, the following extract from my notes may be of interest: "August 27, 1886.—While standing with Mr. S. A. Stewart in a recently-mown meadow, near Portmore Lough, on the eastern side of Lough Neagh, our attention was attracted by a rumbling noise. The day was very fine and warm, and dead calm, not a leaf stirring, and a few very light clouds were in the sky. The noise was like a short distant peal of thunder, but sounded faint rather than distant. While we watched, a whirlwind suddenly appeared in the direction whence the sounds had come [the north], and at a distance of about a hundred yards from us. A quantity of loose hay was instantly whirled upward to a height of about 100 feet, and, after floating about in circles, slowly settled down. A haycock at the spot was much disturbed, and presented the appearance of having endured a gale of wind. The time between the rumbling sound (which closely resembled the distant report of a cannon) and the appearance of the whirlwind was about half a minute, and the whirlwind lasted somewhat over a minute."

In W. H. Patterson's "Glossary of Words of Antrim and Down," we find the following: "Water Guns.—Sounds as of gunshots, said to be heard around the shores of Lough Neagh by persons sailing on the lake. The cause of the sounds, which are generally heard in fine weather, has not been explained." There is no doubt that the sound we heard was the mysterious "water guns," and there is also little doubt that the noise and the appearance of the whirlwind were closely connected.

R. LLOYD PRAEGER.

IN connection with the recent correspondence upon "Remarkable Sounds," the following quotation may be interesting. It occurs as a footnote in a paper by Prof. S. A. Forbes, of Illinois, upon the "Aquatic Invertebrate Fauna of the Yellowstone National Park, &c.," published in the *Bulletin* of the U.S. Fish Commission for 1891 (Washington, 1893), p. 215.

"Here we first heard, while out on the lake [Shoshone Lake, Yellowstone National Park] in the bright still morning, the mysterious aerial sound for which this region is noted. It put me in mind of the vibrating clang of a harp, lightly and rapidly touched, high up above the tree-tops, or the sound of many telegraph wires swinging regularly and rapidly in the wind, or, more rarely, of faintly-heard voices answering each other overhead. It begins softly in the remote distance, draws rapidly near with louder and louder throbs of sound, and dies away in the opposite distance; or it may seem to wander irregularly about, the whole passage lasting from a few seconds to half a minute or more. We heard it repeatedly and very distinctly here and at Yellowstone Lake, most frequently at the latter place. It is usually noticed on still, bright mornings not long after sunrise, and it is always louder at this time of day; but I heard it clearly, though faintly, once at noon, when a stiff breeze was blowing. No scientific explanation of this really bewitching phenomenon has ever been published, although it has been several times referred to by travellers, who have ventured various crude guesses at its cause, varying from that commonest catch-all of the ignorant, 'electricity,' to the whistling of the wings of ducks and the noise of the 'steamboat geyser.' It seems to me to belong to the class of aerial echoes, but even on that supposition I cannot account for the origin of the sound." D. J. SCOURFIELD.

Leytonstone, January 20.

IT may be worth while to put on record the following statements of the distances at which the firing of guns have been heard. They were related to me by the late Prof. C. J. Harris, of Washington, and Lee University, Lexington, Virginia, who, in speaking of the distances at which sounds could be heard, said that during "The War"—the Civil War of 1861–65—he had frequently heard the firing of the guns in battles taking place many miles from Lexington; and so distinct were the reports, that it was easy to distinguish between light and heavy artillery. In particular, I remember his saying that the sound of the cannonading at the Battle of Malvern Hill was distinctly heard at Lexington. Malvern Hill is about 123 miles "as the crow flies" from Lexington. At this battle gunboats were used by the Federals, and the reports of the heavy guns on the boats could be easily distinguished.

He also said that during the Battle of Manassas—or, as it is also called, Bull Run—the cannonading was heard at Lexington. The battle-field is about 125 miles from Lexington. These distances have been furnished me by the Assistant Superintendent of the U.S. Coast and Geodetic Survey, and are accurate within a mile or two. W. G. BROWN.

Washington, D.C., U.S.A., January 3.

The Place of "Pithecanthropus" on the Genealogical Tree.

WRITING to NATURE (January 16), under the above heading, Dr. Eugene Dubois makes the following statement: "In Prof. Cunningham's tree, figured in NATURE of December 5, p. 116, he regards the left branch as all human, the right one as entirely simian, and he placed Pithecanthropus midway between recent Man and the point of divarication." In this assertion there are two inaccuracies. I do not regard the left branch as being entirely human, but merely as representing a hypothetical line of human descent. During the debate which took place at the Royal Dublin Society, I was most careful to insist that at a certain point on such a line (marked on the diagram by a ×, NATURE, December 5, p. 116), we might expect to meet with an individual possessing ape-like and human characters in equal degree; whilst below that point ape-like characters would predominate, and the human characters diminish until, probably, before we came to the junction of the line with the main stem, the latter had reached a vanishing point. But, again, I did not place Pithecanthropus on the mid-point of the line, but much lower down, as may be seen by a reference to the diagram itself, where the upper mark of interrogation (?) indicates the place which I assigned to the fossil cranium.

I would wish to add that my diagram was not drawn with the view of elaborating in any detail a genealogical tree of Man and the Anthropoid apes, but simply for the purpose of eliciting from Dr. Dubois his views regarding the place he wished to assign to Pithecanthropus in relation to Man on the one hand, and the existing Anthropoid apes on the other.

It seemed to me that a definite statement from Dr. Dubois on this point was desirable, seeing that I considered that the title he had given to his memoir was apt to lead to misconception. D. J. CUNNINGHAM.

THE CHEMICAL SOCIETY'S HELMHOLTZ MEMORIAL LECTURE.

IN his Helmholtz memorial lecture, delivered last Thursday, Prof. G. F. Fitzgerald gave an able exposition and development of those branches of the work of the late Prof. Helmholtz which intimately affect chemistry, and at the same time made an important contribution to several much-vexed questions of higher chemical physics. A brief account of the chief points of the lecture is given in the following abstract.

Helmholtz made the great discovery that, by virtue of their vorticity, vortex rings floating in a perfect fluid are unable to destroy or create one another; although these vortices may distort each other, becoming drawn out into thin threads or rolled into spherical balls, one cannot destroy another. This discovery it was that afforded a basis for those speculations of Lord Kelvin which would identify atoms with vortex rings moving in a perfect fluid; the indestructibility of atoms finds a parallel in the permanency of vortex rings, and the two have many properties in common. As, however, our knowledge of vortices has increased, so obstacles to the acceptance of the atomic vortex hypothesis have arisen. Thus the energy and the inertia of vortex rings increase together whilst their rate of motion decreases, so that on raising the temperature of a gas composed of vortex atoms, and therefore increasing the rate of motion of its particles, it would seem that, in some mysterious way, more energy leaves the gas than enters it. Similarly, unless the weight of a body alters appreciably as its temperature changes, it is not easy to see how the simple vortex theory of matter can be true; the difficulty of determining weights at different temperatures of course stands in the way of an experimental examination of this point. Many modifications of the vortex theory have been proposed, but the only statement that can be made with certainty is that the space between the atoms, whatever their nature may be, must be filled with some complicated structure, the postulation of which is essential for the explanation of electro-magnetic actions. It is therefore impossible to believe that atoms are simply thin vortices floating in an otherwise motionless and structureless medium.

A curious analogy is noticeable between the stability of vortex systems and chemical valency. A system of two vortex rings, both rotating in the same direction, assumes a state of fairly stable equilibrium in which the two rotate round one another, whilst a system of three vortex rings is stable in a state in which the vortices are situate at the apices of a triangle. Similarly, a condition of stable equilibrium is possible for systems of four, five, or six rings; a system of seven vortex rings, however, is unstable, and vortex systems generally become unstable when composed of more than six rings. The curious analogy between this result and the fact that the atom of no chemical element requires to combine with more than six monovalent atoms, should be kept in view in default of a sounder dynamical conception respecting the limitation of chemical bonds.

The atomic vortex theory again meets with difficulties in connection with homologous series of organic compounds and with the atomic weights; the atomic weight of mercury is 200, that of hydrogen being unity, and it can be shown that the volume occupied by the mercury atom should be some 2800 times that occupied by the atom of hydrogen, a result hardly reconcilable with the known properties of these elements. Valency also presents obstacles to the theory; thus nitrogen and carbon should be respectively mono- and di-valent unless the vortex rings are doubled on to themselves, and even then the doubling indicates the existence of two allotropic modifications of carbon, a right- and a left-handed form, for which no evidence exists. The vortex theory of atoms and the experimental facts regarding atoms are thus sadly at variance, and much still remains to be done in clearing up the questions at issue.

The theory of semipermeable membranes, which is of such importance in certain branches of physical chemistry, is as yet in a very unsatisfactory state. The absolute disregard of any possible heating effects occurring during osmosis may lead to serious errors, corresponding to those which crept into the theory of galvanic cells by neglect of the thermal effects which arise when electrical currents enter or leave a liquid; possible causes of error, such as these, should be well borne in mind until the theory and practice of semipermeable cells are in better agreement than at present. These semipermeable membranes are frequently regarded as being only some kind of molecular sieves, although they are really much more analogous to Graham's second class of membranes, which only allow the passage of gases soluble in the membrane itself; the laws governing the two kinds of membranes are quite dissimilar. It is not easy to sharply distinguish between physical and chemical permeability when molecular magnitudes are dealt with, and one molecule may pass amongst others not so much by reason of possessing the right size as the right shape. There seems some hope of extending our methods of "chemical filtration" by means of sets of properly constituted diaphragms, each of which is penetrable by certain classes of molecular groups.

The application of thermodynamics to chemical investigations is full of pitfalls; the law of conservation of energy has been often misapplied, and it is not sufficiently realised that the second law of thermodynamics is not strictly applicable to irreversible chemical changes, such as explosions, &c.

The tendency to regard chemical forces as electrical ones is not altogether justifiable; too many instances of irreversible chemical changes exist to permit a parallel between chemical actions and simple reversible electrolysis. Chemical actions are of a far more complex nature than simple electrolysis, and that other than purely electrical forces are operative in solution is indicated by Helmholtz's investigations of electrical diffusion through fine tubes. No statical theory of solid or liquid media which supposes the action of none but electrical forces is possible, for such media would be essentially unstable; as far, then, as solids and liquids can be conceived as statical systems, the postulation of other than purely electrical forces is imperative. The success which has attended the accepted theories of crystal structure and of the asymmetric carbon atom, makes it pretty safe to conclude that many properties of molecules are deducible from purely statical theories of structure.

The enormous increase of knowledge which has attended the assumption that a substance in liquid solution behaves in some important respects like the same substance in a pure gaseous state, has led to the grave error of supposing that the physical conditions of molecules of a substance when gaseous and when dissolved are similar. A dissolved molecule is always within the spheres of action of countless neighbours; its path is of the order of one-hundredth of its diameter, and it receives, perhaps, 10^{14} blows per second, so that its vibrations are comparable with those of radiant heat; in the gaseous state, however, the molecule has a free path thousands of times its diameter in length. The dynamical conditions of gaseous and dissolved molecules are thus absolutely dissimilar. Although it is curious that the osmotic pressure of a dissolved substance should be even roughly identical with the vapour pressure of the same quantity of the substance as a gas under similar conditions of volume and temperature, it is wholly erroneous to attribute this coincidence to a similarity between the dynamical states in the two cases. Osmotic pressure is more nearly related to Laplace's internal pressure in a liquid, which depends on intramolecular forces, than to a gaseous pressure which is practically independent of the forces operating between the molecules. Considerations respecting the capillarity and vapour pressure of solutions and solvents shows that some very close connection exists between osmotic pressure and capillarity, and afford a trustworthy method of applying thermodynamics to the calculation of osmotic pressure.

It is almost impossible to explain dynamically the assumption that free electrically charged ions wander about in a liquid in a condition at all rightly described as one of dissociation. The term "dissociation" should

be restricted to a condition in which the components of a molecule are in no way connected by chemical bonds; the possibility of the independent diffusion of the molecular components through porous membranes would afford a simple test as to whether molecules were really dissociated or not. The term dissociation as applied to electrolytes, in which this independence of the ions does not exist, is obviously a misnomer. There is said to be an electrical force acting between the various oppositely charged ions into which a dissolved molecule separates, which in some way still binds them. Even in dilute solutions this force is very considerable, and must make the condition of charged ions moving independently in the liquid so unstable as to be dynamically impossible unless other important forces operate at the same time. Although the present theory of free ions affords a rough working analogy, yet it is illusory and misleading, and threatens to prevent important advances by its illusive appearance of explanation. It must not be forgotten that the older theories of light and the caloric theory of heat constituted stumbling-blocks long after their inadequacy had been conclusively demonstrated.

Prof. Fitzgerald thus contends that the fundamental conceptions underlying many of the current physico-chemical theories, such as those of osmotic pressure and electrolytic dissociation, are dynamically unsound, so that all attempts to gain an insight of what occurs in solution by their aid are necessarily unsuccessful. He seems to consider that an unyielding adhesion to these theories has led to an illogical habit of thought upon such matters, and has made possible the inaccurate application of thermo-dynamical reasoning. W. J. P.

NEW EXPERIMENTS ON THE KATHODE RAYS.[1]

(1) TWO hypotheses have been propounded to explain the properties of the kathode rays.

Some physicists think with Goldstein, Hertz, and Lenard, that this phenomenon is like light, due to vibrations of the ether,[2] or even that it is light of short wavelength. It is easily understood that such rays may have a rectilinear path, excite phosphorescence, and affect photographic plates.

Others think, with Crookes and J. J. Thomson, that these rays are formed by matter which is negatively charged and moving with great velocity, and on this hypothesis their mechanical properties, as well as the manner in which they become curved in a magnetic field, are readily explicable.

This latter hypothesis has suggested to me some experiments which I will now briefly describe, without for the moment pausing to inquire whether the hypothesis suffices to explain all the facts at present known, and whether it is the only hypothesis that can do so. Its adherents suppose that the kathode rays are negatively charged; so far as I know, this electrification has not been established, and I first attempted to determine whether it exists or not.

(2) For that purpose I had recourse to the laws of induction, by means of which it is possible to detect the introduction of electric charges into the interior of a closed electric conductor, and to measure them. I therefore caused the kathode rays to pass into a Faraday's cylinder. For this purpose I employed the vacuum tube represented in Fig. 1. A B C D is a tube with an opening a in the centre of the face B C. It is this tube which plays the part of a Faraday's cylinder. A metal thread soldered at S to the wall of the tube connects this cylinder with an electroscope.

E F G H is a second cylinder in permanent communication with the earth, and pierced by two small openings at β and γ; it protects the Faraday's cylinder from all external influence. Finally, at a distance of about 0·10 m. in front of F G, was placed an electrode N. The electrode N served as kathode; the anode was formed by the protecting cylinder E F G H; thus a pencil of kathode rays passed into the Faraday's cylinder. This cylinder invariably became charged with negative electricity.

The vacuum tube could be placed between the poles of an electro-magnet. When this was excited, the kathode rays, becoming deflected, no longer passed into the Faraday's cylinder, and this cylinder was then not charged; it, however, became charged immediately the electro-magnet ceased to be excited.

In short, the Faraday's cylinder became negatively charged when the kathode rays entered it, and only when they entered it; *the kathode rays are then charged with negative electricity.*

The quantity of electricity which these rays carry can be measured. I have not finished this investigation, but I shall give an idea of the order of magnitude of the charges obtained when I say that for one of my tubes, at a pressure of 20 microns of mercury, and for a single interruption of the primary of the coil, the Faraday's cylinder received a charge of electricity sufficient to raise a capacity of 600 C.G.S. units to 300 volts.

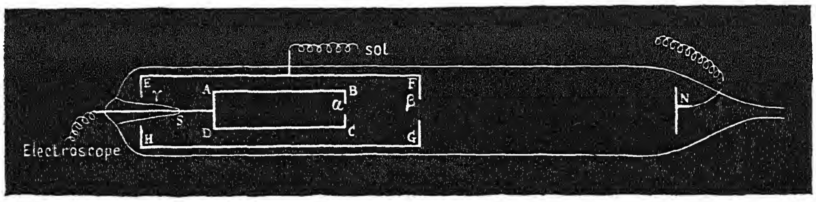

FIG. 1.

(3) The kathode rays being negatively charged, the principle of the conservation of electricity drives us to seek somewhere the corresponding positive charges. I believe that I have found them in the very region where the kathode rays are formed, and that I have established the fact that they travel in the opposite direction, and fall upon the kathode. In order to verify this hypothesis, it is sufficient to use a hollow kathode pierced with a small opening by which a portion of the attracted positive electricity might enter. This electricity could then act upon a Faraday's cylinder inside the kathode.

The protecting cylinder E F G H with its opening β fulfilled these conditions, and this time I therefore employed it as the kathode, the electrode N being the anode. The Faraday's cylinder is then invariably charged with *positive electricity*. The positive charges

[1] Translation of a paper by M. Jean Perrin, read before the Paris Academy of Sciences on December 30, 1895.

[2] These vibrations might be something different from light; recently M. Jaumann, whose hypotheses have since been criticised by M. H. Poincaré, supposed them to be longitudinal.

were of the order of magnitude of the negative charges previously obtained.

Thus, at the same time as negative electricity is *radiated* from the kathode, positive electricity travels towards that kathode.

I endeavoured to determine whether this positive flux formed a second system of rays absolutely symmetrical to the first.

(4) For that purpose I constructed a tube (Fig. 2) similar to the preceding, except that between the Faraday's cylinder and the opening β was placed a metal diaphragm pierced with an opening β', so that the positive electricity which entered by β could only affect the Faraday's cylinder if it also traversed the diaphragm β'. Then I repeated the preceding experiments.

When N was the kathode, the rays emitted from the kathode passed through the two openings β and β' without difficulty, and caused a strong divergence of the leaves of the electroscope. But when the protecting cylinder was the kathode, the positive flux, which, according to the preceding experiment, entered at β, did not succeed in separating the gold leaves except at very low pressures. When an electrometer was substituted for the electroscope, it was found that the action of the positive flux was real but very feeble, and increased as the pressure decreased. In a series of experiments at a pressure of 20 microns, it raised a capacity of 2000 C.G.S. units to 10

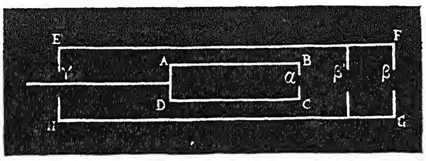

FIG. 2.

volts; and at a pressure of 3 microns, during the same time, it raised the potential to 60 volts.[1]

By means of a magnet this action could be entirely suppressed.

(5) These results as a whole do not appear capable of being easily reconciled with the theory which regards the kathode rays as an ultra-violet light. On the other hand, they agree well with the theory which regards them as a material radiation, and which, as it appears to me, might be thus enunciated.

In the neighbourhood of the kathode, the electric field is sufficiently intense to break into pieces (*into ions*) certain of the molecules of the residual gas. The negative ions move towards the region where the potential is increasing, acquire a considerable speed, and form the kathode rays; their electric charge, and consequently their mass (at the rate of one valence-gramme for 100,000 Coulombs) is easily measurable. The positive ions move in the opposite direction; they form a diffused brush, sensitive to the magnet, and not a radiation in the correct sense of the word.[2]

THE FRENCH MAGNETIC SURVEY OF THE WORLD.

IN Europe, as well as in the United States of America, the study of terrestrial magnetism has for some time played an important part.

M. le Commandant de Bernardières has written a most interesting account of the construction of new magnetic maps of the globe, undertaken by the Bureau des Longitudes. The following are a few facts given by him, which show to what extent it is contemplated to carry out the work.

From the magnetic determinations already obtained, some maps have been made; observatories too, permanent and otherwise, have been built. But the work is not entirely satisfactory. The maps are chiefly the result of observations made by navigators, and are only of limited parts scattered over the face of the earth.

In order to have a *general* magnetic map, numerous observations would have to be made, distributed over all regions, taken as nearly as possible at the same time, and in the same way with similar instruments. To this end the Bureau des Longitudes have appealed to Vice-Admiral Besnard, Minister of Marine, who has promised help, and put at their disposal officers and sailors, and also a great number of instruments. The Colonial Minister has also shown interest in the matter, and promised his assistance in the colonies.

Seven sets of observers have been organised, consisting each of a lieutenant, ensign or hydrographer, and one assistant. These expeditions have been arranged as follows:—

Atlantic Ocean	West Coast of Africa, East Coast of America, Antilles, &c.	M. Schwérer, lieutenant of the ship.
Pacific Ocean	West Coast of America	M. Blot, ensign of the ship.
Pacific Ocean	Oceana	M. Monaque, ensign of the ship.
Indian Ocean	Red Sea, South Coast of Asia, Oriental Coasts of Africa, Madagascar, and other islands	M. Paqué, ensign of the ship.
Chinese and Japanese Seas	Coasts of Indo-China, of China and Japan	M. Terrier, ensign of the ship.
—	Madeira, Canary Islands Azores, Cape Verd Islands, Senegambia	M. de Vanssay, hydrographic engineer.
Iceland	North Sea, Scandinavia, Denmark, Scotland	M. Houette, captain of the frigate, commanding the Iceland station; M. Morache, lieutenant of the ship.

With expeditions in these various parts of the earth, it will be possible to make observations almost simultaneously.

In order to determine the correct value of the magnetic elements, as well as to ascertain the exact variation of these elements, the missions have been supplied with the finest instruments, which have been adjusted at the observatories of Montsouris and Parc Saint-Maur; comparisons will also be made at every magnetic observatory at which they arrive during the expedition. Special instructions have been given with regard to calculations and method of observation, in order to insure a perfect comparison of results.

Six of these expeditions have started, and have communicated already the result of some of their first observations; the work, however, will have to be continued about two more years.

The ship *Manche*, which left France last spring, for Iceland, has returned with a great number of observations, obtained in Cherbourg, Scotland, the Shetland Isles, Iceland, Norway, and Denmark. In the observatory constructed by the *Manche* at Keykiawik, two complete observations of variations were obtained, having each a duration of eight days.

It will be very interesting to compare the results of the present day with those of the *Recherche*, obtained sixty years ago, and since then of several other expeditions. The successful return of the *Manche* certainly indicates that great things may be expected of the other expeditions, and makes it certain that a most important step has been taken by the French Government for the advancement of science.

[1] The breaking of the tube has temporarily prevented me from studying the phenomenon at lower pressures.

[2] This work has been carried out in the laboratory of the Normal School, and in that of M. Pellat at the Sorbonne.

LILIENTHAL'S EXPERIMENTS ON FLYING.

THERE are many of us, no doubt, who are watching with great interest the experiments of Herr Otto Lilienthal in his "Fliegesport and Fliegepraxis." These "Uebungen," which he is making from a hill thrown up in the neighbourhood of Berlin, have, from the very beginning, been rewarded with a distinct success; and it seems that, given time, he may present us, if not with a method of flying, then with an approximation to it, which perhaps at some later date may be more fully developed.

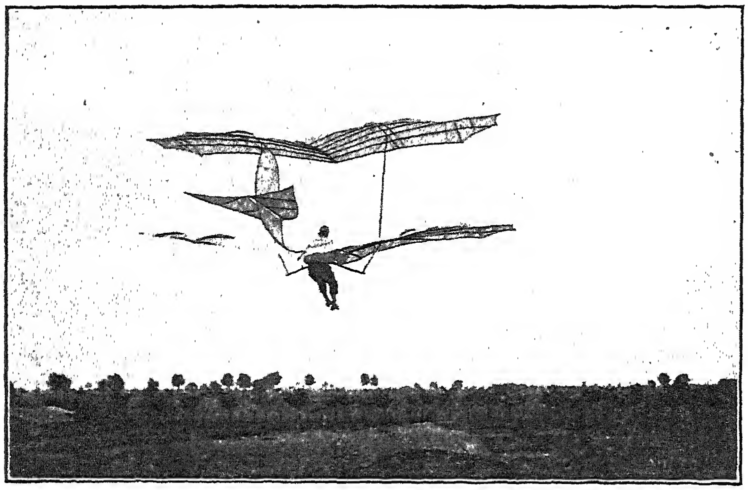

FIG. 1.

His experiments have, up to the present, shown that, by means of such an apparatus as he employs, fairly long flights may be indulged in with perfect safety, provided the operator does not attempt to do too much at the beginning, but contents himself with mastering the first elements of sustaining his equilibrium.

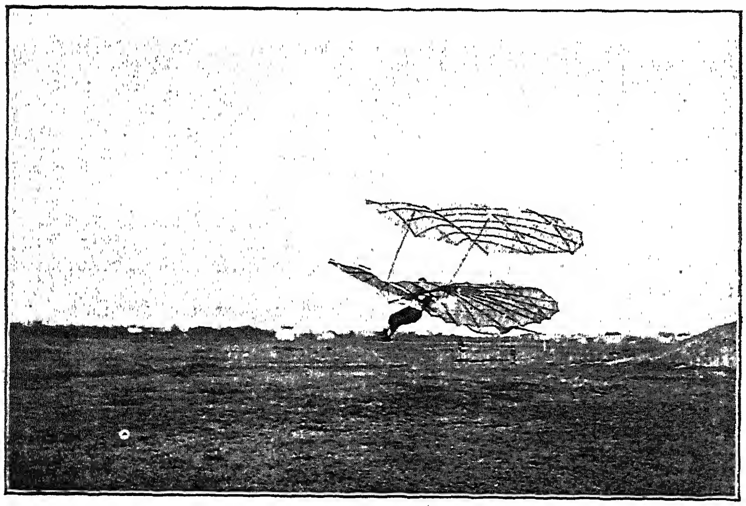

FIG. 2.

In a previous article (NATURE, vol. li. p. 177), a short account was given of Herr Lilienthal's earlier experiments on this subject, and it was then mentioned that falls must be expected in the preliminary trials, until the operator becomes accustomed to the many new conditions which make themselves apparent at every step, before they can be mastered instinctively.

Similar difficulties have, for instance, to be contended with when learning to ride a bicycle. The beginner is at first unable to keep his equilibrium, and so wobbles here and there with the loss of much power, until he eventually finds himself on the ground. This is simply because he is doing something unusual, and is not accustomed to the new conditions. An adept rider, on the other hand, never thinks of the possibility of falling, and quite unconsciously keeps his equilibrium without any exertion or loss of power on his part. So it is with this sailing machine, and it is only with practice that the required head can be obtained and success assured.

In the above-mentioned article, the machine Lilienthal employed consisted of a wing-shaped framework of a slightly curved nature, the advantage of the curved form, both as regards the amount and direction of the resistance, having been previously proved. The tail consisted also of two plane surfaces, one being at right angles to that of the horizontal framework, and lying in the direction of movement, and the other more generally in that horizontal plane, but capable of movement about a fixed point in it.

With the wind blowing at a moderate and more or less constant rate this machine has been found to be very satisfactory, and flights of comparatively long duration have been made with it.

Lilienthal's ambition, however (*Prometheus*, No. 322, p. 148), does not end here; but he looks further ahead than this, and wishes to be able to practise in such strong winds that he can be carried along with them. He, however, remarks that the size of the apparatus puts a certain limit to this; for if the spread of the wings be too large, then the whole arrangement becomes extremely awkward and hard to manage.

Up to the present, although he has practised in moderately rough weather, and had to perform fantastic feats in the air to keep his equilibrium, he has been fortunate in obtaining on nearly every occasion a safe landing. Experience has, however, convinced him that before trying to compete against strong winds in future, he must modify his machine to some extent, in order to make it easier to handle under these more trying circumstances.

To this end experiments were made with wings of various shapes; but these were given up, as it was found that the employment of a new principle, suddenly discovered, gave the required results with satisfaction that was scarcely dreamt of. The idea consisted in using, instead of one large framework covered with some light material, two smaller ones, placed parallel one above the other. These, of course, would, when sailing through the air, have a similar lifting effect; but, besides affording a simple means of increasing the sail-

area without adding to the breadth of the machine, they would decrease very considerably the difficulties, referred to above, with respect to the management of the centre of gravity.

On this principle, Otto Lilienthal constructed his new double-apparatus (Fig. 1), the appearance of which will be noticed from the accompanying illustrations. Each separate surface has an area of nine square metres; thus he is able to employ the very large carrying surface of eighteen square metres with a breadth of only five and a half metres. The upper surface, which is placed at a distance of about three-quarters of a wing-breadth above the lower, proves in no way a disturbing factor in the machine, as might at first be supposed, but develops simply a vertical lifting force. It may be remarked that this double-surface machine is managed in exactly the same way as the single-framed one.

From Fig. 2 it is easy to obtain a good idea of the arrangement adopted, by which the upper surface is fixed rigidly to the lower one by means of two rigid stays, the whole surface being held in position by means of thin wires.

With this new apparatus, Otto Lilienthal has already found that a step in the right direction has been made. The energetic movement of the centre of gravity, and the consequent more safe management of the apparatus, has led him to practise in winds blowing at times over ten metres per second. "These experiments," he says, "have given the most interesting results that I have arrived at since I began." With a wind velocity of six to seven metres per second, the sailing surface of eighteen square metres carried him against the wind in nearly a horizontal direction from the top of the hill, without even having to run at the start, as is generally necessary. More interesting still, is it to learn that, with stronger winds, he allows himself to be simply lifted by the wind from the hill-top, and sail slowly against it. Fig. 3 is such a case in point. The same illustration also shows how strong at times may be the side-motion, the operator having to considerably alter the position of his centre of gravity to retain his equilibrium.

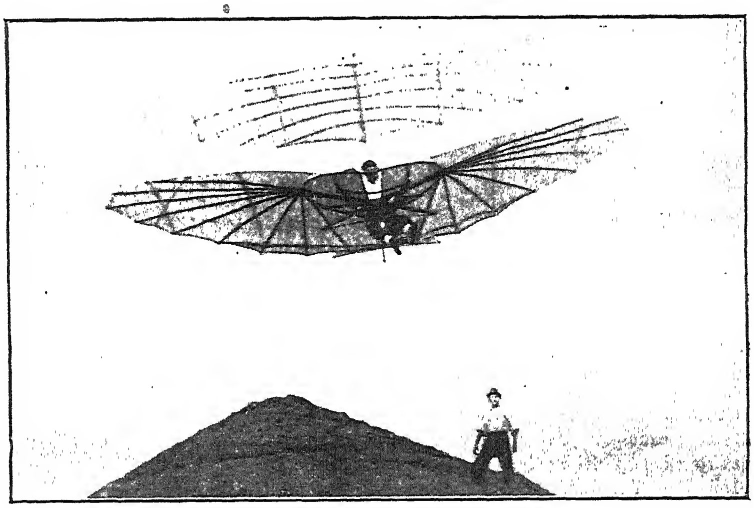

FIG. 3.

As experiments have shown, the sailing path is directed strongly upwards by increasing wind force, and this fact causes him sometimes to be higher in the air than he was at his original starting-point. In this position his apparatus has occasionally come to a standstill; and this leads him to make the following interesting statement: "At these times I feel very certain that, if I leaned a little to one side, and so described a circle, and further partook of the motion of the lifting air around me, I should sustain my position. The wind itself tends to direct this motion; but then it must be remembered that my chief object in the air is to overcome this tendency of turning to the left or right, because I know that behind and under me lies the hill from which I have started, and with which I would come in rough contact if I allowed myself to attempt this circle sailing. I have, however, made up my mind, by means of either a stronger wind or by flapping the wings, to get higher up and further away from the hill, so that, sailing round in circles, I can follow the strong uplifting currents, and have sufficient air space under and about me to complete with safety a circle, and, lastly, to come up against the wind again to land."

It may be remembered that Lilienthal has previously employed some mechanical aid, such as the flapping of the wings: an illustration of the apparatus so arranged was given in the article already referred to above (NATURE, vol. li. p. 178). Perhaps he will apply the same arrangement to the lower framework of his present apparatus, and thus accomplish the end he is wishing to attain.

One can quite understand that sailing against the wind is one thing, and with it another. In the latter case, since the framework is inclined slightly upwards in the direction of motion, the wind would meet the sailing surface from above and shoot the operator, arrow-like, to the ground if he were unable to come up again quick enough to the wind. That such circle sailing will be most probably successfully accomplished by Herr Lilienthal seems certain, but the first few attempts may prove, perhaps, rather rough.

The recent experience of Otto Lilienthal has thus shown that by means of his new apparatus a very close approximation to flying has been attained.

Should he, however, find that the accomplishment of circling is not attended by any great difficulty, and there appears no reason why it should, then there seems no doubt that an important step will have been made, and the future development of this *Fliegesport* will depend nearly directly on the *Fliegepraxis*.

It is interesting to notice that in America this Lilienthal-method is about to be tested. We have in the British Isles already a follower in Percy S. Pilcher, of Glasgow University, but his experiments at Cardross, in Dumbartonshire, have not as yet proved very successful, owing to the wings of his apparatus being too much inclined. He is, however, busy with the construction of a new machine, which will have a sail-area of 300 square feet (= 27·6 square metres). The experience of Lilienthal has shown, however, that with such a large expanse this machine will only be able to be used in moderate winds with safety. If its construction be not already too far advanced, it would seem advisable to add the second or upper surface, since its presence has been shown to be attended by greater stability and easier management of the whole apparatus.

W. J. S. L

DEATH OF MR. ALEXANDER MACMILLAN.

WE much regret to record the death of Mr. Alexander Macmillan, one of the founders of this journal. This is not the place to give a long account of his career. We may limit ourselves to the statement that outside the field of scientific workers there were few who possessed a greater sympathy with scientific aims, few who had a keener insight as to the place science should occupy in our national life and in our educational systems. It was the hope that a more favourable condition for the progress of science might be thereby secured that led him to enter warmly into the establishment of this journal in 1869. Mr. Macmillan was born in 1818, and died on Saturday last, at his residence in Portland Place.

NOTES.

M. MAURICE LŒWY, the distinguished French astronomer, has been elected a corresponding member of the Berlin Academy of Sciences.

ELON COLLEGE, of North Carolina, has received an endowment of 100,000 dollars from a resident of New York City. The faculty will not reveal his name.

MME. W. HUBER has presented a sum of 20,000 francs to the Paris Geographical Society, in remembrance of her husband. The Society has made the donor a life member, and has devoted the money to establish, under the name "Prix William Huber," a silver medal to be awarded annually to the author of the best work on the structure of mountains and valleys, or on glaciers and mountain lakes.

ACCORDING to the New York *Nation*, Portugal is about to follow the example of some greater Powers, and celebrate a quater-centenary of its own. At the request of the Geographical Society of Lisbon, the Government has just determined to celebrate, with much pomp, in 1897, the four-hundredth anniversary of the expedition which, on July 8, 1497, set out, under the command of Vasco da Gama, for the discovery of the route to India round the Cape of Good Hope. Few details of the celebration have as yet been settled upon, but it is expected that special expositions will be opened at Lisbon, and many scientific congresses held, to which the world will be invited.

WE have already referred to some of the honours given in commemoration of the centenary of the French Institute. How freely France distributes her decorations to men of science will be seen from the following list, given in the *Revue Générale des Sciences*, of the recent nominations to, and promotions in, the Order of the Legion of Honour. Grand Officer: M. J. Bertrand, Secrétaire Perpétuel of the Academy of Sciences. Commanders: MM. C. J. Bouchard, P. E. Duclaux, M. Lœwy, E. J. Marey, Members of the Academy of Sciences. Officers: MM. P. Appell, A. d'Arsonval, F. A. Fouqué, A. Gautier, E. Grimaux, H. Léauté, H. Moissan, E. Perrier, Members of the Academy of Sciences, and MM. A. Houzeau, R. Lépine, F. Raoult and E. Stephan, Correspondants of the same Academy. Chevaliers: MM. R. Blondlot, l'abbé A. David and G. E. Sire, Correspondants of the Academy of Sciences; and MM. Chappuis and Guillaume, of the Bureau international des Poids et Mesures.

WE have on several occasions called attention to the blunders which are made, and the disputes in which the country is involved from time to time, because of the unintelligent way in which the work of various Government departments is carried on. Each branch of the public service, instead of being advised by a scientific staff, is controlled by an officialdom which believes in its own omniscience; a condition of things as deplorable as it is derogatory to national honour and advancement. As we have before pointed out, administrators of departments in which questions involving scientific knowledge continuously arise are, to put the point mildly, *not* chosen on account of their scientific qualifications, and they have to pick up their information as best they can, the result being that they arrive at unsound decisions, and create dissatisfaction everywhere. The *Engineer* of January 17 has something to say which strongly supports our complaint of the neglect of scientific knowledge in the public service. Referring to Admiralty contracts, our contemporary says: "The duty of the Admiralty is to obtain the best possible ships, engines, guns, &c., that can be had; and that those who have to consider the tenders ought to know when a tender is too high or too low. In a word, they ought to know the value of what they propose to buy. Whether the knowledge does or does not exist in the Controller's department, we are unable to say; apparently it does not. The actual method of obtaining ships is strictly analogous to that adopted by a man who, totally ignorant of what a dwelling-house ought to cost, first gets drawings from an architect, and then advertises for tenders. Having obtained them, he proceeds to pit the tenderers against each other, assuming that in this way he will get the best value for his money. The mere mention of this method of doing business will be enough to condemn it in the eyes of our readers. But there is ample evidence available that the Whitehall people do not know what is the proper price to pay for work or materials, and to this ignorance on the one hand, and on the other to a fear of being cheated based on that ignorance, is no doubt due the bargaining and bartering which, during the last few years, have gone on at Whitehall, and have at last become so vexatious that it is matter of common talk among those firms who have laid themselves out to execute Admiralty orders." It is clear that if the relations between the Admiralty and the shipbuilding and engineering firms of the country are to be of a cordial description, the present system of conducting business will have to be greatly altered, and the sooner the alteration comes the better it will be for the country's welfare.

MR. F. E. WILLEY, of the Royal Gardens, Kew, has been appointed Curator of the newly-founded Botanic Station at Sierra Leone. Mr. J. M. Henry has retired from the post of Superintendent of the Baroda State Gardens. He was sent out from Kew in 1867, and after twelve years' service in Madras and Bengal was appointed to Baroda in November 1879.

DR. JOHN S. BILLINGS, Director of the Department of Hygiene in the Pennsylvania University, has been elected librarian of the new consolidated libraries of New York, representing the Lennox library, the Astor library, and the Tilden bequest. Dr. Billing's Index Medicus, and the Index Catalogue of the Surgeon-General's Library at Washington, furnish stupendous evidence of his capacity for cataloguing, and, with his experience in other directions, make him eminently fitted for the responsible post he has taken.

MR. A. G. CHARLETON presided on Friday, the 24th inst., at the Criterion Restaurant, over the twenty-third annual dinner of the old students of the Royal School of Mines. About a hundred and twenty guests were present, amongst these being the professors at the School and several distinguished visitors. In proposing the toast of "The Mining and Metallurgical Indus-

tries," the Chairman commented upon the relation of peace and monetary matters, and showed how the School of Mines was of the highest importance in training men to open up gold and other mining centres. Profs. Roberts-Austen and Le Neve Foster replied for metallurgy and mining, respectively. The toast of "The Professors" was proposed by Prof. Page, and replied to by Prof. Judd. Mr. G. T. Holloway proposed "The Learned Societies," and Prof. Tilden responded. "The Health of the Old Students" was dealt with by Mr. B. H. Brough and Mr. S. H. Cox. The question of the formation of a register of the old students was referred to by several of the speakers, and a guarantee fund for its publication was raised.

A NOTE received from Mr. John Plummer, Sydney, New South Wales, calls attention to the way in which science is represented in the colony. The Royal Society of New South Wales originated in 1821 as the Philosophical Society of Australasia, the present name being adopted, by Royal sanction, in 1856. The Linnean Society of New South Wales was established mainly by the efforts of the late Sir William Macleay, a devoted naturalist, in 1875, and has numbered among its members many of the leading scientific men in Australasia. The Royal Geographical Association, established in 1883, has branches in Victoria, South Australia, and Queensland. The headquarters of the Australasian Association for the Advancement of Science, based on the lines of the British Association, are in Sydney. The meetings of the Association are held alternately in the various colonies. Among other scientific associations in Sydney are the New South Wales Zoological Society, branches of the British Astronomical and British Medical Associations, Australian Economical Association, Pharmaceutical Society, Engineering Association, Insurance Institute, Institute of Architects, Institute of Bankers, Electric Club, Institute of Surveyors, &c.; not a bad record for a country which has but recently completed the first century of its existence, and is yet practically in its infancy as a nation.

A HYGIENIC EXHIBITION will be held at Warsaw during the present year. The *Journal* of the Society of Arts says that there are nine Committees at work, to whom have been assigned the following subjects: (1) Air, water, light; food in general, and articles connected with the above; also kitchen utensils, paints, wall-paper, and poisonous vegetables. (2) The question of sterilisation; also the utensils used for the culture of bacilli, showing exhaustively the method of ascertaining their presence and the means for their destruction. (3) Human dwellings in general, past and present, and the latest improvement in hygienic building. (4) The hygienic mode of caring for children; construction of school-houses, all systems of school education, and school-rooms and furniture. (5) The hygiene of industry; the hygienic conditions prevailing in the homes of labourers, shops, and factories; also food, and drink, and vital statistics. (6) The history and statistics of hygiene and the modern hospitals of the world. (7) The literature and history of pharmacy, patent medicines, furniture, and medical instruments, and all pharmaceutical utensils. (8) Statistical plans, diagrams, drawings, and all printed matter on the subject of hygiene, meteorology, geology, hydrography, and anthropology, in all their detail, and all sciences connected therewith. (9) The manner of living, dwellings, &c., of all classes of the population from a sanitary point of view. Awards of gold, silver, and bronze medals will be made, and also diplomas and letters of honour.

THE French Meteorological Office has recently issued its *Annales* for the year 1893, consisting of three parts: (1) memoirs, containing discussions on thunderstorms, distribution of hail, terrestrial magnetism, &c.; (2) observations made at stations in France and its colonies; and (3) a very detailed account of the distribution of rainfall. From the introductory text we see that weather forecasts are regularly issued to seaports and to agriculturists, and also warnings of storms. In both of these departments a large amount of success has been achieved, part of which is attributed to the regular receipt of telegrams from the Azores and from America, a comparison of these data allowing a more accurate idea to be formed of the changes which approach from the Atlantic Ocean. Observations are regularly collected from ships, and the observers, both on land and at sea, are encouraged in their work by the presentation of medals to those who have kept the best registers. Comparative observations are made at the Central Office and on the Eiffel Tower; the next year will complete a series of five years' observations, when a discussion of the more important results obtained will be undertaken, with especial reference to the influence of altitude on the various meteorological elements.

A SIMPLE instrument for recording the time of occurrence of an earthquake is described by Prof. C. F. Marvin in the *U.S. Monthly Weather Review*. A heavy lead weight is suspended on a short steel link, to which it is pivoted by means of a sharp-pointed screw, the point being just above the centre of gravity of the weight. A similar pointed support is provided for the top of the link, which hangs from a small projection in the frame of the instrument. The link is prolonged upwards as a needle about 6 inches long, the top of which passes through a small hole in a plate connected with the frame. The plate is electrically insulated from the rest of the instrument. A movement of the ground is magnified by the end of the needle, and the contact of the needle with the sides of the hole in the plate can, by connection with suitable electrical apparatus, be made to stop a clock or produce an automatic record on a sheet of paper. The instrument is a modification of one devised by Prof. Marvin in 1885, and has been in operation at the U.S. Weather Bureau since the winter of 1892–93. The recording apparatus used with it is the so-called "weekly anemometer register," and the time of a disturbance can be read to less than half a minute. It will be seen from this brief description that Prof. Marvin's seismoscope is almost identical with that used to start the revolving plate in Prof. Ewing's well-known seismograph.

THE first number of *The Scalpel* contains an article, by Mr. Lennox-Browne, on the new serum treatment of diphtheria, in which the writer comments upon the statistics derived from its application here and on the continent respectively, and attempts to explain the great discrepancy which so far exists between British and foreign results. Without entering into all the details of the controversy, there is one point which may be of some significance in the discussion; and this is the complaint made to the Clinical Society, that with the English serum supplied, no indication was given of the varying strength with which it was endowed. It may be of interest to know that in Germany the antitoxic serum is subject to State control as regards its preparation, the estimation of its activity, and its sterility, and that each phial which is issued, bears as a guarantee the official control number, as well as the date of the official test of the serum. The fact that in England such striking results have not so far been obtained as on the continent and in America, cannot alter the fact that we have undoubtedly in the serum-treatment of diphtheria a new departure in therapeutics, the far-reaching importance of which can hardly be exaggerated, and certainly not denied.

THE number of icebergs met between the Cape of Good Hope and Australia are vastly greater in some years than in others. Within the past few years, for instance, an extraordinary accession of enormous icebergs has occurred. As an explanation of this, it has been suggested that unusual falls

of snow may account for it by accelerating the motion of the ice; but Mr. H. C. Russell, F.R.S., remarks, in a paper read before the Royal Society of New South Wales in September last, that the circumstances forbid the acceptance of this view, because the motion of the glacier depends mainly on the declivity down which it is descending, and that does not alter, and the piling up of snow could not in one year cause such a marked increase in the rate of flow as would be necessary to account for the enormous increase in number of icebergs which appear from time to time. There must evidently be a force sufficient to break off the icebergs which are slowly forming on shore, and to do it at irregular periods separated by many years. He is of the opinion that the true cause resides in the volcanoes of the Antarctic continent, when they burst forth in eruption, and by the act so shake the foreshores, that the icebergs are broken off from the glaciers. In connection with Mr. Russell's paper, it is interesting to note a report, issued from the U.S. Hydrographic Office, descriptive of the floating ice seen during 1892 and 1893 in the South Atlantic east of Cape Horn. It is said that the icebergs were of such size that they could not have been formed on small, low-lying islands, but only on a large continent of such height that great glaciers could be formed.

Is there a connection between crime and the weather? The relations between certain meteorological conditions and many diseases has been fairly well established, and more knowledge about the connection is likely to be obtained now that a department having for its object the collection of statistics referring to climate and health has been formed in the U.S. Weather Bureau. And if bodily disease is affected by atmospheric changes, why not those mental diseases which result in the perpetration of crimes? Several attempts have been made to reveal a connection between the moods and impulses of the people and the weather, and a description of the results obtained in the latest of these investigations is contained in the current number of the *American Meteorological Journal*. The investigator is Mr. C. E. Linney, Director of the Illinois State Weather Service, who has considered the police records of the city of Chicago for each month in the years 1888–1894, the total number of arrests for each month, and for each division of crime, being examined with his "weather eye" open. While it is admitted that there are some cases which seem to go against the general rule, Mr. Linney thinks that the results do show a marked increase in crime with the increase in temperature, probably daily, at least for the months, seasons, and the year. Also that there is an increase in crime with a marked deficiency in rainfall, temperature conditions remaining normal; and again a greater increase where both conditions are aggravating causes. As for humidity, there seems to be no special connection, and also little connection with the cloudiness, except possibly a slight increase in clear, and a slight decrease in cloudy, weather. On the other hand, it is thought that the figures show a decrease in crime with a deficiency in temperature, especially during winter months, or with excess in rainfall in summer, and a greater decrease when both are restraining causes. Mr. Linney also thinks his results indicate that there is a decrease in crime with a north-east over a south-west wind. Perhaps the day will come when police stations will possess a full equipment of meteorological instruments, by reference to the readings of which police inspectors will regulate their vigilance.

NOS. 5 and 6 of the "Records of the Botanical Survey of India" are devoted to a report on a botanical tour in the Lakhimpur District, Assam, by Mr. G. A. Gammie; and notes on a journey from Poona to Nagotna, by Mr. G. M. Woodrow.

WE have received a copy of the memoir of the late Mr. Frederic Kitton, the well-known diatomist. His life affords one of the numerous instances of the great additions to our scientific knowledge due to men immersed in business, who can only devote to science their hard-earned leisure.

A CATALOGUE just received from the General Electric Company shows to what a vast extent the electrical industry has grown. The catalogue, which runs into nearly one thousand quarto pages, appears to include illustrations and descriptions of almost every invention known in connection with the application of electricity to useful purposes, and an abundance of information of value to electricians, while students will obtain from it a good idea of modern electrical work.

NOS. 4 AND 5 (vol. iii.) of the "Contributions from the United States National Herbarium," issued by the Department of Agriculture, have reached us. The former is devoted to a report, by Mr. J. M. Holzinger, on a collection of plants made by Mr. J. H. Sandberg and assistants in Northern Idaho in the year 1892. The latter contains a report, by Prof. J. M. Coulter and Mr. J. N. Rose, on Mexican Umbelliferæ, mostly from the State of Oaxaca, collected by Mr. C. C. Pringle and Mr. E. W. Nelson; and descriptions of plants, mostly new, from Mexico and the United States, by Mr. J. N. Rose.

MR. ARTHUR LISTER, the monographist of the Mycetozoa, who recently presented to the British Museum a magnificent collection of these organisms, together with a number of microscopic slides, has now prepared a "Guide to the British Mycetozoa," founded on these collections, which can be obtained in the Botanical Gallery of the Museum. It contains a most valuable, though concise, account of the life-history of these interesting structures, and a synopsis of the British genera and species. Each genus is illustrated by at least one woodblock drawn by the pencil of Miss Galielma Lister.

A "Review of Mineral Production in India" for 1894, compiled by Mr. G. Watt, has been published by the Indian Government. It is carefully prepared, and as regards the important materials salt, coal, and petroleum, the statistical returns of production, import and export, are complete. Iron ore is also fully treated; but it was not found possible to give complete statements of other minerals, though a great deal o information, both statistical and descriptive, has been brought together. In view of the great difficulties in the way of obtaining full information, the result is very satisfactory, and will probably lead to greatly improved reports in the future.

WITH the January number, the *National Geographic Magazine*, published by the National Geographic Society, Washington, commences a new series, and makes its first appearance as a monthly publication. It is intended that the magazine shall be the exponent of the geography—physical, political, and commercial—of the New World; in fact, the aim is to be American rather than cosmopolitan. The articles in the first number are "Russia in Europe," by the Hon. Gardiner G. Hubbard; "The Arctic Cruise of the U.S. Revenue Cutter *Bear*" (with illustrations), by Dr. Sheldon Jackson; and "The Scope and Value of Arctic Exploration," by General A. W. Greely.

THE eleventh volume of "Travaux et Mémoires" of the International Committee of Weights and Measures, has just come to us from MM. Gauthier-Villars, together with a volume containing the "Procés-verbaux" of the meetings of the Committee in 1894. Under the title, "Determination expérimentale de la valeur du mètre en longueurs d'ondes lumineuses," the former contains a detailed account of Prof. Michelson's work in connection with the use of the light-wave as the ultimate standard of length. There are two other papers in the volume, viz. "Mètres prototypes et étalons," by M. J. René Benoît and

M. C. E. Guillaume, and "Nouvelles déterminations des mètres étalons du Bureau international," by the same authors.

WE have received the 22nd and 23rd Annual Reports of the Geological and Natural History Survey of Minnesota (for 1893 and 1894). Among the contents of the latter are a criticism on the late Dr. G. H. Williams's explanation of the Archæan greenstones, by N. H. Winchell; a preliminary report on the gold region of Rainy Lake, by H. V. Winchell and U. S. Grant; an historical sketch of Lake Superior mining, by H. V. Winchell; and a study of the late Glacial earth-movements of the St. Lawrence basin, by Warren Upham. Geologists will be interested to know of the issue of an official "List of Publications" of the Geological Survey of Canada (Ottawa: 1895), which includes all reports, with their separate contents, maps, and certain papers on Canadian geology, reprinted from various publications.

THE ninth annual report of the Liverpool Marine Biology Committee contains an account of much useful work done at the Port Erin Station during the past year. (1) In his consideration of the submarine deposits of the Irish Sea, Prof. Herdman suggests the recognition of a neritic group of deposits in addition to the pelagic and terrigenous deposits defined by Murray. The neritic deposits are largely organic in origin, formed from the remains of plants and animals living on the bottom, and so differ on the one hand from the terrigenous deposits derived from the waste of land, and on the other from the deep-sea varieties due chiefly to the accumulation of the remains of pelagic organisms. (2) So far as experiments with drift-bottles have been able to show, the prevailing currents on the west of the Isle of Man seem to be towards the Irish coast, and on the east towards the Lancashire, Cheshire, and Cumberland coasts; these observations are interesting on account of the existence of flat-fish spawning grounds in the neighbourhood of the Manx coast. (3) The report also furnishes additional evidence in favour of the Darwinian view that closely-related species are not, as a rule, found together. In addition to the investigations on these general problems, the report includes various contributions in regard to the local fauna.

THE 1896 edition of that very comprehensive volume, the "Annuaire du Bureau des Longitudes," has now been issued. To say that no year-book is of greater service to astronomers and physicists than this "Annuaire," is but to record the opinion of all workers in the domain of physical science. The present edition has been brought thoroughly into line with recent knowledge. M. Lœwy has added a brief note on the proper motion of the sun, and the apex of the sun's way. M. Cornu contributes two new notes—one on the bright lines in the spectrum of the chromosphere recently identified with those of terrestrial substances, and the other on the identification of lines in stellar spectra. The list of minor planets has been brought up to 416; and some changes have been made in the list of double-star orbits. M. Moureaux gives the values of the magnetic elements determined at 644 points in France; and M. Cornu contributes new chapters on specific heats, and on the latent heats of fusion and vaporisation of water. Among the articles, we notice one on action at a distance and waves, and another on Fresnel's works, both by M. Cornu; and there is also an article on the proposed magnetic survey of the earth, by Captain de Bernardières; and an account, by M. Janssen, of his third ascent to the observatory on the top of Mont Blanc.

MESSRS. DULAU AND CO. have made arrangements to publish a work on "The Coccidæ of Ceylon," by Mr. E. E. Green. All the species at present recognised in Ceylon, including several new genera and numerous new species, will be described, and illustrated by 120 coloured plates. The work will be published in four parts, for which Messrs. Dulau are now inviting subscriptions. In the prospectus announcing the proposed publication is an inset, in which the opinion of members of the B.A. committee on the Coccidæ of Ceylon is set forth. It is there pointed out that what is known of the distribution of this cosmopolitan group justifies the belief that many of the new species from Ceylon described by Mr. Green will prove, as inquiry advances, to be world-wide. The Committee therefore recommend the work to the consideration of subscribers, believing that it "will be of great assistance to gardeners and to naturalists generally, and of considerable value to those engaged in economic entomology or in the management of plantations in any part of the world, as well as to systematic entomologists and morphologists."

SEVERAL new editions of scientific works have lately been received. Messrs. E. and F. N. Spon have published the third edition of Prof. J. H. Cotterill's classic volume on "The Steam Engine considered as a Thermodynamic Machine." A few slight changes and additions have been made in the appendix, but the book has been practically reprinted without substantial alteration. The eleventh edition of "Discoveries and Inventions of the Nineteenth Century," by Mr. Robert Routledge, has been published by Messrs. G. Routledge and Sons. The text has been emended. and the volume has been enlarged by a few pages of notes, and by new sections dealing with some of the engineering achievements and scientific discoveries of the last five years. The final part (vol. iii. part iv.) of the tenth edition of "Quain's Elements of Anatomy" (Longmans, Green, and Co.), edited by Profs. Schäfer and Thane, has now appeared. Its subject is Splanchnology; the anatomical descriptions belonging to which have been revised, and in many cases rewritten, by Dr. J. Symington, while the histological portion has been re-edited by Prof. Schäfer. It is proposed to issue a chapter on superficial anatomy, in the form of an appendix to the work. The fourth edition has been issued of Mr. W. T. Lynn's slender book on "Remarkable Comets." From the useful list of the dates of the returns of interesting comets, we see that, in the spring of this year, Faye's comet (period 7½ years) is due, and in the spring or summer, Brook's comet (period 7 years). All the information in the book has been carefully brought up to date.

THE additions to the Zoological Society's Gardens during the past week include a Black-faced Kangaroo (*Macropus melanops*, ♀) from Australia, presented by Mr. E. Mitchell; a Himalayan Bear (*Ursus tibetanus*, ♀) from Upper Burmah, presented by Captain Gale; a Slow Loris (*Nycticebus tardigradus*) from Upper Burmah, presented by Captain J. W. Carrothers; a Salt-water Terrapin (*Clemmys terrapin*) from the West Indies, presented by Mr. J. Lea Smith; Seven Galliot's Lizards (*Lacerta galloti*), a Delalande's Gecko (*Tarentola delalandii*) from Madeira and Tenerife, presented by Mr. H. B. Hewetson, two Indian Jerboas (*Alactaga indica*) from Baluchistan, purchased.

OUR ASTRONOMICAL COLUMN.

THE DOUBLE STAR 70 OPHIUCHI.—Of the numerous orbits which have been computed for this well-known double star, that derived by Dr. Schur in 1893 is perhaps entitled to greatest confidence. Nevertheless, even in the short interval which has since elapsed, Dr. See finds that the companion is several degrees in advance of the theoretical position based on Schur's orbit. In explanation of this, as well as of other departures from the orbit which appear on close investigation, Dr. See suggests that the companion is attended by a dark satellite, moving in a retrograde direction with a period of about thirty-six years, the period of the visible pair being a little less than ninety years. The distance of the companion from the centre of gravity of itself and satellite is probably about $0''\cdot 3$; and a circular orbit with node and inclination identical with the similar elements of the visible pair sufficiently explains the observed changes of position angle and distance. Adopting the parallax $0''\cdot 2$, the

semi-axis major of the primary orbit is 22·74 astronomical units, while that of the secondary orbit is 1·5 astronomical units, and the combined mass is 1·6 times that of the sun. The whole system of 70 Ophiuchi is thus contained in a space less than that occupied by the solar system; the orbit of the bright companion being intermediate in size between those of Uranus and Neptune, while the action of the dark satellite causes it to describe a secondary orbit corresponding in size with that of Mars (*Astronomical Journal*, No. 363).

MINOR PLANET PHOTOGRAPHY.—The great value of the photographic method of recording the positions of known minor planets, and in searching for new ones, is admirably illustrated by the results obtained by M. Charlois (*Bulletin Astronomique*, January). Between November 18, 1894, and August 29, 1895, forty-one plates were exposed by him at the Nice Observatory on suitable parts of the sky, and only nine of these failed to show traces of the objects sought. In the remaining photographs forty-four known planets and eleven new ones were recognised. Four of the new ones were of the 11th magnitude, three of the 12th, one of the 13th, and three of the 14th, while eleven of the old planets were of 10th magnitude or brighter. The newly-discovered planets are thus among the smallest of this class of bodies. Up to the end of last year the patience of M. Charlois had been rewarded by the discovery of eighty-three minor planets, or a little more than one-fifth of the total number at present known.

THEORY OF COMETS' TAILS.—It has long been imagined that the phenomena of comets' tails are in some way due to a solar electrical repulsion, and additional light is thrown on the subject by recent physical researches. Several investigators have shown that when ultra-violet light falls on an uncharged body the surface disintegrates, the particles which fly off being charged negatively, while the body itself becomes positively charged. Applying this to the case of a comet, Prof. Fessenden suggests that negatively charged particles are emitted from that side of a comet which is turned towards the sun, while the nucleus has a positive charge (*Astrophysical Journal*, vol. iii. No. 1). According to J. J. Thomson's experiments, the fact that the C line of hydrogen is brighter than the F line indicates that the sun's chromosphere is negatively electrified, and hence the disintegrated particles of the comet will be subjected to four forces; namely, the force due to gravitation, a second force to the repulsion of the negative charge on the sun, a third due to the attraction of the positively charged nucleus, and a fourth due to the repulsion of all the other similarly electrified particles. The shape of the tail is the resultant effect of these four forces. The observed effects do not demand an improbably great solar potential, the value calculated being 15,000 volts. Accepting the theory, the contraction of the head, the partition of comets, multiple tails, and other appearances seem to find a reasonable explanation. The increasing positive charge of the nucleus as the sun is approached will result in an increased solar electrical attraction, and the effect will be the same as that which would be produced by a resisting medium; that is, the period will be shortened, as in the case of Encke's comet.

The fact that the most frequently observed spectrum of a comet's tail is like that of a candle flame, indicates, according to J. J. Thomson's experiments, that the particles of carbon are negatively electrified, and this is quoted in favour of the theory. It may be pointed out, however, that there is no such direct evidence to show that the nucleus is positively charged, as required by the theory.

THE ROTATION PERIOD OF VENUS.—A valuable contribution to the study of the rotation period of Venus has been made by Prof. Tacchini (*Atti Reale Acad. Lincei*, vol. v. p. 3). Observations made at the Collegio Romano during last summer, tended in favour of Schiaparelli's view that the rotation period of the planet is 224·7 days, that is, equal to the sidereal revolution. He now announces that continued observations, made under the best atmospheric conditions towards the end of 1895, have led to the same conclusion. The observations terminated on December 19, and on some occasions they extended over very considerable intervals on the same mornings. On November 28, for example, work was commenced at 5.45 and continued until 11 o'clock, and during this time the same features were constantly observed on the illuminated part of the planet. A nebulous arc on the dark part of the planet, near the southern cusp, observed in September last, was not seen in the recent observations.

THE INTERNATIONAL GEODETIC CONGRESS AT BERLIN.

LAST month, in the new Reichstag palace, in Berlin, the official international Congress of Geodesy met together. The members represented seventeen States of Europe, Asia, and America.

At this conference the delegates of France were: MM. H. Faye, Vice-President of the Bureau des Longitudes; Tisserand, Director of the Paris Observatory; Bouquet de la Grye, the retired Engineering Hydrographer in charge of the Marine; Bassot, Superintendent of the Geodetic Section of the Geographical Service of the Army; and Ch. Lallemand, Director of the General Levelling of France.

The Congress was welcomed, in the name of the Prussian Government by Dr. Bosse, Minister of Public Instruction. After recalling the fact that the International Geodetic Association was founded by the Prussian General Baeyer, Dr. Bosse briefly sketched the history of progress made in the different sections of geodesy during the last ten years, under the happy influence of the Association.

In reply to the Minister, M. Faye, President of the Association, very appropriately remarked that although Germany has done much for geodesy in the last fifty years, still France has the honour of having, during the last century, set the example.

Following this Prof. Foerster, Director of the Berlin Observatory (President of the Congress), described the recent discovery of the variation of latitude.

M. Fergola (Director of the Naples Observatory) has proposed since 1883 that observations should be organised in a permanent manner in observatories equally distributed round the earth, and situated at more or less the same latitude, in order to observe the small possible movements of the terrestrial axes. The first signs of these movements, noticed by M. Küstner at the Berlin Observatory, were reported to the Conference held at Salzburg in 1888 by the International Geodetic Association. The Association took up the question, and instituted two years afterwards an astronomical station of observations at Honolulu (Sandwich Isles), to control the results made in Europe. The success of this undertaking has now led the permanent commission of the Association to propose the realisation of M. Fergola's plan. This realisation will be greatly facilitated by the recent construction of a special photographic telescope, of which the first results were very interesting.

We will confine ourselves to naming some of the principal scientific communications made to the Congress. M. de Kalmar (Austrian delegate, and reporter on accurate levelling) announced the fact that, in the last three years, the total length of these levellings in Europe has increased from 20,000 kilometres, and exceeds to-day 120,000 kilometres. Colonel Bassot reported that three geodetic bases have just been measured in Roumania with the instruments of the Geographical Service, and with the help of French officers. Another base must be measured next in Turkey under the same conditions. M. Bouquet de la Grye announced that the Bureau des Longitudes have just undertaken, with the help of the officers of the French Marine, the execution of a new magnetic map of the world. M. Lallemand reported, amongst the principal networks of accurate levellings of Europe, the existence of systematic errors—the cause as yet unknown—the probable value of which, although much greater than those of accidental errors, only considered up till now, is calculated to be between 0·1 mm. and 0·2 mm. per kilometre for the French, Spanish and Prussian networks. This being so, the researches and efforts of those in charge of great levelling undertakings should certainly aim at reducing the systematic errors.

According to verifications made in Austria by Colonel Sterneck, and confirmed by other observers, the intensity of gravity has a slight diurnal oscillation. The communication of the captain of the ship *Von Kalmar* states that the officers of the Austrian Marine have determined the intensity of gravity in thirty-nine stations, situated in different seas of the world. Prof. Vogler, of Berlin, exhibited an accurate levelling instrument (*niveau de précision*) constructed on the principle of the cathetometer, and metallic levelling rods, formed of two rods of steel coupled with a rod of zinc, and covered with a layer of aluminium. These new arrangements would permit the inventor to reduce the accidental errors of the levelling; but it is doubtful if it would be the same for systematic errors.

The principal and most laborious task of the Congress consisted in drawing up a new diplomatic convention, in place of

that which, since 1886, has governed the existence of the Association, and expires next year. For this reason, important modifications have been introduced into the future functions of the Association.

In view of the construction and maintenance of international stations for geodetic or astronomical observations, its budget will be increased from 20,000 to 75,000 francs.

Under the new organisation, the various German States have been fused into the German Empire with one vote. The old permanent commission, which used to meet once a year, now disappears. Only the general conferences will be continued, and they will take place every three years, as formerly. In these assemblies special commissions will be formed for each branch of study of the Association.

M. Faye has been unanimously re-elected as President of the new Association, with General Ferrero, Italian Ambassador in London, as Vice-President, and Dr. Hirsch, Director of the Observatory in Neuchâtel (Switzerland), as Secretary.

MEETINGS OF AFFILIATED SCIENTIFIC SOCIETIES IN AMERICA.

AN important series of scientific meetings was held at Philadelphia, December 26-28, under the leadership of the American Society of Naturalists, and including six other Societies. The opening address of President Edward D. Cope to the Naturalists' Society was on the formulation of the natural sciences. A discussion on the flora and fauna of the Antarctic and adjacent regions occupied most of the time of this society. Angelo Heilprin opened the discussion. He said that very little was known about the Antarctic region. It appeared to him that the coast-line of this region did not outline a continent, but only a group of islands. The supposed continent had been regarded as destitute of vegetable life till lichens were discovered there last year. It is thought from geological formations that the continent was once connected with Australia, South America, and perhaps Africa. W. B. Scott said that a study of fossils of animals shows that Australian forms are found in South America, but no South American forms in Australia; thus indicating that there was first a connection between Australia and the southern continent, and later between South America and the southern continent.

N. L. Britton gave a list of plants, and Theodore Gill of fresh-water fishes, to show the connection between the southern continent and Australia and South America.

The officers elected for the Naturalists' Society are: President, W. B. Scott; Vice-Presidents, W. G. Foster, C. O. Whitman, and Theodore Gill; Secretary, H. C. Bumpus; Treasurer, J. B. Smith.

There was a large attendance at the meeting of the Geological Society of America. President N. S. Shaler (in the chair) read a paper on the relations of geologic science to education. Among other papers read were one by C. R. Van Hise, on the movements of rocks under deformation, and a description, by Sir Robert Bell, of the land about Hudson Bay.

Officers elected were: President, Joseph Le Conte; Vice-Presidents, Charles H. Hitchcock and Edward Orton; Secretary, H. L. Fairchild; Treasurer, J. C. White; Editor, J. S. Brown.

The American Psychological Society listened to the annual address of the President, J. M. Cattell, and to a large number of papers by members. An interesting discussion on "Consciousness and Evolution," was opened by William James, and participated in by E. D. Cope, J. M. Baldwin, C. Sedgwick, G. T. Ladd, G. S. Fullerton, J. H. Hyslop, D. S. Miller, and Wesley Mills.

The Anatomical Society of America was briefly addressed by the President, Thomas Dwight. An interesting paper was read by Burt G. Wilder, on "The Cerebral Fissures of Two Philosophers." The brains referred to were those of Chauncey Wright, of Cambridge, and James Edward Oliver, of Cornell, both of which the lecturer exhibited.

Officers elected were: President, Frank Baker; Vice-Presidents, B. G. Wilder and F. J. Shepherd; Secretary and Treasurer, D. S. Lamb.

The American Morphological Society had papers by C. S. Minot, Bashford Dean, and others, and elected the following officers: President, E. L. Mack; Vice-President, H. F. Osborne; Executive Committee, E. G. Conklin and W. Patten.

A meeting of the American Physiological Society was held, at which several papers were read.

The meeting of the American Folk-lore Society was, of course, the most popular. Washington Matthews presided, and read a paper on the poetry and music of the Navajoes. He finds that the tribe has many legends, songs, and formulated prayers. They have an elaborate religion, with symbolism and allegory that might vie with the Greeks. Daniel G. Brinton read a paper on "American Cuss Words," and J. H. McCormick on "Folklore of the Southern Negroes." Captain John G. Bourke read "Notes on some Arabic Survivals in the Language and Folklore of the Rio Grande Valley," in which he traced the similarity of names which the Mexican uses for his common articles of food with those used by the Moslem; and also showed similarity of customs of the two nations.

Officers elected were: President, John G. Bourke; Vice-Presidents, Stewart Culin, Franz Boaz; Councillors, J. W. Ellsworth; Hall Chatelain, J. H. McCormick.

A general lecture was given on Thursday evening by Prof. Wm. B. Scott, on the "Lacustrine Formations of North America and their Mammalian Fossils." The vast plains east of the Rocky Mountains were, in the Pliocene age, fresh-water lakes. Large numbers of fossils, particularly mammals, have been taken from them. Prof. Scott argued the identity of the American fauna of that age with that of France and the valley of Lausanne in Switzerland at the same period.

The affiliated societies were entertained during the days of session by the University of Pennsylvania, and a banquet was given on Friday evening at the Hotel Lafayette. Prof. Cope presided, and the address of welcome was made by Dean Fullerton, of the University.

GEOLOGY IN GLASGOW UNIVERSITY.[1]

YOU are doubtless aware that last year I entertained and expressed the rash expectation that I should not again meet a class as lecturer on geology. "I thought to pass away before, and yet I still am here." An explanation is therefore necessary; I must, in fact, detail the history of the subject in this University, so as to purge myself of censure in respect that the University is, in this particular, behind the time, and far behind what Glasgow, above all, has a right to expect that its University should be.

When I came to Glasgow the old custom prevailed of interlarding the lectures on zoology with those on geology. In my time in Edinburgh, Edward Forbes gave four lectures on zoology, setting aside Friday for geology. In 1867 I separated the two subjects, lecturing twice daily during that summer, and raising a brief revolt amongst the medical students, who thought themselves defrauded of their rights. Brief, for the clamour died quickly when they found themselves at liberty to attend the second lecture without paying a fee; their abnormal thirst for knowledge at once contented itself with what was required for the professional examinations. This was the first complete course given in Scotland, and anticipated by four years the foundation of the Murchison chair in Edinburgh. In 1872, on the establishment of a degree in science, geology was made compulsory for that, as it had previously been for the certificate of proficiency in engineering science. Thereon I began to urge the claims of a subject which had been thus quietly introduced to a prominence not previously granted to it in this city. The Mining School started in Anderson's College some years before had collapsed, those who owed wealth to their mineral property taking no interest in the effort which not even the excellence of Mr. Prior as a teacher could sustain. The hearty support given me in my crusade by Dr. (now Sir Charles) Cameron deserves to be recorded, for he was the only one who appreciated the importance of the movement, the only one who stirred a finger to help me. Wealthy coal- and iron-masters saved their money, some by the Mrs. McLarty plea that they did well enough without trained men, others by modestly saying that they could not properly intrude where their wealthier neighbours saw no need for action. I need not comment on the want of public spirit, of patriotism displayed, which astonished me more perhaps than it would now; but it seemed, and seems strange that a country which boasted Hutton, Playfair, Hall, Macculloch C. Maclaren, Hugh Miller, Lyell, Murchison, A. C. Ramsay

[1] From Introductory Lecture to Course of Geology in Glasgow University by Prof. John Young.

should be without a chair in the subject which they had raised from dependence on mineralogy to the rank of an independent science. Still more did it astonish me, and the astonishment is unabated, that no one among those who owed money to the discoveries of geology was prepared to spend a penny in the way of gratitude. It was not among the wealthy that Pringle Nichol's genius had kindled the zeal for knowledge.

I carried my plaint to the Science Commission, the first Universities Commission, and finally to the second Commission, created in 1889 to "improve the teaching" in the Universities of Scotland. To all the same tale was told, with increasing earnestness as time went on, and the evils correspondingly increased. It was worse than absurd to expect one man to teach two subjects, either of which was more than any one could follow, even with ample time at his command, so rapid were the advances and so unexpected the specialisations enforced by the discovery of new methods and new fields of inquiry. The medical students were always the more numerous class, and the increasing stringency of the regulations for examinations left me no choice but to devote myself to those whom I had to teach summer and winter. Since 1867 the progress of Geology has been marvellous, Mineralogy has entered on a new phase, Microscopy has assumed an indisputable position as arbiter in problems that never could have been discussed, never perhaps have been raised without its aid. I had no time for the field work, which I had carried on as long as possible. Before the G. A. Clark scholarship was founded I had employed lecturers at my own cost to supplement my class work in Mining and Chemical Geology. Thereafter these graduates did as much as possible when they happened to take special interest in my subject. After many years of disappointment and drudgery, such as, I hope, my successors will be spared, drudgery which has deprived me of the chance, save at rare intervals, of original work, with joy I hailed the new, the present Commission with its instruction to "improve the teaching," for now surely was a Commission about to secure for this University, for Scotland, for science, what Murchison in loyalty to his native country and to his beloved studies had rendered possible for Edinburgh. The Commission is now approaching the end of its sittings, and I am still the "double-barrelled gun" that Murchison called me when I took leave of him on resigning the Survey appointment I had held.

In 1874 Mrs. Honyman Gillespie endowed my chair with £200 a year in respect of Geology, and named me a trustee on her gift, a position I accepted, as it was through an indirect and, let me add, an unwitting suggestion of mine that the benefaction was decided on. My intervention, later on, in the case of the W. Baxter scholarship was direct. It was made a proviso that the Professor of Natural History should not vacate the geological lectureship in the event of a chair of Geology being founded unless an equal stipend were continued to him during his incumbency. It shows how carefully Mrs. Gillespie and her advisers had considered the circumstances, that they thus removed from the incumbent any inducement to delay for personal reasons the separation of the two subjects, which the endowment was implicitly intended to bring about. After the evidence I submitted to the Commission, I was amazed to learn that they contemplated the creation of a new chair, not of Geology, but in a subject new to the Scottish Universities, not compulsory for a degree but optional; nay, it is one of six subjects which the candidate for M.A. may select from, viz. English, French, German, Italian, Spanish, History; a collocation which tempts to the suspicion that the subject of imperative necessity was, after all, an after-thought. Such an addition meant diminution of the fee fund, but this concerned my colleagues interested in the financial consequences. My concern was that a subject which an unreformed university had deemed of sufficient importance to have included twenty years before in the requirements for a degree should be passed over, while the new chair of Pathology was the recognition of an exactly parallel want. No; not exactly, for the pathologist had always had ample opportunities for study and research, undisturbed by the need of teaching even a cognate subject, far less one widely apart from his proper work. Parallel, however, in so far as its relation to a degree, the time this relation had existed and the compulsion of attendance were concerned. In contrast with the position of History, let me tell you the relations of Geology: it is compulsory for the degree of B.Sc. in Agriculture, and the certificate in Engineering Science; it is optional for B.Sc. in Pure Science and Engineering; optional also for M.A. Need I say that it is not to the addition of History I object, but to the circumstances attending the addition. The new subject was made to hang loosely to the University, yet it was at once raised to the rank of a professorship, and the means of endowing Geology finally diverted. It seemed a first duty to provide for the better teaching of a degree subject, and under this impression I addressed a very strong remonstrance to the Commissioners. When the evidence and correspondence are published, the reading will be curious and interesting. The interest would have been discounted if the meetings of the Commission had been public, but there would have been less disappointment if precedent had been departed from. After my protest had been disregarded another source of help was revealed, the Bellahouston Trust. The trustees have acted with great generosity, and would have doubled their benefaction by speed had the matter been solely in their hands. It would be wrong to comment on negotiations still pending after two years, but I may say that the salary demanded by the Commissioners as the condition of their consent to the separation of the subjects is not fully realised; the University has no longer in its power the money, which with the Honyman-Gillespie fund and the Bellahouston gift would have met the requirements of the Commissioners. No doubt a lectureship might be established, and perhaps the legal difficulties might be got over; but this is not what the subject is entitled to, either on its own merits or in respect of the position it has so long held in the University curriculum. Here the matter rests.

I hope to have made it clear to those who have blamed me for remissness that I have done all that I can; that the only wrong thing which has brought me into this impass was my voluntary separation of the two subjects. I was younger and more sanguine then. My colleagues in St. Andrews and Aberdeen are still safe in this respect, and I would advise them to keep as they are; the new chairs will come more rapidly.

I regret that no acknowledgments are due to others besides Sir C. Cameron. The General Council of the University has never mentioned the case of Geology: it would not have helped them to any increase of power. The University Court—I mean that created by the Act—has done what it could to forward the chair; it erred, as I think, only in assenting to the creation of another chair without giving due consideration to the elder degree subject, rather to the degree subject, for the other is only an option. The position of the Commissioners is less easily understood, and in the absence of evidence it is but right to conclude that they had sufficient reason for the course they have taken; what it is will appear in their report. My chief complaint goes back of these; it is directed against the mineral proprietors, who have left till now unfulfilled the duty they owe to science and their city. Had the moderate sum I asked twenty years ago been then contributed, there would have been by this time a well-endowed chair, and Glasgow would have been on a footing of equality with Edinburgh as a school of science. It is painful, by way of contrast, to read of the munificence with which citizens have endowed the Mining School of Chicago, to cite one of the many American colleges where public and private spirit have vied in securing the best training that money and skill can give for their engineers, where the presidents of colleges ask and receive abundantly.

But do not imagine that you will not be taught geology. It is true that you will not learn all that I wish you had opportunity of learning. Not one, but three chairs would really content me; but, on the other hand, you will have your attention directed to aspects of the science which another might pass by. It is the practical side of the teaching on which the deficiency lies. If I cannot make you go through the methods of microscopic investigation as we do in the zoological laboratory, you will hear the conclusions to which microscopists are leading us. You will learn the bearing of biological speculation on geology, the value of fossil evidence from the zoological side, and the direction in which we shall probably have to travel in that most important quest, that geological grail, the estimate of geological time.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. P. E. Bateman, Fellow of Jesus College, has been appointed an Assistant Demonstrator in Experimental Physics at the Cavendish Laboratory.

The Conference on Secondary Education, previously arranged

for the Long Vacation, will be held in Cambridge during April next, probably towards the end of the month. A large concourse is expected.

Science states that the late Franklin Baldwin, of North Grafton, Mass., has made the following bequests, to take effect on the death of his wife:—Wellesley College, 50,000 dollars to found a chair in Mathematics in memory of his daughter, Katie Emma Baldwin; Smith College, Northampton, 12,000 dollars for scholarships; the University of Vermont, 10,000 dollars for scholarships; Dartmouth College, 6000 dollars for scholarships. The residue of the estate (some 20,000 dollars) is left to Clark University. It is also stated that Mrs. E. G. Kelly, of Chicago, will erect a chapel, at a cost of 100,000 dollars, for the University of Chicago, as a memorial to her brother.

THE following are among recent appointments abroad:—Dr. C. A. Strong to be Lecturer on Psychology in Columbia College; Prof. L. S. Luther to be President of Kenyon College, Gambier, Ohio; Prof. Theodore von der Goltz to be Professor of Agriculture in the University at Bonn; Dr. Dock to be Professor of Pathology and Bacteriology at Jefferson Medical College, Philadelphia; Prof. W. I. Blake to be Professor of Geology and Mining in the University of Arizona; Dr. Hüfner to be Professor of Physiological Chemistry at Strassburg; Dr. H. Rubens, Privat-docent in Physics in the Physiological Institute at Berlin, to be Extraordinary Professor; Dr. L. Neumann, Extraordinary Professor of Geography at Freiburg, to be Ordinary Professor; Dr. Max Le Blanc to be Extraordinary Professor of Physical Chemistry at Leipzig; H. F. Wiebe and Dr. K. Feussner, of the Charlottenburg Reichsanstalt, to be Professors; Dr. A. Weiss to be Assistant in the Mineralogical Institute of Greifswald University. Among recent nominations are: Dr. Otto Mügge to the chair of Mineralogy at Königsberg; Dr. Klemenčic to be Professor of Physics at Innsbruck.

ONE of the best products of the Technical Education movement is the *Journal* of the Essex Technical Laboratories—a monthly bulletin issued by the Technical Instruction Committee of the Essex County Council. The current number contains short descriptions of tuberculosis in cattle, the influence of various manures on pasture, the pruning of trees, the growth of plants, and other subjects, most of them instructively illustrated. A note at the end of the *Journal* announces that "The resources of the County Technical Laboratories are always at the disposal of correspondents as far as such services do not interfere with the regular work of the classes. Such work as testing germinating power and purity of seeds, identification of grasses, weeds, &c., examination of diseased plants and injurious insects, bacteriological examination of milk, &c., may be cited as the kind of help hitherto rendered to inquirers." By affording such opportunities for the acquisition of knowledge, and by the encouragement to observation and exact work offered in the *Journal*, the Essex Technical Instruction Committee is doing work which will benefit the county and the nation.

A MOVEMENT was started last year to secure greater facilities at the University of Paris for such prolonged study with the acquisition of learned degrees as hitherto has attracted English and American students chiefly to Germany. The *Times* correspondent at Paris now calls attention to the promulgation, a few days ago, of a decree reforming the Licence ès Sciences. Partially owing to the greater liberty permitted in the choice of studies, the possibility of moving from one University to another, and the privilege of being examined when they wish, English and American students have hitherto patronised almost exclusively the German Universities. The new decree will permit France to offer, at least as far as the scientific faculties are concerned, attractions equal or superior to those of Germany. As compared with the old regulations, the important provisions of the new decree are as follows:—First, the principle of election is introduced into the groups of studies chosen by the student; secondly, the student may migrate from one institution to another; and, thirdly, he may pass his examinations as he chooses, either singly or *en bloc*. After taking the Licence, the student may secure the doctor's degree upon presenting a satisfactory dissertation. Under the German system the candidate submits his thesis first and passes his examination afterwards, the doctorate being the only recognition he receives. In France, on the contrary, the student by passing his examination first will secure a certificate for every subject which he takes up, and will receive the Licence when he has completed the whole group, regardless of whether he ever takes the doctorate or not.

THE annual general meeting of the Association of Technical Institutions was held on Friday last. The Right Hon. A. J. Mundella, M.P., was elected president for the year, in succession to Mr. W. Mather. In his presidential address, Mr. Mundella referred to the systems of technical education abroad, and said that England was suffering from her past neglect and from over-confidence. As a consequence of the industrial training which the people of Switzerland had received, that country had exported a greater proportion of manufactured articles per head of her population than any other nation in the world. This he attributed wholly to education, the country being without coal and iron. German manufacturers also had the great advantage of employing a body of highly-disciplined men, who thoroughly understood the technique of their occupation. He held that if this country wished to make further progress in technical education there must be co-operation by employers. Elementary education should also be improved, and children should remain a longer time at school. The Association of Technical Institutions existed for the purpose of developing industrial education, but he warned them against becoming mere grant-earners. In a discussion that followed, upon the new syllabus for practical chemistry, regret was expressed that the Department of Science and Art still requires students in the elementary stages to have had practice in qualitative analysis. The alternative scheme for the award of grants based upon attendances as well as examination was discussed, and several alterations in the conditions of the scheme were suggested. Other subjects which were considered by the Association were the standard of success in the Department's examinations last May, and the Report of the Royal Commission.

SCIENTIFIC SERIALS.

American Meteorological Journal, January.—The audibility of fog-signals, by Prof. H. A. Hazen. The recent grounding of a passenger steamer on Great Gull Island in a dense fog, within five thousand feet due west of a second-class siren which was sounding at the time, calls attention to several points referred to in a paper by the same author in the journal for October last. This siren has been heard to a distance of twenty miles under favourable circumstances; but the captain of another steamer, which approached the island from the west at the time of the accident, states that his look-out was unable to hear any sound as they approached the island, whereas, after passing, the whistle could be plainly heard.—Atmospheric phenomena in the Arctic regions in their relation to dust, by Prof. W. H. Brewer. The author states that none of the fogs in high latitudes are so white and opaque as those seen south of lat. 50°, and that it is rare that they are so opaque that large dark objects cannot be seen at a distance of two hundred feet. In the Greenland seas the fogs were, as a rule, very much wetter. Often when the fog was so transparent that objects could be seen for half a mile or even a mile from the ship, the water would drip like rain from the rigging. On returning to the south, where the fogs were very dense and objects could not be seen at a ship's length, there was a marked contrast in their wetness; the air did not appear as if entirely saturated. The dust particles in the air over the southern waters were ample to collect all the moisture, while in the Greenland fogs condensation went on as if there was not nearly dust enough in the air to supply the demand.

Bulletin de l'Académie Royale de Belgique, Nos. 9–10.—At the request of M. Spée, astronomer at the Royal Belgian Observatory, a sealed packet was opened which had been deposited by him on January 8, 1887, and contained the description of an apparatus to enable astronomers to obtain the spectroscopic conditions of a total solar eclipse for the observation and photography of the corona and prominences. It is best described as a body generated by the revolution of a longitudinal section of a direct-vision spectroscope about its longer side, thus producing a series of cones and cylinders. This body is used for the spectroscopic analysis of a cylindrical beam of light proceeding from the chromosphere, and obtained by means of a circular slit of diameter equal to that of the sun's image suitably inserted in the telescope. The less highly refractive glass may also be replaced by a liquid, thus leading to considerable simplification, or the whole may be replaced by a circular grating. It should be noted that an apparatus very similar to this was described by Mr. C. Zenger in 1893.—Does a net impede the

passage of winged insects? by Felix Plateau. The difficulty experienced by insects in passing through a net with meshes three or four times their own size has been variously explained. Some attribute it to the resemblance to a spider's web, others to the apparent multiplicity of obstacles. Experiments made with nets of various shapes and materials show conclusively that the peculiarity of insects in this respect is due to the construction of their eyes, which are more adapted to the perception of motions or changes in surrounding objects than to the perception of form. When flying, insects are incapable of distinguishing a net from a continuous translucid surface, and it is therefore only very rarely that an insect will fly straight through it. It must strike the meshes or alight on them, and will then pass through as it would through any hole of the same size.

SOCIETIES AND ACADEMIES.

LONDON.

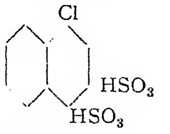
Royal Society, January 16.—"The Rotation of an Elastic Spheroid." By S. S. Hough, Isaac Newton Student in the University of Cambridge.

Recent researches on latitude-variation have brought to light the phenomenon of a periodic motion of the earth's axis of rotation in a period of 427 days. This period being in excess of the theoretical period of 305 days hitherto accepted, Prof. Newcomb has proposed to account for the extension by the failure of the old theory to take into consideration the flexibility of the solid parts of the earth. The author gives an analytical investigation of the motion of a solid body when slightly disturbed from a motion of simple rotation about a principal axis, taking into account elastic distortions due to variations in centrifugal force; the results are found to agree in the main with those obtained by Prof. Newcomb from geometrical considerations. The analysis deals with the case of a homogeneous spheroid of revolution, the ellipticity being such that the body is free from strain when rotating uniformly. Such a spheroid, if of the same size and mean density as the earth and rotating with the same angular velocity, would oscillate in a period of 232 days if perfectly rigid; it is shown that this period would be extended to 335 days in virtue of elastic distortions if the rigidity were equivalent to that of steel. In the case of the earth the period would be still further prolonged in consequence of variations in density, and the period which corresponds to the above degree of rigidity is estimated at about 440 days; whence it is concluded that the observed period may be accounted for by supposing that the earth is capable of elastic deformation, and that its effective rigidity is slightly in excess of that of steel.

Physical Society, January 24.—Captain Abney, President, in the chair.—Mr. Campbell Swinton exhibited some photographs which he had taken by Prof. Röntgen's method. These included several of metal objects inside wooden and cardboard boxes, and a very clear and sharp photograph of the bones of the hand.—Mr. E. Scott showed some geometrical instruments invented by himself and Signor Monticolo. The instrument designed by Signor Monticolo is intended for drawing arcs of circles of such large radius that compasses cannot be employed. It can be used to trace arcs of circles of which the radii vary from 50 cm. to infinity. The second instrument exhibited was a modified form of hatchet planimeter, which Mr. Scott has devised with a view of avoiding some of the defects of the ordinary form of instrument; thus, to avoid the cutting of the paper, which occurs when the knife-edge is sharp, and the side-slip, which occurs when the knife-edge is blunt, the author uses a wheel with a sharp edge. To avoid the inclination of the instrument to one side, which may easily occur with the ordinary form, a flat celluloid plate with a dot at the centre is used as the "tracing point," this plate being kept pressed flat on the surface of the paper. A small wheel with a recording disc is attached, and may be used to measure the distance between the first and last position of the knife-edge. Mr. Scott also described a form of planimeter which he had invented, and in which the l . c and cylinder movement is used to perform the integra on.—Mr. C. V. Boys said that an instrument designed by Mr. Clarkson had been exhibited before the Royal Society, which was capable of drawing arcs of circles of large radius. This instrument only drew an approximation to a circle, but the approximation was so close that it nowhere was more than the thickness of a thin ink line away from the truth. It would be interesting to hear from the author whether Signor Monticolo's instrument drew a rigorously exact circle or not. The upright position of the hatchet planimeter might be secured by using two wheels in place of one. The planimeter described was really a modified form of one he (Mr. Boys) had described before the Society in 1881. Mr. Blakesley gave a short geometrical proof showing that the curve traced by Signor Monticolo's instrument was rigorously an arc of a circle. Mr. Blakesley also drew attention to the fact that the instrument in its present form cannot be used to trace the arc on both sides of the zero line.—Dr. C. V. Burton described an idea for an instrument for drawing circular arcs, which had occurred to him, depending on the use of two wheels of different radii connected by an axle carrying a tracing-point. In the absence of the author, a paper by Prof. J. D. Everett on resultant tones was read by Dr. Burton. The author, after giving a short summary of the Helmholtz theory of the production of resultant tones, goes on to discuss his objections to this theory, and to elaborate a theory of his own. This theory depends on the consideration that, if you analyse into a Fourier series a periodic curve which is compounded of two simple harmonic motions of frequencies n and m, then only two terms are obtained. If, however, some error has been originally made in adding the two simple harmonic motions together, this error being repeated for each wave, then in addition to the two terms of frequency n and m there will be obtained, when the curve is analysed, a term of frequency f, where f is the greatest common measure of n and m. This term of frequency f the author calls the common fundamental of the tones n and m. The "error" in the production of the compound curve the author supposes to be produced during the transmission of the sound by the ossicles of the ear. In support of his theory the author finds that in the violin where the sound-post, like the ossicles of the ear, transmits the vibrations from one portion of the instrument to another, it is easy by sounding two strings in conjunction to obtain combination tones which agree in frequency with those required by this theory. Thus, when the major sixth (3 : 5), the major second (8 : 9), or the minor seventh (5 : 9) are sounded, the fundamental (1) is clearly heard and also felt by the hand holding the instrument. The author has also succeeded in picking out and strengthening this resultant tone by holding a Helmholtz resonator in contact with the body of the violin.—Dr. C. V. Burton, after explaining several portions of Prof. Everett's paper, said that he (Dr. Burton) considered that the author's view in many ways seemed to fit in with the observed facts better than the accepted theory, but still did not appear itself quite free from objection. Prof. Everett supposes that the first term in a Fourier series is always the most important, and although in most cases which occur in practice this may be so, it hardly seems legitimate to take this as a characteristic of a Fourier series.—The thanks of the Society having been given to Prof. Everett and Dr. Burton, the meeting adjourned to February 14.

Chemical Society, December 19, 1895.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read: The liquefaction of air and research at low temperatures, by J. Dewar.—Researches on tertiary benzenoid amines. (1) Derivatives of dimethylaniline, by Miss C. de B. Evans. On heating dimethylaniline with chlorosulphonic acid only the para-sulphonic acid is formed; fuming sulphuric acid must be used in order to obtain the meta-sulphonic acid. The bromination and nitration products of these sulphonic acids are described.—Experiments on the formation of the so-called ammonium amalgam, by J. Proude and W. H. Wood. Solutions of phenols in aqueous ammonia contain ammonium salts because they give ammonium amalgam on addition of sodium amalgam; no mercurial froth is obtained from ammoniacal aqueous solutions of several inorganic salts, so that these contain no ammonium salts. Ammonium salts, when fused or dissolved in anhydrous solvents, cause no swelling of the sodium amalgam; the presence of water seems essential to the formation of ammonium amalgam.—The molecular volumes of organic substances in solution, by W. W. J. Nicol. The atomic volumes of the various elements may be accurately determined from the molecular volumes of organic substances in solution; the constants thus obtained differ somewhat for different solvents.—2 : 1 β-naphthylaminesulphonic acid and the corresponding chloronaphthalenesulphonic acid, by H. E. Armstrong and W. P. Wynne. The 2 : 1 β-naphthylaminesulphonic acid is converted, by the Sandmeyer method, into 2 : 1-β-chloronaphthalenesulphonic acid of which a number of derivatives are described; 2 : 1 : 4′-β-naphthylaminedisulphonic acid is ob-

tained by sulphonating the amido-acid with fuming sulphuric acid.—1 : 3-α-naphthylaminesulphonic acid and the corresponding chloronaphthalenesulphonic acid, by H. E. Armstrong and W. P. Wynne.—Studies on the constitution of tri-derivatives of naphthalene, No. 15. The disulphonic acids obtained by sulphonating 1 : 3-α-naphthylamine- and 1 : 3-α-chloronaphthalene-sulphonic acids, by H. E. Armstrong and W. P. Wynne. On sulphonating these two acids with fuming sulphuric acid, disulphonic acids of corresponding constitutions are obtained; the acid prepared from the amido-acid may be converted by Sandmeyer's method into the acid having the constitution



obtained from the 1 : 3-α-chloro-acid.

Zoological Society, January 14.—Dr. W. T. Blanford, F.R.S., Vice-President, in the chair—A communication was read from the Rev. W. J. Holland, containing a preliminary revision and synonymic catalogue of the butterflies of the family Hesperiidæ of Africa and the adjacent islands, with descriptions of some apparently new species. The total number of species of African Hesperiidæ catalogued by Mr. Holland was 349, of which twenty-one were new to science. Fourteen new genera were characterised.—A communication was read from Dr. Arthur G. Butler, which gave an account of a collection of butterflies obtained by Mr. R. Crawshay in Nyasa-land between the months of January and April 1895. Many of the species in this consignment had been obtained at considerable altitudes. It was therefore surprising that comparatively few of them proved to be undescribed, though some of the new forms were of exceptional interest. Nine species altogether were characterised as new.—Mr. P. Chalmers Mitchell read a paper on the intestinal tract of birds.—Mr. F. G. Parsons read a paper on the myology of rodents, in continuation of a former paper read before the Society in 1894.—Mr. F. E. Beddard, F.R.S., gave an account of some earthworms from the Sandwich Islands collected by Mr. R. L. Perkins, and appended descriptions of some new species of *Perichæta*. Of the nine species of earthworms of the Sandwich Islands Mr. Beddard was unable to say that any one was indigenous.—A communication from Mr. Oscar Neumannn gave the description of a new species of antelope obtained during his expedition to East Africa in 1892–95, which he proposed to name *Adenota thomasi*, in honour of Mr. Oldfield Thomas.

Royal Microscopical Society, January 15.—Annual meeting.—A. D. Michael, President, in the chair.—After the annual report and the Treasurer's statement of accounts had been read and adopted, the following were elected as officers and Council for the ensuing year:—President: Albert D. Michael. Vice-Presidents: Rev. Edmund Carr, Frank Crisp, Dr. Richard G. Hebb, Edward Milles Nelson. Treasurer: William Thomas Suffolk. Secretaries: Prof. F. Jeffrey Bell, Rev. W. H. Dallinger, F.R.S. Members of Council: Conrad Beck, Alfred W. Bennett, Dr. Robert Braithwaite, Thomas Comber, Edward Dadswell, George C. Karop, the Hon. Sir Ford North, Thomas H. Powell, Charles F. Rousselet, Prof. Charles Stewart, John Jewell Vezey, Thomas Charters White.—The President, Mr. A. D. Michael, then delivered his annual address. The subject taken was the anatomy of the Acari. It was pointed out that the ordinary text-book definition of an Acarus as a creature in which abdomen and cephalothorax are completely fused is not correct, but that still the great characteristic of the anatomy is concentration; this was illustrated by the author's recent researches relative to the brain and nerves of the Hydrachnidæ (water mites) and other families. The address then dealt with the alimentary organs fully, and several remarkable modifications of the different organs to meet the wants of various creatures were explained.

Paris.

Academy of Sciences, January 20.—M. A. Cornu in the chair.—On two new invariants in the general theory of algebraic surfaces, by M. E. Picard.—On keeping up the motion of a pendulum without interference with its time of oscillation, by M. G. Lippmann. In a pendulum clock certain minute impulses must be given by the movement to the pendulum to overcome the energy losses due to friction, and these interfere to a slight extent with the natural period of vibration. In an ordinary precision clock, attention is directed rather to keeping this disturbance constant than to eliminating it. That a given instantaneous impulse, however, considered by itself, should give rise to no disturbance, it is necessary and sufficient that it should take place exactly at the instant that the pendulum passes through its position of equilibrium. An electrical arrangement is described which fulfils this condition.—On the circulation of the air in the soil, by MM. P. P. Dehérain and Demoussy. A description of an apparatus for the experimental study of the porosity of soils. Air is sucked out from the bottom of a layer of soil of fixed dimensions, and the steady difference of pressures hereby set up is measured, this increasing with the porosity of the soil. The same apparatus serves for the study of the passage of water through soils.—The law of equivalence in the transformations of energy in animals, by M. A. Chauveau. Experimental details of the relation between the work (positive and negative) done by the muscles and the carbon dioxide excreted by the lungs. The conclusion is drawn from these experiments that the mechanical work done by the muscles in lifting a weight requires only an equivalent expenditure of energy. This is stated by the author to be the first experimental demonstration of the law of equivalence for work arising in the activity of animal tissues.—On the specific heats of gases and the properties of the isotherms, by M. E. H. Amagat.—A note on some experiments of M. Witowski on the thermal constants of air between 0 and $-140°$.—Morphology of the limbs of the bony fishes, by M. A. Sabatier.—On the problems of variations relating to double integrals, by M. G. Kœnigs.—On the flexure of beams, by M. M. Duplaix.—Difference in the action of ultra-violet light on static and dynamic critical potentials, by M. R. Swyngedauw. Some experiments in support of a law announced in a previous note.—On a spherical Crookes' tube, showing the reflection of the kathode rays by glass and metal, by M. G. Séguy.—On the reflection and refraction of polarised light, by M. E. M. Lémeray. A geometrical interpretation of some formulæ of Fresnel.—On the solubility of sodium thiosulphate in alcohol, by M. P. Parmentier. Ordinary sodium thiosulphate has been obtained in two modifications, melting at 32° and 47°·9 respectively. Solubility determinations on these, and also on the superfused salt, gave results which are not in agreement with the experiments on the same subject previously published by M. Brunner. The conditions of equilibrium are very complex, and do not appear to follow any simple law.—On the nitrosulphides of iron, by MM. C. Marie and R. Marquis. A new method of preparing Roussin's salt. Sulphide of iron and sodium nitrite are treated at 100° with carbon dioxide. On cooling the pure salt crystallises out, the results of the analyses of which best agree with the composition $Fe_3S_2N_5O_6 + 1·5\ H_2O$. The reactions towards boiling alkali solutions, and water at 200° were examined, but the complete study of the products is reserved for a future paper.—Action of carbonyl chloride upon some hydrogen compounds, by M. A. Besson. The reaction with phosphonium bromide is given by the following equation

$$6PH_4Br + 5COCl_2 = 10HCl + 6HBr + 5CO + 2PH_3 + P_4H_2.$$

Hydriodic acid gives carbon monoxide, hydrogen chloride, and free iodine only, no derivative corresponding to carbonyl iodide being formed. With phosphonium iodide the principal reaction is

$$4PH_4I + 8COCl_2 = 16HCl + 8CO + P_2I_4 + 2P.$$

Hydrogen phosphide, PH_3, is without action upon carbonyl chloride, as is also H_2S in the cold. At 200°, however, the latter gives carbon oxysulphide, COS.—On dichloralglucose and monochloralglucosane, by M. J. Meunier. A study of the condensation products obtained from chloral hydrate and glucose under the action of sulphuric acid.—The weight and composition of the dead covering layer of forests, by M. E. Henry. Figures are given for two classes of deposit, under fully-grown trees, and under brushwood. The weight of the dead layer gradually increases with time for about ten years, and then remains very nearly constant (about 7000 kg. to 8000 kg. per hectare). Complete chemical analyses are given, rendering it possible to construct a chemical balance-sheet for the forest.—The volcanic tufas of Ségalas (Ariège), by M. A. Lacroix. These tufas present a remarkable analogy with the basaltic tufas of Auvergne. A microscopical examination showed that they are undoubtedly volcanic, consisting of labroadorite and andesitic scoria.—On the discovery of a tertiary stratum bearing land

fossils in the neighbourhood of Liverdun (Meurthe-et-Moselle), by M. Bleicher. The fossils include the bones of large mammals and terrestrial shells, including one species of Helix. The shells are rarely intact. As regards the age of this deposit, the evidence points to its being Tertiary, or possibly Pliocene, certainly not Quaternary. This is the first proof of the formation of purely continental land deposits at that time, and in the east of France.

BERLIN.

Physical Society, November 22, 1895.—Prof. von Bezold, President, in the chair.—Prof. Thiesen gave an account of some of his scientific publications; of these, the first deals with a comparison of various mercurial thermometers, of which two were made of Jena glass and one of hard French glass. The others deal with the thermal expansion of solids and liquids. Among these the first treats of the so-called thermic after-effect. and this the author explained by the assumption of minute non-conducting particles distributed throughout the conducting substance. He further developed this hypothesis into mathematical formulæ. The second deals with the linear expansion of rods of glass and zinc, and the third with the relative coefficients of expansion of water, mercury and glass between 0° and 100° C.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, JANUARY 30.

ROYAL SOCIETY, at 4.30.—On the Rhythmic Contractility of the Spleen: Prof. Schäfer, F.R.S., and B. Moore.—The Electrical Measurement of Starlight. Observations made at the Observatory of Daramona House, Co. Westmeath, in January 1896. Second Report: Prof. G. M. Minchin, F.R.S.—Contributions to the Chemistry of Chlorophyll. No. VII. Phylloporphyrin and Hæmatoporphyrin: a Comparison: E. Schunck, F.R.S., and Dr. L. Marchlewski.

INSTITUTION OF MECHANICAL ENGINEERS, at 7.30.—Telemeters and Range-Finders for Naval and other Purposes: Profs. Barr and Stroud.—Calculation of Horse-power for Marine Propulsion: Lieut.-Colonel Thomas English.

SOCIETY OF ANTIQUARIES, at 8.30.

FRIDAY, JANUARY 31.

ROYAL INSTITUTION, at 9.—National Biography: Sidney Lee.

INSTITUTION OF MECHANICAL ENGINEERS, at 7.30.—Notes on Steam Superheating: William H. Patchell.

INSTITUTION OF CIVIL ENGINEERS, at 8.—(1) Ironfounding in Green Sand; (2) Malleable Cast-Iron: F. A. Lart.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—The Collected Mathematical Papers of Arthur Cayley, Vol. ix. (Cambridge University Press).—Evolution and Man's Place in Nature: Prof. H. Calderwood, 2nd edition (Macmillan).—Ice-Work Present and Past: Prof. T. G. Bonney (K. Paul).—Traité de Chirurgie: A. Le Dentu and P. Delbet, tome i. (Paris, Baillière).—Graphic Arithmetic: H. D. Ellis, charts 1 and 2 (Philip).—Géométrie Descriptive: A. Gouilly (Paris, Gauthier-Villars).—Remarkable Comets: W. T. Lynn, 4th Edition (Stanford).

PAMPHLETS.—Die Gletscherlawine an der Altels am 11 Sept., 1895 (Zürich).—Misure Assolute degli Elementi del Magnetismo Terrestre: Dr. L. Palazzo (Roma).

SERIALS.—Annuaire de L'Académie Royale des Sciences, &c., de Belgique, 1896 (Bruxelles).—Bulletin Ditto, tome 30, No. 11 (Bruxelles).—Journal of Malacology, Vol. 4 (Dulau).—Revista Sperimentale di Freniatria e di Medicina Legale, Vol. xxi. Fasc. 4 (Reggio Nell' Emilia).—Astrophysical Journal, January (Chicago).—Quarterly Review, January (Murray).—English Illustrated Magazine, February (198 Strand)—Good Words, February (Isbister).—Sunday Magazine, February (Isbister).—Longman's Magazine, February (Longmans).—Chambers's Journal, February (Chambers).—Natural Science, February (Rait).

CONTENTS.

THURSDAY, FEBRUARY 6, 1896.

RECENT PSYCHOLOGICAL LITERATURE.

Outlines of Psychology. By Oswald Külpe. Translated by E. B. Titchener. Pp. xi + 462. (London: Swan Sonnenschein and Co. New York: Macmillan and Co., 1895.)

Studies in the Evolutionary Psychology of Feeling. By Hiram M. Stanley. Pp. viii + 392. (London: Swan Sonnenschein and Co. New York: Macmillan and Co., 1895.)

Mental Physiology. By Theo. B. Hyslop. Pp. xv + 552. (London: J. and A. Churchill, 1895.)

Moral Pathology. By Arthur E. Giles. Pp. viii + 179. (London: Swan Sonnenschein and Co. New York: Charles Scribner's Sons, 1895.)

PROF. TITCHENER has followed up his translation of Wundt's "Vorlesungen über die Menschen- und Thierseele" by performing the same office for Külpe's "Grundriss der Psychologie." This book is one of the most important of recent additions to psychological literature, and it is very fortunate that the task of translation should have fallen into such able hands. The result is an extremely accurate and readable version, supplemented by a new section on the experimental investigation of memory and association, written on the author's suggestion, an index of names, and several minor additions. Prof. Külpe has an acknowledged position as an experimental psychologist, and belongs to the school of Wundt, but his general attitude differs to some extent from that of his master, and more nearly approaches pure presentationism or associationism. The synthetic view of mind as built up of simple elements is rigorously followed, perhaps too rigorously, when the processes which are concerned in reaction time experiments are brought under the heading of connections of elements. The book has two chief divisions; the first deals with the elements of consciousness, which are divided into sensations and feelings, the former being subdivided into those peripherally excited, or, as more commonly called, presentational elements, and those centrally excited, or representational elements. The problems of association and memory are discussed under the latter heading. In the second division two modes of connection of these elements are considered. The first is termed fusion, of which the most striking instances occur in the cases of hearing and of the emotions. The latter are regarded as fusions of sensations and feelings. The second mode of connection was termed by Külpe "Verknüpfung," and this has been translated "colligation." This division is chiefly devoted to spatial and temporal relations. These are regarded as depending on "colligation" of the conscious elements. As regards spatial perception, however, the author inclines towards a nativistic position; and if this were definitely adopted, this subject would come under the elementary conditions of consciousness, and would have to be treated in its more usual place in connection with sensation. This is the least satisfactory part of the book. A comparatively short final division deals with the nature of attention, which is held to be a special state of consciousness in which the elements already described are presented, and is not regarded as a condition or process apart from the conscious content. The author's attitude here seems to be separated by very little from that of the presentationist school. As already stated in NATURE, when noticing the German edition, the book is likely to be largely used as a text-book.

Mr. Hiram Stanley, in his book on the evolutionary psychology of feeling, endeavours to establish the view, of which Horwicz has hitherto been the most prominent advocate, that feeling is the primitive mental state. Mr. Stanley supposes that consciousness first appeared as pain; that the state of the first conscious organism was one of unconsciousness with transient flashes of pain, and that similarly the psychical life of very young infants consists of intermittent pains interrupted by long intervals of sleep. The cognitive side of mind is held to be a later development. Fear is regarded as the primitive emotion which arises with cognition of object and with power of representation. Progress in sensibility is regarded as dependent on effort stimulated by pain; higher mental developments being only attained as the result of severe struggle. The evolution of mind is regarded as dependent on the stimulating influence of pain on volition. Unfortunately these highly interesting conclusions are not reached in a very scientific manner. The contradiction to the principles of evolution involved in the supposition that any of the specialised mental states experienced by us can be primitive, does not appear to have occurred to the author. The conclusions do not appear to be adequately based either on observation or experiment; the view, already mentioned, that the conscious state of the infant is mainly one of pain, appears to be derived from Preyer. The reader is often left in doubt as to whether statements made by the author are facts or opinions; thus, in considering the priority of touch and pain, it is stated that "a man in a 'brown study' inadvertently touching a hot stove has pain, then warmth, then touch sensation"; we are not told whether this order has been actually observed by any one; it is certainly opposed to common experience. Although the author's method is not scientific, and his conclusions questionable, the book has many points of interest. In considering the emotions, there is much skilful psychological analysis; the knowledge of previous thought on the subject is considerable, and there is much that is stimulating and suggestive. The chapter on desire may be mentioned as especially interesting.

Dr. Hyslop's book deals with the relations of the nervous system and the mind, especially in their bearings on mental disease, and a large part of the book is devoted to pathological questions. The book seems to be directed against the materialistic views which prevail among those who have to do with mental disease, at any rate in this country. Current hypotheses about the physiological basis of the higher mental processes are discussed and vigorously criticised, but less attention is paid to the positive knowledge which we possess, especially in relation to sensation and perception. The experimental aspect of psychology is almost wholly neglected, even when it is of a physiological nature, as in much recent

work on the bodily accompaniments of feeling and emotion.

The idea of "moral pathology" is very much in evidence at present, underlying as it does the work of Lombroso and his school. Dr. Giles' book is of a very different kind. It is an unpretentious sketch of moral defects from the point of view of the physician, considered under such headings as causation, diagnosis, prognosis and treatment. The work cannot be regarded as an important contribution to ethical science, but it is written brightly and with common sense. The principles which regulate diagnosis and treatment in medical practice are applied with considerable ingenuity to moral disease. There is an interesting chapter in which the idea of morbid diathesis is applied, and several types of character which predispose to moral disease are sketched.

PROTOTYPES OF THE FUNGI.

Protobasidiomyceten. Untersuchungen aus Brasilien. Von Alfred Möller. Pp. xiv + 179. (Jena: Fischer, 1895.)

THE present work forms the eighth part of Dr. Schimper's "Botanischen Mittheilungen aus den Tropen." The author is well known for his mycological researches, having previously contributed two parts to the above-named communications—"The Fungus-Gardens of some South American Ants," and "Brazilian Fungus-Flowers." To Elias Fries is due the credit of having first reduced the previous chaotic condition of mycology to an intelligent and scientific standpoint; even much beyond what could have been expected, considering that naked eye characters, or at most when aided by a pocket lens, were only available. Berkeley and Tulasne followed, and, aided by the microscope, added greatly to our knowledge of the minute structure and affinities of the various groups of fungi, a knowledge which has been in some instances more readily utilised than acknowledged by their successors. Later, De Bary's classical work indicated clearly what could be done, by means of pure cultures, towards the elucidation of the life-history of species, and a knowledge of true affinities; a method which is being developed at the present day by Brefeld, to the extent that the last-named author has presented us with his idea of the gradual evolution of the fungi, from their algal ancestors to the highly differentiated, asexual condition, represented by the members of the Basidiomycetes. As usual in classifications based on progressive morphological development, connecting links between groups that the evidence at hand suggest as forming a natural sequence, are not always forthcoming. The purport of the work under consideration is to make known a series of such connecting links or primitive types of the great group of fungi known as the Basidiomycetes; and if the author's conclusions prove to be well founded, the neighbourhood of Blumenau, in the province of Santa Catharinea, Brazil, where the material was collected, must be looked upon as a veritable garden of prototypes of the higher fungi.

Brefeld's conception of the Basidiomycetes, characterised by a single feature, the basidium or spore-bearing organ, which must be a terminal, clavate, or sub-cylindrical cell, bearing at its apex four—less frequently two—slender prolongations, or sterigmata, each of which bears a spore at its tip, is accepted, and the evolution of this group from the Ustilagineæ is bridged over by six families, collectively constituting the transition group called Protobasidiomycetes. Four of the transition families agree in having the basidium furnished with transverse septa, hence formed of two or more superposed cells, and bearing the spores laterally. In the remaining two families the basidia are vertically divided into four lobes, each of which runs out into a sterigma bearing a spore at its apex. The sub-families and genera of these families are considered as furnishing transitions to the Basidiomycetes proper. The following illustrate the value of these transition stages, being new sub-families and genera included in the Tremellaceæ, one of the families described above as having vertically divided basidia:—

Protopolyporeæ: Tremellaceæ with the aspect of the hymenium like that of the Polyporeæ.

Protohydneæ: Tremellaceæ with the hymenium resembling that of the Hydneæ.

Genera are as follows:—

Protomerulius: Macroscopic appearance that of the genus Merulius, but with basidia of the Tremellæ.

It is doubtful as to whether the author's view of transition groups, as illustrated above, will be accepted by mycologists. The genus *Merulius* is a typical Basidiomycete, so far as its basidia are concerned, but that something looking superficially like *Merulius*, but having basidia of a lower type, is the prototype of *Merulius*, appears to be more a matter of faith than of conviction. The same argument is applied everywhere; the general appearance is that of some well-known family or genus of the Basidiomycetes, but the structure of the basidia is that of the Protobasidiomycetes.

A wider knowledge of living species, or even a careful study of the material in any large herbarium, will in all probability convince the author that the lower forms of the Basidiomycetes are very plastic, nearly all the simpler genera being superficially mimicked by the unstable species of *Tremella* and its allies. On the other hand, it is not unusual to find specimens belonging to the simpler genera of the true Basidiomycetes presenting a superficial resemblance to species of *Tremella*, &c. As examples may be mentioned *Corticium arachnoideum*, Berk., which is sometimes a typical *Corticium* with a dense, waxy hymenium; at others the substance is very loose, dry, and the basidia scattered, when it mimicks *Hypochnus;* or again, *Coniophora puteana*, Cke., *Forma cerebella*, Sacc., on account of the Merulius-like hymenium. The author has considered structures worthy of sub-family and generic rank, what others would not consider as entitled to rank as a variety of a species.

Nevertheless, if all the author's deductions cannot be accepted, we are at the same time greatly indebted for the large amount of additional knowledge, the result of careful and conscientious investigations, carried out under most favourable conditions, pertaining to those primitive forms of the Basidiomycetes, which hitherto had received but scant attention.

GEO. MASSEE.

OUR BOOK SHELF.

Étude chimique du Glycogène chez les Champignons et les levures. Par Dr. G. Clautriau, Assistant a l'institut botanique, Université de Bruxelles. (Hayez, 1895.)

THE absence of starch from the tissues of the fungi has been generally considered as correlated with their inability to form carbohydrate food material from the CO_2 of the atmosphere, and for a long time it was considered that such carbonaceous reserve materials as they possessed existed only, or at any rate chiefly, in the form of fatty or oily bodies. Within comparatively recent years it has been shown by Errera and other observers that this does not represent the whole of the facts, and that though starch is absent, a very nearly allied body, glycogen, replaces it. The work under notice is a record of some very careful researches, carried out at the Botanical Institute at Brussels, to ascertain the true nature of this glycogen, and whether it is identical or no with the glycogen found in the liver and muscles of many animals.

The chief obstacle in the investigation is due to the peculiar nature of the vegetable organism. Apart from the question of extracting a material like glycogen from a tissue in which cell membranes form a very prominent feature, there remains the difficulty that very many of the decomposition products of cellulose are dissolved by the same solvent, and form mucilaginous material which it is extremely difficult to separate later from the extract of the fungi. The author of the book has with very great pains elaborated a method which enables him to prepare the glycogen in a pure state, and without a very great loss of material. The details of his process are too long to narrate in full; they may be briefly indicated by saying that the fungus is dried at a sufficiently high temperature to destroy the enzyme which is present with the carbohydrate, and reduced to powder by various means. The powder is repeatedly extracted with dilute caustic potash solution till no more glycogen is dissolved. The mucilaginous matter is got rid of by causing an inert inorganic precipitate to be formed in the solution which carries down the mucilage, but leaves the glycogen in solution. The latter is then purified, by treatment which is very fully detailed.

The glycogen has been thus prepared from many species of fungi, including Boletus, Amanita, Phallus and others, also from several yeasts.

Prepared thus, and examined side by side with the animal product obtained from the liver of the rabbit, the two appear to be identical. The solutions are faintly opalescent, and deflect the plane of polarisation to the same extent in the two cases. Both yield maltose when acted on by saliva, and dextrose when boiled for some time with weak mineral acids. Their percentage composition is the same, corresponding, according to the author, to the formula $6(C_6H_{10}O_5)+H_2O$.

The latter portion of the work is devoted to an examination of the chemical and physical properties of glycogen, particularly its relation to iodine, with which it gives a characteristic brown colouration.

Dr. Clautriau is to be congratulated on making a valuable contribution to our knowledge of the carbohydrate metabolism of the group of plants with which he has been engaged.

Popular Telescopic Astronomy. By A. Fowler, A.R.C.S., F.R.A.S. Pp. vi + 77. (London: George Philip and Son, 1896.)

ASTRONOMY has no direct bearing upon industry, therefore it is neglected in this utilitarian age. Technical education is made to include such subjects as political economy, problems of poverty, and great painters; but the authorities which decide what is or is not technical knowledge, draw a line at celestial science. The result is that astronomy is more studied for its own sake than any other science. But by merely reading popular astronomical literature, it is not possible to obtain a truly scientific knowledge of the heavenly bodies; personal observation of the varying aspects of the midnight sky, and of the chief characteristics of celestial objects is essential practical work compared with which book learning is as nothing. Two obstacles have hitherto prevented a wide enjoyment of the beauties of celestial scenery—first, the prohibitive prices which opticians charge for even small telescopes; and secondly, the absence of small and trustworthy guides to the heavens, suitable for those who have no idea what to seek and where to look. There are several most valuable works for the initiated amateur, but few are of a kind that the unexperienced observer finds intelligible. Mr. Fowler's little book removes both the obstacles referred to. In the words of the sub-title, it is a book showing "how to make a 2-inch telescope, and what to see with it," and very admirably is the promise of the title-page fulfilled. The telescope described is made by each student in the course of Astronomical Physics at the Royal College of Science, South Kensington. By following out the instructions given, a serviceable instrument can be constructed, capable of bringing into view a multitude of stars and sights beyond the range of the unaided vision. There can be no doubt that whoever makes his own telescope, not only performs thereby a valuable exercise in optics, but he is not likely to make such foolish mistakes as the astronomical tyro who procures his polished instrument from the opticians, and looks upon it as akin to a box of tricks.

Two chapters of the book are taken up with the details of the construction of the telescope, and hints on the practical use of it. Then come descriptions of star seasons, accompanied by four maps showing the chief constellations; and the remaining seven chapters are devoted to observations of the sun, moon, planets, comets, stars, double stars, star-clusters, and nebulæ. The whole of the work explained can be easily understood and readily performed. The book is practicable as well as practical; every instruction in it can be carried out, every observation described bears the impress of experience. Astronomy will gain more by the publication of this little volume than by the issue of a score of works of a descriptive character.

Anleitung zur Molekulargewichtsbestimmung. Von Dr. Gotthold Fuchs. (Leipzig: Wilhelm Engelmann, 1895.)

THIS little book of 41 pages is specially written as a laboratory guide to the methods of determining molecular weights from observations of the freezing-point and boiling-point of solutions made by means of the Beckmann pieces of apparatus. It contains short historical accounts of the theory of the two methods, and descriptions of the apparatus, including the latest modifications, and the modes of making the observations. Lists of data for calculating results when using different solvents, and numerous examples of the kind of values obtained, taken from Beckmann's papers, are also included. The author is careful to direct attention to the anomalies likely to be met with, and has succeeded in writing a trustworthy account of the present condition of these two widely used methods. J. W. R.

Recettes de l'Électricien. By É. Hospitalier. Pp. vi + 352. (Paris: G. Masson, 1895.)

AN electrician's pocket-book, full of workshop receipts, and containing numerous hints of use in electrical laboratories. In the selection of the receipts, the author has exercised discretion, and in their arrangement he shows that he understands exactly the requirements of electrical artificers and engineers.

LETTERS TO THE EDITOR.

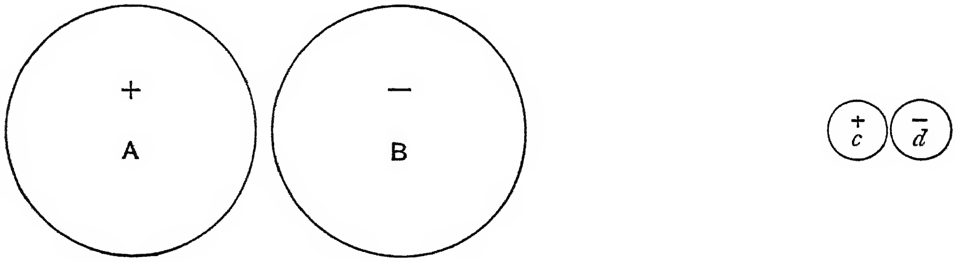
[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Velocity of Propagation of Electrostatic Force.

DR. BOTTOMLEY'S note published in NATURE of January 23, quotes an extract from my Baltimore Lectures of October 1884, in which this subject is spoken of, with an illustration consisting of two metal spheres at a great distance asunder, having periodically varying opposite electrifications maintained in them by a wire connecting them through an alternate current dynamo.

For an illustration absolutely freed from connecting wire and all complications, consider four metal spheres, A, B, *c*, *d*, with their centres all in one straight line;—their relative magnitudes and positions being such as shown in the accompanying diagram. Let each of the four be initially electrified, A and *c*, positively, B and *d*, negatively. Let the charges on *c* and *d* be so strong that a spark is only just prevented from passing between them by the influence of B and A. Let A be gradually brought nearer to B till a spark passes between them. Will the consequent spark between *c* and *d* take place at the same instant or a little later? It is not easy to see how this question could be answered experimentally; but remembering the wonderful ingenuity shown by Hertz in finding how to answer questions related to it, we need not perhaps despair to see *it* also answered by experiment.

The elastic solid theory restricted to the supposition of incompressibility (which is expressed by Maxwell's formulas) makes the difference of times between the two sparks infinitely small.



The unrestricted elastic solid theory gives for the difference of times the amount calculated according to the velocity of the condensational-rarefactional wave.

But I feel that it is an abuse of words to speak of the "elastic solid theory of electricity and magnetism" when no one hitherto has shown how to find in an elastic solid anything analogous to the attraction between rubbed sealing-wax and a little fragment of paper; or between a loadstone or steel magnet and a piece of iron; or between two wires conveying electric currents. Elastic solid, however, we must have, or a definite mechanical analogue of it, for the undulatory theory of light and of magnetic waves and of electric waves. And consideration of the definite knowledge we have of the properties of a real elastic solid, which we have learned from observation and experiment, aided by mathematics, is exceedingly valuable in suggesting and guiding ideas towards a general theory which shall include light (Old and New), old and new knowledge of electricity, and the whole of electro-magnetism. KELVIN.

The New Actinic Rays.

MAY I point out that an unnecessary amount of energy is being expended on Röntgen's photographs—I mean electrical energy.

I have succeeded in obtaining perfectly sharp and fully-exposed negatives from an action of four minutes' duration, even when a thin aluminium plate is placed in front of the sensitive film, and the rays are excited in a Crookes' bulb connected direct (*i.e.* with no Leydens inserted) with the secondary terminals of an Apps' induction coil, which gives (in its present condition) a three-inch spark in air when worked, as in the present experiments, by three small accumulator cells. This is much smaller, however, than that used in the published experiments of others who have been doing similar work.

University College, London. ALFRED W. PORTER.

THE accompanying photograph may perhaps interest those who are engaged in the photography of invisible objects. It was taken in the following way. Upon a piece of board I placed a sensitive plate, on this a penny-piece with the obverse side downwards, and on the top of the penny-piece a $\frac{1}{16}$-inch cedar board. The whole was exposed to the light emitted by the burning of sixteen inches of magnesium ribbon at a distance of six inches. I developed with pyro-ammonia. An inspection of the photograph will show a distinct image of the Queen's head.

On repeating the experiment with fifteen inches of magnesium ribbon at six inches, but without the use of the cedar board, the part of the plate surrounding the coin was solarised, whilst the part underneath was over-exposed, so that no trace of the image was visible.

I then repeated the last experiment, using a slow lantern-plate, and burning four inches of ribbon at nine inches distance; on development a faint image of the Queen's head was visible. Hence it is only a matter of exposure and development to produce a much better result than the one presented.

The phenomenon does not appear to be due to the varying thickness of the coin, since the impression of the reverse side has not modified the result, but rather to the different *directions* in which the penetrating rays are refracted from the irregular refracting surface on to the sensitive plate. W. SAUNDERS.

[A FAINT image of the Queen's head is quite visible upon the print received from Mr. Saunders, but it will not bear reproduction.—ED. NATURE.]

A STORY was current at Cambridge some forty years ago that an aspirant to mathematical honours replied to the question, "Construct a prism through which no ray can pass," in the terms following:—

"Take a prism of *wood*: then if no ray passes through, what was required is done. But if a ray does pass through, *paint it*."

Surely a marvellous anticipation of Röntgen's X-rays!

R. B. H.

The Stress in Magnetised Iron.

I AM glad that Dr. Chree, in his letter published in NATURE of January 23, has raised a discussion of this matter, regarding which, as he says, the most contradictory statements are to be found. For some time I have been aware that the passage referred to in my book on "Magnetic Induction in Iron" requires correction. The magnetic stress, $B^2/8\pi$, in a long rod or ring uniformly magnetised, is there spoken of as if it were of the same nature as a simple longitudinal stress of compression, producing a contraction of the length in consequence of the elasticity of the metal. Dr. Chree, if I understand him rightly, would treat it as of the same nature as a simple longitudinal stress of tension, producing an elongation of the iron.

But it now seems clear to me that both of these views are equally wrong. There is no proper comparison, in the general state of magnetised iron, with the stress in a loaded pillar or the stress in a stretched rope.

Take the case of a uniformly magnetised ring, where we have no complications due to end effects. Imagine a plane of section, and call the halves of the ring A and B. According to the first view, A is, as a consequence of the magnetisation of the ring, pushing against B, and B against A. According to the other view, A is pulling B, and B is pulling A. But if A is either pushing or pulling B, the equilibrium of B demands that some other force must act on it to balance this push or pull. No such

force exists. We cannot conceive the action at any section to be simply a stress of push or a stress of pull.

What we know from experiment is that, if the ring be actually cut in two, and a piece of, say, paper be put between the halves, the paper will be squeezed with a stress equal to $B^2/8\pi$. Also, that a pull of that amount would be required to separate the two halves of the ring.

This means that when they are separated by paper the half-ring A is pulling the half-ring B towards it, and the paper is pushing the half-ring B in the opposite direction with the same force, namely $B^2/8\pi$ per square centimetre of the section.

Of course we may, if we please, say that when there is no paper interposed, each half-ring is both pulling and pushing the other. If a mechanical analogy is wanted, it might be found by imagining a stiff tubular ring with a stretched india-rubber band inside it. Suppose, further, that when such a ring is cut through at any section the india-rubber band is not cut, but only its stiff envelope. Then if we try to separate the halves, we have to apply a force equal to the pull in the rubber band. And when the halves are allowed to come together with a piece of paper between them, they will squeeze it with the same force.

Mr. Shelford Bidwell and Dr. More have done what is equivalent to asking whether the change of length which a ring undergoes when it is magnetised can be accounted for by what I have here called the pull of the rubber band acting to shorten the stiff tube in which it is stretched, the tube being treated as having the same section and the same modulus of elasticity as the real iron ring has.

But I see no ground for treating this purely hypothetical strain as a "correction" to be applied, either one way or the other, to the observed changes of length.

The case illustrated by Dr. Chree (on p. 270) is a special one. He there considers the middle piece of a long magnetised bar, separated by actual gaps from the end-pieces from which it has been cut. To preserve the gaps, the end-pieces must be held fixed. He shows that under these conditions the middle-piece is in a state of tensile stress. So it is, but only because of the pull which the other pieces apply to it across the gaps. Make the iron continuous by closing up the gaps, and the tensile stress disappears.

To discuss the sign of the magnetic stress at all in the case of a closed ring, seems much like discussing whether a man sitting in a clothes-basket exerts a pull or a push when he tries to lift it by the handles. J. A. EWING.

Engineering Laboratory, Cambridge, January 28.

DR. CHREE'S letter in NATURE of January 23 corrects an error which it is curious has prevailed so long, and in part forestalls a communication Mr. H. Nagaoka and I had intended to make on the subject of magnetic stress. It might, however, be added that the expression $B^2/8\pi$ used by Dr. More (*Phil. Mag.*, October 1895), and originally given by Mr. S. Bidwell, for the magnetic stress causing changes of length, is incorrect also on another ground, viz. that this quantity is on Maxwell's theory the magnetic stress *in air* (where, according to the ordinary convention as to dimensions, $B = H$) and not in iron, where the expression is necessarily of a different form.

In conjunction with Mr. Nagaoka, I hope before long to discuss this subject more fully.

The Astronomical Theory of a Glacial Period.

MR. CULVERWELL has pointed out to me that I am in error when I include him among those writers who think that the problem of glacial periods is to be solved by considering only the varying amounts of sun-heat at different epochs. On referring to his paper, which I had not at hand when I wrote, I find that this is the case, and that he is careful to limit his calculations as giving only the variations of temperature due to *direct* sun-heat. He also discusses, though very briefly and inadequately, the effects due to *transference* of heat from one area to another. Although willingly making this correction at his request, I am still, after another perusal of his paper, quite unable to see that it finally disposes of Croll's theory, much less of that modification of it which I have myself set forth.

ALFRED R. WALLACE.

The Fall of the Altels Glacier, September 11, 1895.

JE vous adresse aujourd'hui un travail sur l'Avalanche du Glacier de l'Altels, que vient de publier la Commission des Glaciers de la Société helvétique des Sciences naturelles et qui complète l'intéressant article de Miss Maria M. Ogilvie: "The Gemmi Disaster" (NATURE, vol. lii. p. 573).

Ce travail rédigé par Mr. Heim n'est pas tout à fait définitif en ce que plusieurs points touchant à l'histoire antérieure du glacier de l'Altels n'ont pu être résolus encore. Il serait important de tirer au clair ces points pour pouvoir déterminer avec exactitude les causes de l'avalanche du 11 sept. 1895; mais, pour cela, il nous faut des *photographies* du glacier de l'Altels prises avant l'avalanche et remontant jusqu'à quelques années en arrière si possible. Après avoir fait depuis plusieurs mois des recherches peu fructueuses à cet égard je prends la liberté de m'adresser à vous, Messieurs, pour donner quelque publicité à ces lignes. Persuadé que beaucoup d'amateurs ont photographié l'Altels de l'W., ou du N.W., je les prie de bien vouloir me communiquer leurs épreuves, en indiquant la date (au moins le mois et l'année) à laquelle la photographie a été prise.

En vous remerciant d'avance de votre obligeance, je vous prie, Messieurs, d'agreér l'assurance de ma considération distinguée.

LEON DU PASQUIER.
Secrétaire de la Commission des Glaciers.

Neuchâtel, le 21 janvier.

Remarkable Sounds.

IN Major Head's "Forest Scenes" (London, 1829, p. 205), I have found the passage already quoted by Mr. C. Tomlinson (p. 78, *ante*), subjoined with this phrase: "It being, in real fact and without metaphor, the voice of winds imprisoned on the bosom of the deep." In a similar manner, Olaus Magnus describes the similar sounds thus: "Mais es lacs Septentrionaus gelés, on oit sous la glace une tempête aussi horrible, à raison des vens enfermés sous la glace, qu'on fait d'un tonnerre provenant de la gràde épesseur des nuës." ("Histoire des pays Septentrionaus," Paris, 1561, fol. 21, *b*).

Sebastian Münster, in his article on Iceland, says:—"Car la glace divissee par loppins et brisee en plusieurs parties tourne à l'entour de ceste isle l'espace de huyt moys, et se froisse de si grande impetuosité contre le rivage, qu'elle rend un son horrible et espouantable, et semble advis que ce soit le gemissement ou brayement d'une voix humaine. Cela fait que les plus idiotz croyêt que les âmes des hommes sont la tormentees de froid." ("La Cosmographie universelle," Basle, 1552, p. 1051.) Against this error Arngrimus Ionas writes, but at the same time he admits that "this ice at sometimes by shuffling together maketh monstrous soundings and cracklings, and againe at sometimes with the beating of the water sendeth forth an hoarse kind of murmuring." (Hakluyt, "Principal Navigation," 1599, vol. i. p. 563.)

If it be taken into consideration that so often in the volcanic craters and thermal springs[1] man found the types of the perpetual Abode of Fire, a suggestion would seem quite reasonable that the so-called "Cold Hells" of the Buddhists[2] and the Tauists[3] had been the outcome more or less of such dreary, icy sounds.[4] KUMAGUSU MINAKATA.

January 31.

The Antiquity of the Finger-Print Method.

IN my letter on this subject that appeared in NATURE (vol. li. p. 199, December 27, 1894), I have suggested that the ancient Japanese usage on divorce-papers of the finger-marks was probably adopted from the Chinese "Laws of Yung-Hwui"

1 *Cf.* Hardy, "Manual of Buddhism," second edition, p. 27. I remember a note in NATURE about the Indian confusion of thermal springs with the hell, but at the present moment cannot refer to the number and page.

2 See Beal, "A Catena of Buddhist Scriptures from the Chinese," 1871, p. 36.

3 See "Twan Ching-Shih, Yu-yang Tsah-tsu," Japanese edition, tom. ii. fol. 3, *b*.

4 Indeed, according to Münster, the Icelanders of old believed that their hells were in both the Hecla and the ice.

(*circa* 650-55 A.D.), issued under the reign of the third emperor of the Tang. As these "Laws," however, are nowadays lost,[1] I had but little hope to investigate further the matter. However, elsewhere a passage has lately been found, giving confirmation to my view that the Chinese usage of the finger-prints for identification was current in the time of the same dynasty of Tang.

In the Arabian "Relation des Voyages" (translated by Reinaud, Paris, 1845, pp. 42-43), the merchant Sulaiman, who made several voyages to China and India in the middle of the ninth century A.D. (the time in which the above-mentioned dynasty in China was going to decline), tells us as follows: "Les Chinois respectent la justice dans leurs transactions et dans les actes judiciaires. Si un homme prête une somme d'argent à quelqu'un, il écrit une billet à ce sujet; l'emprunteur, à son tour, écrit un billet, qu'il *marque avec deux de ses doigts réunis, le doigt du milieu et l'index*.[2] On met ensemble les deux billets. On les plie l'un avec l'autre, on écrit quelques caractères sur l'endroit qui les sépare, en suite, on les déplie et on remet au prêteur le billet par lequel l'emprunteur reconnaissait sa ditte. Si, plus tard, l'emprunteur nie sa dette, on lui dit: 'Apport le billet du prêteur.' Si l'emprunteur prétend n'avoir point de billet, qu'il nie avoir écrit un billet accompagés de sa signature et de sa *marque*, et que son billet ait péri, on dit à l'emprunteur qui nie la ditte: 'Déclare par écrit que cette ditte ne te concerne pas; mais, si, de son côté, le creancier vient à prouver ce que tu nies, tu recevras vingt coups de bâton sur le dos, et payeras une amende de vingt mille (fakkoudj) de pièces de cuivres.'"

February 3. KUMAGUSU MINAKATA.

Earthquake of January 22.

ON the morning of January 22 a shock of earthquake was felt throughout Northern Switzerland, and at many places in Southern Germany from Ulm to Strassburg. At Basel the shock was strong enough to awaken many persons, and a crackling noise was heard by almost all observers. The direction of the shock appears to have been from north-east to south-west. The seismometer at the Bernoullianum Observatory indicated 46 min. 16 sec. after midnight (mean European time). According to newspaper reports, the shock was more severely felt in the neighbourhood of Freiburg than here.

A very slight shock occurred also on January 1, 6h. 38m. 54s. in the morning. ALBERT RIGGENBACH.

Basel.

MAGNETIC INFLUENCE OF THE PLANETS.[3]

AN attempt to discover a direct magnetic influence emanating from the planets is described in "Magnetismus der Planeten," by Ernst Leyst. For this purpose the author makes use of the observations taken at St. Petersburg and Pawlowsk during the years 1873-1889, and calculates the average magnetic declination for the days at which the planets are at their greatest and least distance from the earth; also for those days at which the planets are at their greatest eastern and western elongation. The numbers so obtained show certain regularities, which are considered sufficiently marked to indicate a true effect of the planetary configurations. According to the tables given, the declination is increased by 0·2 minutes of arc when Venus is nearest, and is diminished by 0'·32 when it is furthest away. Mercury acts in the opposite direction, diminishing the declination by 0'·29 when it is nearest, and increasing it by 0'·20 when it is furthest. The backbone of an inquiry like this ought necessarily to be found in a careful discussion as to how far an accidental combination of figures could account for the apparent effect. The magnetic declination is subject to so many changes which to us seem accidental, that if we take a certain number out of the whole series of daily averages, they must necessarily show deviations. The whole question then turns on the discussion whether the effects found by Mr. Leyst are sufficiently large and regular to be considered as real. This part of the subject is, unfortunately, treated in an insufficient manner, and, for this reason, the author has not in my opinion made out his case.

We may, however, from Mr. Leyst's numbers, draw the conclusion that even if the effect is a real one, it cannot, as the author considers, be due to an ordinary magnetic force depending in its magnitude on the distance of the planets. Within a few days of conjunction that distance does not vary appreciably, and Mr. Leyst should therefore get more trustworthy results by taking account not only of the days of conjunction, but of a group of days immediately surrounding the configurations. The necessary data are supplied by Mr. Leyst, and it appears that taking Mercury, for instance, the diminution of declination is reduced from 0'·29 to 0'·20 when the preceding and following days are taken into account; while when five days altogether are considered, there is a further reduction of the effect to 0'·15, and when a month is taken, in the middle of which the inferior conjunction lies, there is only a deviation of 0'·08 from the average declination. The other planets show the same fact. The average effect of all the planets amounts to 0'·33, which is reduced to 0'·26, 0'·17, and 0'·08 when the three days, five days, and the month nearest to conjunction are taken into calculation. If the effect is a real one, it must be due to some other cause than an ordinary magnetic action, for it practically vanishes two days before or after conjunctions, when there is very little change in the relative positions of sun, planet, and earth. Mr. Leyst himself draws attention to the rapid diminution of the supposed planetary influence within a few days of conjunction, but considers it to be an argument in favour of his view.

The amplitude of the diurnal variation is discussed; and here, of course, also a planetary effect is found, which, curiously enough, is greater for Neptune and Uranus than for Venus and Mercury. The "probable error" of the result is considered, and is calculated to exceed the supposed effect in the case of Mercury, Mars and Saturn, and to amount to about two-thirds of the effect in the case of Venus, Uranus and Neptune. The author draws the conclusion that the planetary influence is "certain" for the three latter planets and Jupiter.

It is hardly necessary to follow the author further in the complicated results he deduces, by separating what he calls the "primary" and "secondary" extremes, the primary and secondary amplitudes, and the irregular and periodic part of the diurnal variation; the primary and secondary quantities being affected in opposite directions by the mischievous Mercury. In fairness to the author, it must be stated that some of the effects of that planet are found to be in the same direction when the whole period of fifty synodic revolutions is divided into two, which are separately considered. Nevertheless, a careful perusal of Mr. Leyst's work leads to the conclusion that he has not proved his case. Among the many improbabilities of magnetic influences which are hanging over us, that of a planetary effect may for the present be set aside.

ARTHUR SCHUSTER.

[1] K. Konakamura in "Nipon Rikishi Hyôrin," Tôkyô, 1893, vol. vi. p. 24.

[2] In a translation by E. Renaudot (Paris, 1718, p. 33), and thence in Pinkerton's "Collection," London, 1811, vol. vii. p. 192, this sentence is rendered thus: "When any person commences a suit against another, he sets down his claim in writing, and the defendant writes down his defence, which he signs, and *holds between his fingers*." Here no mention is made of finger-marks; instead of it a meaningless clause is given. Reinaud says Renaudot committed errors in his version ("Introduction," p. ii.), and the present case is apparently one.

THE STORY OF HELIUM.[1]

PROLOGUE.

DURING the last decade, as most of you know, our literature has been enriched by a recrudescence of the short story, generally dealing with very modern human affairs of various kinds from many different standpoints.

But these modern stories, and others that might be referred to, are not the only ones now available. During the last sixty years Egypt, Babylonia, and other countries which might be named, now here and now there, have supplied us with other stories—most precious indications which enable us to study, into a far-reaching past, the beginnings of man's history. These stories, as you also know, were not very easily deciphered—they were all of them hidden away in strangest script; but the hieroglyphics and cuneiform characters, which at first seemed to have absolutely no meaning whatever, have bit by bit been unravelled by the genius of linguistic explorers, until at length we may say that the students of Archæology are in possession of more or less complete histories of the most ancient peoples of the world.

All these histories have not yet been completely written; but my point is that they have been begun, and that even for the beginning of them the greatest skill has been required to transmute the strange hieroglyphics which were first employed by ancient peoples into modern equivalents, so that we can understand what they wished to convey. Here we are in presence of man's earliest attempt at any language; but the story which I, your President, have to tell you to-night, has a very different origin to this, for the reason that, although it is a story, and written, it is true, in hieroglyphics, the hieroglyphics are of nature's invention, and not man's.

The story or fairy tale of science, which has placed us in possession of the most precious truths regarding every star which shines in space, is a story written in nature's hieroglyphics in every ray of light which reaches this planet of ours from the tiniest star.

Now, of course in the hour at my disposal to-night it is impossible for me both to tell you a story, and spend much time upon the alphabet in which the story is written, but there are just one or two words about the alphabet that may be useful. One key to these hieroglyphics, this light story, which is hidden in every ray of light, is supplied to us by the rainbow, which teaches us that the white light with which nature bountifully supplies us in sunlight, is composed of rays of different kinds or of different colours. Many of you know that there is an almost perfect analogy between these coloured lights and sounds of different pitches.

The blue of the rainbow may be likened to the higher notes of the key-board of a piano, and the red of the rainbow, on the other hand, may be likened to the longer sound waves, which produce the lower notes; and as we are able in the language of music to define each particular note, such as B flat and G sharp, and so on, so in these celestial hieroglyphics we are enabled to do exactly the same thing with perfect definiteness, by considering the wave-length of the particular colour with which we have to deal, so that having these wave-lengths we may determine the quality of every kind of light which reaches the human eye, whether from a terrestrial light source, the sun or any other celestial body, including the shooting stars which some of us are hoping to see to-night.

Well, the result of the study of this hieroglyphic language has been that we can in that way determine the chemical source of every light of different colour which can be thus examined in any celestial body, provided always we can obtain the same light-note from some terrestrial substance when we experiment upon them at temperatures high enough to set them glowing in our laboratories. We can determine therefore, by such means, whether in different parts of space we have the same chemical substance, or whether in different stars we are dealing with substances perfectly and completely distinct.

Imagine these hieroglyphics, then, more or less translated, on the principle I have indicated to you, by the labours of Kepler, Newton, Fraunhofer, and other later workers; so that in the case of anything shining anywhere, we can eventually find out something about its chemical and its physical constitution.

Another part of the prologue, before I begin my first chapter, brings us to another line of study, that is to say, the telescopic and visual observations of heavenly bodies.

I take you back to the year 1706, when there was a total eclipse of the sun, visible in Switzerland, and there was one Stannyan, who gave an account of what he saw at Berne. After describing the phenomena of the eclipse he wrote, referring to the sun: "His getting out of his eclipse was preceded by a blood-red streak of light." Of course, in the prephotographic days no autobiographical record of that particular eclipse was obtainable, but we possess photographic records of other similar later eclipses, which may be taken as representing what Stannyan saw, for, in all, the blood-red streak referred to by him has been seen.

The phenomena photographed in all eclipses now-a-days indicate to us Stannyan's observation, for in all, certainly the sun, in getting out of his eclipse, is preceded by a blood-red streak of light, which we now know to represent one of the solar envelopes to which I gave the name of chromosphere in 1868.

Here then ends the prologue, and I begin the first chapter of my story.

CHAPTER I.

In the year 1868, the new alphabet to which I have referred was first utilised in endeavouring to unravel the message which was conveyed to us by a most interesting eclipse observed in India. The "blood-red streak" was now subjected to minute analysis, because practically the spectroscope was now first utilised. The diagrams will indicate the kind of record with which we have to deal in studying these celestial hieroglyphics. We are in one part dealing with the long waves of light, the red; we are in the other dealing with the shorter waves of light, the blue. The work done in that eclipse is indicated by the bright lines—the hieroglyphics—which, when translated as they have been, describe for us the chemical nature of the particular stuff in the sun, which made him put on a blood-red appearance "on his getting out of his eclipse." Taking the notes in the light scale which are lettered in the ordinary spectrum of light, chiefly sunlight, in order that they may be easily recognised and remembered, we learn the particular qualities of the light emitted by the blood-red streak.

We have one quality represented by the line D, another at C, and another at F. Hence the observers in 1868 could tell us very much more about the particular chemical substances which were present in that blood-red streak than Stannyan could, because spectroscopy had not been invented in his day. According to the diagram (Fig. 1), one of the lines is in the position of D. One observer said it was "at D, or near D," and almost the whole of my story depends upon that distinction.

Soon after this eclipse was observed in India, a method, long before suggested, of studying the blood-red streak surrounding the sun without waiting for an eclipse was brought into operation.

By this method it was quite easy to make observations, whenever the sun was shining, perfectly free from any of the difficulties attending the hurry and the worry and the excitement of an eclipse, which lasts only a few seconds.

Further, as the method consists of throwing an image

[1] Presidential Address, Vesey Club, Sutton Coldfield, November 12, 1895, by Prof. J. Norman Lockyer, C.B., F.R.S.

of the sun, formed by a telescope, on to the slit of a spectroscope, so that the spectrum of the sun's edge and of the sun's surroundings can be seen at the same time, exact coincidence or want of coincidence between the bright and dark lines can be at once determined. I may

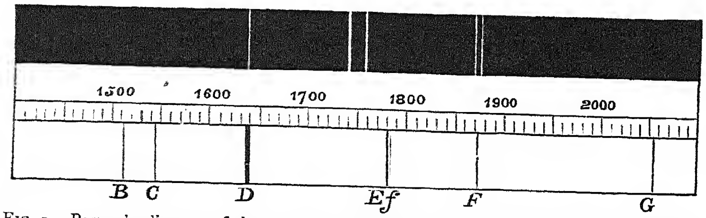

FIG. 1.—Pogson's diagram of the spectra of the sun's surroundings in the Eclipse of 1868. The bright lines seen are shown in the upper part of the diagram; the chief lines in the solar spectrum, red to the left, blue to the right, are shown in the lower part.

remind you that during an eclipse this is not possible, as the ordinary spectrum of the sun, with its tell-tale dark lines, is invisible because the sun, as we ordinarily see it, is hidden by the moon.

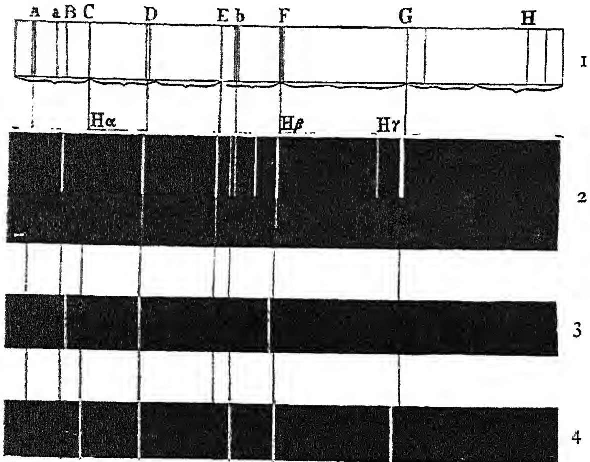

FIG. 2.—Summation of the observations of the spectrum of the sun's surroundings in the Eclipse of 1868. (1) Solar spectrum showing the position of the chief lines (2) Rayet's observations of bright lines. (3) Herschel's observations of bright lines. (4) Tennant's observations.

Working, then, under such very favourable conditions, it was seen that there was certainly a red line given by this lower part of the solar atmosphere coincident with the very important line in the solar spectrum which we call C.

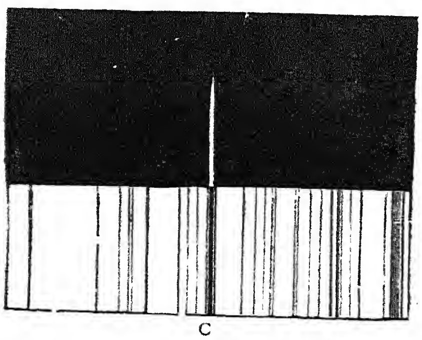

FIG. 3.—The exact coincidence of the red line with the dark line C determined by the new method.

Another part of the spectrum in the blue-green was examined, and there again it was seen that the parts outside the sun gave us a bright line exactly in the position of the obvious dark line in the solar spectrum which is called F; so that with regard to those two most important lines, there was no doubt whatever that we were dealing with the substance which produces these dark lines in the solar spectrum.

Fig. 5 is a diagram of the yellow, or rather the orange, part of the solar spectrum, showing two very important lines, which are called the lines D, due to the metal sodium, the investigation of which was just as important in solving these celestial hieroglyphics as the Rosetta stone was important in settling the question of the Egyptian ones.

Pogson, in referring to the eclipse of 1868, said that the yellow line was "at D, or near D." You will see from this diagram that the new method indicated that "near D" was the true definition. The line in this position in the spectrum, unlike the other two lines which I have indicated, has no connection at all with any of the dark lines in the ordinary solar spectrum. We were therefore perfectly justified in attaching considerable importance to this divergence in the behaviour of this line, taking the normal behaviour to be represented by the two strong lines in the red and the blue-green. The new line was called D^3 to distinguish it from the sodium lines D^1 and D^2.

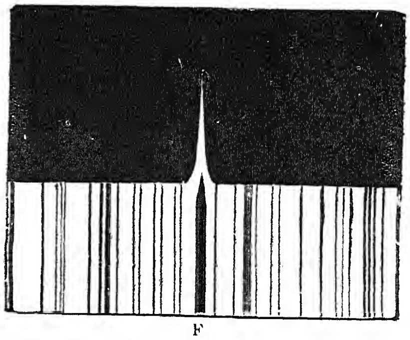

FIG. 4.—The exact coincidence of the blue-green line with the dark line F.

A considerable amount of work was done with regard to the yellow line. It was found that there was no substance in our laboratories which could produce it for us, whereas in the case of the line D we simply had to burn some sodium, or even common salt, in a flame to produce it, and the other lines in the red and the blue-green were easily made manifest by just enclosing hydrogen in

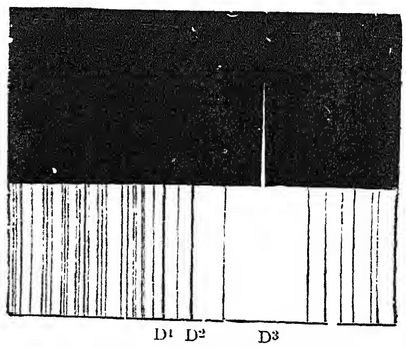

FIG. 5.—The want of coincidence of the range line, D^3, with the dark lines D^1 and D^2.

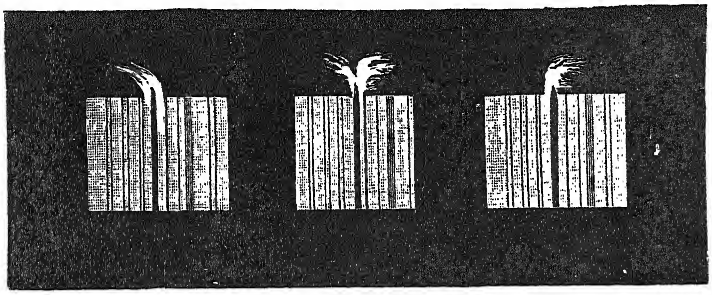
a vacuum tube, and passing an electric current through it, or observing the spectrum of a spark in a stream of coal-gas.

Now at the first blush it looked very much as if this

line was really due to the same element which produced the others at C and F, and it was imagined that the reason we did not see it in our laboratories was because it was a line which required a very considerable thickness of hydrogen to render it visible. That was the first idea, and Dr. Frankland and myself found that there was very considerable justification for this view, because a simple calculation showed that the thickness of the solar atmosphere, which was producing that yellow line under the conditions which enabled us to see it in our instruments by looking along the edge of the sun, was something like 200,000 miles.



A B C

FIG. 6.—Changes of wave-length of the F hydrogen line when a solar cyclone is observed. A, the change towards the red indicates the retreating side of cyclone. C, the change towards the blue indicates the advancing side. B, the whole cyclone is included in the width of the slit, and both changes of wave-length are visible.

Hence, in order to get a final decision on this point, there was nothing for it but to tackle the question from a perfectly different point of view, and the different point of view was this. The work had not gone on very long before one found minute alterations in the positions of these lines in the spectrum; the blue line, for instance, might sometimes be slightly on one side, and sometimes on the other of its normal position. Further work showed that in these so-called "changes of wave-length" we had a precious means of determining the rate of movement of the gases and vapours in the solar atmosphere.

Fig. 6 indicates how these changes of wave-length are shown in the spectroscope. The lines are contorted in both directions, and sometimes to a very considerable extent, indicating wind-movements on the sun, reaching, and sometimes exceeding, 100 miles *a second!*

Well, then, you see we had here a means of determining whether the yellow line was produced by the same gases which gave the red and blue lines, because if so, when we got any alteration in the position of the red and blue lines, which always worked together, we should get an equivalent alteration in the position of the yellow one.

I found that the yellow line behaved quite differently from either the red or the blue line; so then we knew that we were not dealing with hydrogen; hence we had to do with an element which we could not get in our laboratories, and therefore I took upon myself the responsibility of coining the word helium, in the first instance for laboratory use.

This kind of work went on for a considerable time, and what one found was, that very often in solar disturbances we certainly were dealing with some of the lines of substances with which we are familiar on this earth; but at the same time it was very remarkable that when the records came to be examined, as they ultimately were with infinite care and skill, it was found that not only did we get this line in the yellow indicating an unknown element associated with substances very well known, like magnesium, but that there were many other unknown lines as well. Within a few months of my first observations, several new lines about which nothing was known were thus observed. The place of this orange line I determined on October 20, 1868. Among many other lines behaving like it, two at wave-lengths 4923 and 5017 were discovered in June 1869, and afterwards another at 6677, while Prof. Young noted another in September 1869, at 4471. He wrote:

"I desire to call special attention to 2581·5 [Kirchhoff's scale], the only one of my list, by the way, which is not given on Mr. Lockyer's. This line, which was conspicuous at the Eclipse of 1869, seems to be *always present* in the spectrum of the chromosphere. . . . It has no corresponding dark line in the ordinary solar spectrum, and not improbably may be due to the same substance that produces D^3."

This same line was noted also by Lorenzoni, and named *f*.

Then with regard to solar disturbances. Let me refer in detail to a diagram indicating some results arrived at by the Italian observers. We are dealing with the spectroscopic record of two slight disturbances in a particular part of the sun's atmosphere. The spectroscope told us that in that region there was a quantity of the vapour of magnesium which was collected in that place. Then we find that another substance, about which we again know nothing whatever, is also visible in that region, and then we get the further fact that in those particular disturbances we get four other spectral lines indicated as being disturbed, and of those four lines we only know about one.

In that way it very soon became perfectly clear to those who were working at the sun, that in all these disturbances, or at all events in most of them, we were dealing to a large extent with lines not seen in our laboratories when dealing with terrestrial substances; this work went on till ultimately, thanks to the labours of Prof. Young in America, we had a considerable list of lines coming from known and unknown substances which had been ob-

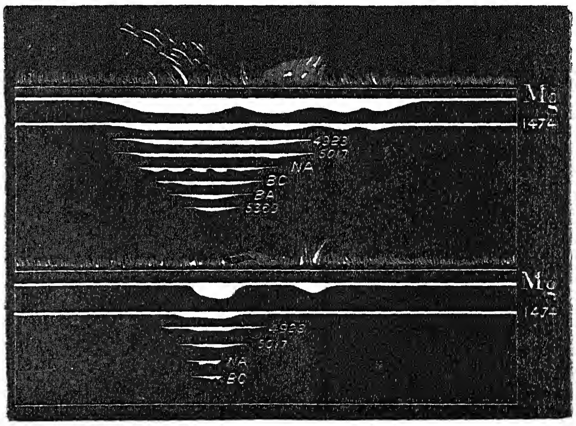


FIG. 7.—Tacchini's observations of two slight solar disturbances showing the height to which the layers of the different gases extend. Magnesium vapour is highest of all, and is furthest extended; next comes a gas of still unknown origin, indicated by a line at 1474 of Kirchhoff's scale, and so on.

served under these conditions in the solar chromosphere and Prof. Young was enabled to indicate the relative number of times these lines were visible. For instance, the lines which are most frequently seen under these conditions he indicated as represented by the number 100, and of course the line which was least frequently

seen would be represented by 1; and therefore from these so-called "frequencies" we got a good idea of the number of times we might expect to see any of these disturbance-lines, when anything was going on in the sun.

It was this kind of work which made Tennyson write those very beautiful lines:

> "Science reaches forth her arms
> To feel from world to world"

And then he added:

> "and charms
> Her secret from the latest moon."

I mention this because Tennyson, whose mind was saturated with astronomy, had already grasped the fact that what had already been done was a small matter compared with what the spectroscope could do; and now the prophecy is already fulfilled, for by means of the spectroscopic examination of the light from the stars we can tell that some of them are double stars, that is to say, in poetic language, stars with attendant moons. Although we can thus charm the secret from each moon by means of the spectroscope, to see the moon it would require a telescope not 80 feet long, but with an object-glass 80 feet in diameter, because the closer two stars are together the greater must be the diameter of the object-glass, independently of its focal-length and magnifying power.

(*To be continued.*)

THE CAMBRIDGE NATURAL HISTORY.[1]

THE second volume of this series (vol. v.), to make its appearance is devoted, with the exception of articles on the Prototracheata (pp. 3–26) and Myriapoda (pp. 28–80), to the Insecta, which will occupy also the whole of vol. vi.

Mr. Sedgwick gives a concise account of *Peripatus*, which, being derived mainly from his own well-known papers, does not call for extended notice; the descriptions of anatomy and development are written in a somewhat technical style, but are not over-elaborated. If it were thought necessary to reprint an easily-accessible list of the known and doubtful species, it should certainly have been revised. No records are noted since 1888; *P. juliformis* is given as a doubtful species, whereas at most it is incompletely characterised, and *P. trinidadensis* actually figures as "n. sp." A map, serving as frontispiece, shows the distribution; but the records from Peru and Chili seem scarcely to justify the inclusion of so much of the arid western littoral of South America.

Myriapoda are not a fascinating subject, but Mr. Sinclair's article, though slight and somewhat wanting in style, gives many particulars of interest about them. The author is clearly a morphologist rather than a systematist, and has made a serious mistake in employing a classification so antiquated as that of Koch, who knew little of extra-European forms, and whose characters, if rightly transcribed, are far from accurate. Mr. Sinclair prefers to disregard the work of systematists who have dealt with separate families only; but a system by Bollman of the whole class (or classes, according to some specialists), published in 1893 in *Bulletin* xlvi. of the United States National Museum, has been overlooked. In the section on development no mention is made of the reversal of the embryo referred to on p. 216 of the work. This was a matter for the editors, as is indeed the whole subject of embryology. The details of early embryonic development are so similar, that there is a risk of useless repetition and of insufficient stress on points of difference unless some co-operation is instituted among contributors. The figures of species are copied from Koch's "Die Myriapoden," and, though the fact is not stated, that of *Cermatia variegata* was drawn from an example which had lost six pairs of legs!

In no branch of zoology has the influence of modern morphological and biological research been of slower growth than in entomology; the subject is so complex, so dominated by taxonomy and an unwieldy literature, that few entomologists have the energy to leave their immediate field of study in order to gain any general knowledge of the natural history of insects. For this the responsibility rests largely with the authors of the many text-books on entomology, who for the most part have been content to follow an antiquated method, basing their work on a substructure of classification, and ignoring families of the highest interest from all points of view except those of the collector and systematist, in order to fill their pages with a tedious procession of names and useless details.

For many years there has appeared no such valuable or original work on insects as this of Dr. Sharp promises to be, when completed. The author has rid himself of the chains of the systematist, and has endeavoured, in

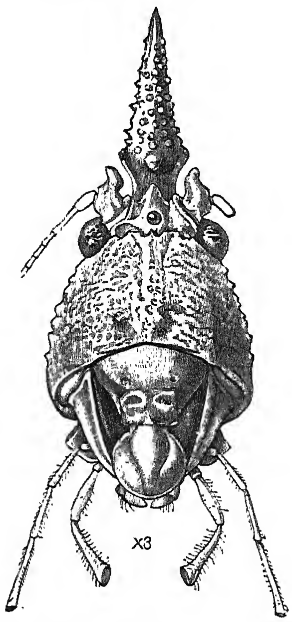

FIG. 1.—Front of head of *Copiophora cornuta*, female. Demerara.

the most thorough and catholic spirit, to give a just view of the many points of interest, whether in structure, development or habits, which attach to this, the richest class of the animal kingdom.

In such a task, one does not look for novelty in facts or theories, though there is ample evidence of independent thought and investigation. It is in the selection and treatment of subjects that Dr. Sharp's originality is shown, and in these the book stands absolutely alone. It is a real and new pleasure to read a work of so broad a scope, in which so much is entirely unknown except to the closest students of recent literature, in which families such as *Thysanura*, *Hemimeridæ*, *Embiidæ*, or *Termitidæ* are adequately treated, and where due regard is paid to the writings of students such as Brauer, Grassi, or Cholodkowsky.

Though familiar insects are by no means neglected, and much that is interesting and new is said even about the earwig and cockroach, the number of strange and rare forms discussed is quite extraordinary. No one knows the literature of the subject better than the author,

[1] "Peripatus, Myriapods, Insects." By A. Sedgwick, F. G. Sinclair, and D. Sharp. Pp. xii + 584. (London: Macmillan and Co., 1895.)

who has ransacked it in a way that it would have been hopeless to attempt without the preparation gained by many years' work in connection with the *Zoological Recor..*

His style is graphic and pleasant and, even when he is most erudite, he is never dry. Nevertheless, the book will appeal with more force to the expert than to the beginner. The definitions are often vague, notably in the chapter on external structure. This arises less from any fault in the author's method than from a reluctance to give definitions which do not embrace all known variations from a common type. To those who can read between the lines this vagueness presents no difficulty, but we suspect that the general reader will fail sometimes to get a clear conception of the subject. The insufficiency of our present knowledge is a favourite and over-emphasised text of the author, who does not conceal his dislike both to generalisation and the acceptance of morphological axioms. Though he rarely expresses his opinion, even on matters where it would be most welcome, in a remarkable footnote (p. 91) he suggests that the wings, equally with the legs, are "appendages." He might be thought to protest against the limitation of the term to a single homologous series, but his remarks on the possibly duplex origin of the thoracic somites tend to negative this view. That there can be any homology between the legs and wings is a dangerous suggestion to hint at in a work not intended solely for critical readers.

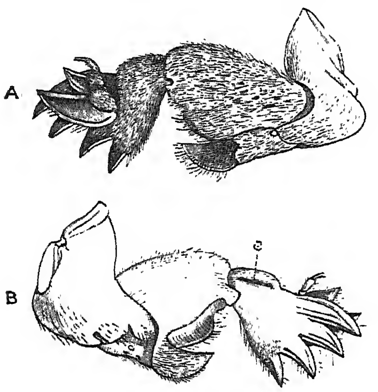

FIG. 2.—Front leg of the mole-cricket. A, outer; B, inner aspect; *c*, ear-slit.

Where so much is novel, it is impossible, within the limits of a notice, to touch on even a small part of the subjects dealt with in the work: the development of the antennæ in *Forficulidæ*, the mimetism of *Mantidæ*, the economy of the Termites, the insects of the coal-measures, the formation of galls, these are examples of many topics discussed in the light of the most modern researches.

The chapters in this volume treat of external and internal structure, development and classification, and, out of the nine orders proposed, of the Aptera, Orthoptera, Neuroptera, and part of the Hymenoptera (Sessiliventres and Parasitica). The remaining orders will occupy vol. vi. of the series.

Of the chapter on development the most suggestive part is that on metamorphosis. Dr. Sharp urges that this phenomenon is yet very imperfectly understood, owing to our ignorance of the underlying physiological changes, and that nothing can be postulated about it without taking into account the processes of embryonic development and of such deviations from the normal course as hypermetamorphosis and the extraordinary changes undergone, for example, by parasitic Hymenoptera. The view that ecdysis is correlated solely with growth, is rejected in favour of Eisig's suggestion that it is a means of excretion.

It follows that metamorphosis is here regarded as of subordinate importance in classification, and though the usual definitions of its extent are rejected, no alternative scheme on a physiological basis is proposed. It is quite unlikely that entomologists will adopt the author's extreme views, but these pages, the result of much thought, will come as a surprise to those who have a comfortable belief in the fixity of the accepted degrees of metamorphosis, degrees which, as Camerano has said, are purely scholastic.

Sexual phenomena, such as heterogamy or dimorphism, are treated only in connection with the forms which exhibit them, but at the end of the chapter on internal anatomy there is a short paragraph on parthenogenesis and pædogenesis. It is nowhere indicated that the latter is an extreme form of the more general phenomenon of neotenia, alluded to under the *Termitidæ*.

Little importance is attached to the threadbare question of the division of the class into orders, and in the arrangement here adopted for convenience and without discussion the undue complexity of some recent systems has been, we think, wisely abandoned. Nine orders are indicated: the Neuroptera include the Pseudoneuroptera and Mallophaga, and two small orders only are kept separate, the Aptera (for Thysanura and Collembola) and the Thysanoptera. The extension of Neuroptera to its original limits is in accordance with the views of some recent writers, for example, Brongniart. But with respect to the Aptera, which is coterminous with Brauer's Apterygogenea, attention has not been paid to Grassi's recent admission that the Thysanura, in common with all existing insects, may be derived from winged forms. They present many primitive features, but these are compatible with their place as the lowest Orthoptera, the homology of the abdominal styles with the legs having been lately seriously questioned. Though the inclusion of the Mallophaga in Neuroptera is not new, it is a pity that no reasons are given for an association which, however sound, is hard to appreciate.

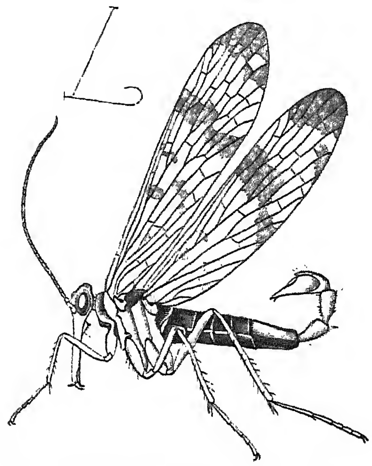

FIG. 3.—*Panorpa communis*, male. Cambridge.

Of the variety of subjects in the chapters on the separate orders, we have already spoken. The Hymenoptera, being more homogeneous, are treated in somewhat less detail than the others. A figure of some of the manifold forms assumed by the petiolate abdomen would have been welcome, and among structural points there is no reference to the strange nipper-like front tarsi of *Gonatopus*.

In the chapter on *Acridiidæ*, no mention is made of the fact, important in connection with the migratory

instinct, that the permanent homes of locusts are situate in sterile land, and it would have been well to remove the common misconception that the winged swarms are the chief enemies of the agriculturist; it is against the march of the larvæ, here graphically described in the words of an eye-witness, that he has specially to guard.

There are a few inaccuracies and examples of loose expression, of which one or two may be mentioned. The author states that "the anterior portion of the intestine is the smaller, and is frequently spoken of as the colon," whereas elsewhere he alludes specifically to the ileum, which is often distinguishable. Certain glands in connection with the uterus are twice called the "serific," once the "sebific" glands; which term is meant is not clear. He adapts the term "instar" from Fischer to denote the form of an insect during a "stadium," that is, between consecutive ecdyses, but elsewhere he speaks not quite consistently of different instars as connoting a change of form, as well as of stadium. The reference to Chatin's views on the morphology of the mandible, would lead one to suppose that Chatin had found articulated mandibles in *Embia*. This is not the case; Chatin merely compared the parts of the mandibulate mass with the joints of the maxilla, and did so for many mandibulate insects and not *Embia* alone.

The standard which this work sets, if followed throughout the series, will leave the "Cambridge Natural History" without a rival. The book is one to be read not merely by entomologists, whose work it will certainly influence, but by general zoologists. The attention paid to insects in zoological teaching is quite disproportionate to the place they occupy in the animal kingdom; but hitherto zoologists have had no guide to what is best worth knowing on the subject.

The volume presents all the beauty and finish which mark its precursor in the series. The illustrations, original or from original papers, are admirable; some of these we are permitted to reproduce. Fig. 120 has been drawn in an inverted position and is not quite clear, and a much better figure of *Cylindrodes* than the one given, accompanies Gray's original account of the genus.

W. F. H. BLANDFORD.

MEDICAL APPLICATIONS OF RÖNTGEN'S DISCOVERY.

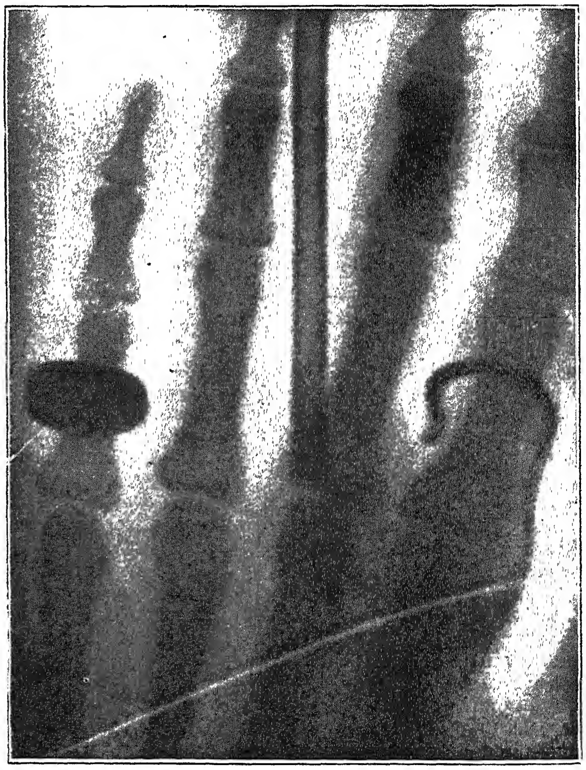
THE new photography has received the official recognition which is usually given to scientific discovery in Germany. Prof. Röntgen has been honoured by the Emperor, and the Prussian Minister of War has caused experiments to be made in order to discover whether the method can be applied successfully to army surgery. A series of photographs of bone injuries have shown so clearly the nature of the wounds and the position of imbedded projectiles that it has been determined to carry on the experiments on a larger scale.

Medical science seems likely to benefit much by the application of Prof. Röntgen's discovery. The *British Medical Journal* thinks, as an aid to diagnosis of obscure fractures and internal lesions generally, the new photography will be of great value. From our contemporary we note that already a beginning has been made in this direction, and Prof. Mosetig, of Vienna, has taken photographs which showed with the greatest clearness and precision the injuries caused by a revolver-shot in the left hand of a man, and the position of the small projectile. In another case the same observer detected the position and nature of a malformation in the left foot of a girl with entire success. Prof. Lannelongue, of Paris, has also been successful in photographing some of his cases in his ward at the Trousseau Hospital, and, assisted by MM. Oudin and Barthélemy, has submitted to the Academy of Sciences several negatives of human limbs. One of them represented a diseased thigh-bone. The destroyed central portions had been penetrated by the light, forming white blotches on the plate. Another photograph was that of a tuberculous affection of the bone in a child's hand. The disease had been diagnosed, but photography brought complete confirmation to the diagnosis.

The Berlin correspondent of the *Lancet*, referring to the practical use being made of the discovery, says in one case a finger which had sustained a compound fracture, and from which a sequestrum had been removed, was photographed by the new process, and the regeneration of the bone was thereby made visible. In another case the position of a piece of glass embedded in the tissues was ascertained by the same method. Similar reports come from other Universities, as, for instance, from Berne, where Prof. Kocher has photographed a needle in a woman's hand; it had made its way under the skin some time ago, and had not been found by any other means.

A CONTRIBUTION TO THE NEW PHOTOGRAPHY.

NUMEROUS pictures are now being taken by means of the new method. The accompanying illustration, which we owe to the kindness of Prof. Nernst, and the original of which was made by him in the Physical-chemical Laboratory at Göttingen, represents a human hand as



photographed by means of the Röntgen rays. It will be seen that the flesh is very nearly transparent for these rays, while the bones, the gold ring, the piece of wire, and the glass tube are practically opaque. The ring and wire, which were naturally in contact with the flesh of the fingers, appear in the illustration as if suspended in the air

WILLIAM J. S. LOCKYER.

NOTES.

M. MOISSAN has been elected President of the Chemical Society of Paris.

M. ROUCHÉ has been elected Académicien libre of the Paris Academy of Sciences, in the place of the late Baron Larrey.

MR. ALEXANDER AGASSIZ, having finished his surveys of the coral-formations in the West Indies, has made arrangements to explore the Great Barrier Reef of Australia, and proposes to leave America for Brisbane, for that purpose, with a staff of assistants, early in March next.

THE valuable conchological collection formed by the late Miss Jane Saul, was bequeathed by her to the University of Cambridge, and has lately been received by the Museum of Zoology. The collection is principally remarkable for the magnificent series of the genus *Cypræa*, in which are included several species of great rarity.

OUR U.S. correspondent writes: "The announcement was made last August, that the New York Botanical Garden had received 250,000 dols. of the 500,000 dols. necessary to start it properly. Progress is now reported in raising the remaining 250,000 dols., Mrs. Esther Herrman, of New York, having contributed 5000 dols. Miss Helen Gould, sister of Countess Castellane, has given Vassar College 8000 dols. to endow a scholarship. Mr. Abram Abraham, of Brooklyn, recently empowered the President of Cornell University to purchase the Oriental library of Ernest Rénan as a gift to the University, but news has just been received that the widow of Rénan's publisher has given the library to the Bibliothèque Nationale. It is announced that the electrical exhibition to be held at New York, May 4–June 1, will be the most elaborate ever held in America. Barnard College, one of the new colleges for women, has recently raised a fund sufficient to secure it a permanent home, and will erect a $500,000 building next spring, on the corner of 119th Street and Boulevard New York, near the new site of Columbia College, with which Barnard is affiliated."

THE *Pharmaceutical Journal* states that a Committee has been appointed by Prof. Alfred Dohme, Chairman of the Scientific Section of the American Pharmaceutical Association, to direct investigations in the pharmacognosy, chemistry, biology, histology, &c., of drugs. The Committee consists of Prof. A. B. Prescott, of Ann Arbor, President; Prof. Edward Kremers, University of Wisconsin; Prof. L. E. Sayre, University of Kansas; Prof. John U. Lloyd, President of the Cincinnati College of Pharmacy; Prof. Samuel P. Sadtler, Philadelphia College of Pharmacy; and Dr. Charles Rice, Chairman of the National Committee on the Revision of the United States Pharmacopœia.

A NEW immense domain, full of interest for the naturalist and the anthropologist, is now opened for scientific exploration by the great Trans-Siberian railway. Last month the rails were laid on this line as far as Krasnoyarsk, on the Yenisei, and next summer the explorer will be able to reach by rail the banks of the Yenisei, at a distance of 3057 miles from St. Petersburg. With the cheapness of railway communication in Russia—a second-class return ticket from St. Petersburg to Omsk (2673 miles) costs about eight pounds—and the facilities opened for navigation by the great rivers running northwards, Siberia is sure to become soon a favourite field for scientific explorers.

SOME information concerning the Russian geological expedition which visited Novaya Zemlya last summer, was given by the geologist, M. Tchernyscheff, at the meeting of the Russian Geographical Society on January 2, and at the Mineralogical Society on January 8. The Matochkin Shar, which divides the great island into two parts, was visited, but could not be explored over its full length, on account of the ice stocked in its eastern portion. The expedition crossed Novaya Zemlya in the latitude of Karmakuly, and returned laden with rich geological collections. Undoubted proofs have been found of the secular raising of, at least, the southern island of Novaya Zemlya. This island is built up of Palæozoic rocks (Devonian and the "Artinsk" strata), which are covered with Post-Tertiary deposits. It bears traces of a wide glaciation which was followed by submergence, as shown by several beach-terraces, wide deltas, and lakes. At the present time it is in a period of upheaval.

UPON application of the Middlesex County Council the Home Secretary has made the following order, dated January 29: 1. "The Wild Birds Protection Act, 1880," shall apply within the county of Middlesex to the wryneck (cuckoo's mate or snake bird), swallow, martin (2), swift, bearded tit (reedling or reed pheasant), shrikes, kestrel, merlin, hobby, buzzard, honey buzzard, osprey, and magpie, as if those species were included in the schedule to the said Act. 2. The taking or destroying of the eggs of the following wild birds is prohibited within the county of Middlesex, viz. nightingale, goldfinch, lark, nightjar, woodpeckers, kingfisher, cuckoo, owls, kestrel, buzzard, honey buzzard, merlin, hobby, osprey, wryneck (cuckoo's mate or snake bird), swallow, martins (2), swift, bearded tit (reedling or reed pheasant), shrikes, magpie, wheatear, stonechat, whinchat, red start, fly catchers, sedge warbler, reed warbler, blackcap, garden warbler, wood warbler, willow warbler, chiff-chaff, white throat, lesser white throat, long-tailed tit, nuthatch, wren, gold-crested wren, wagtails (4), hawfinch, linnet, buntings (3), starling, landrail or corncrake, and coot.

PROF. IRA REMSEN describes in *Science* an interesting case of the accumulation of marsh gas under ice. It appears that a number of skaters were on a large artificial lake upon which remarkably clear ice had formed. In various places white spots were noticed in the ice, suggesting air-bubbles. Some one bored a hole through one of these white places, and applied a flame to the gas, which took fire. This led to further experiments, and it was found that, by boring a small hole, a long thin jet of flame could be obtained, and this continued for some time. The gas was marsh gas, formed by the decomposition of the vegetable matter at the bottom of the lake. Prof. Remsen remarks that this method of demonstrating the formation of marsh gas in nature is, from the æsthetic point of view, a great improvement on the usual method described in text-books, which consists in stirring a pool of stagnant water with a stick, and collecting the gas that rises to the surface. He suggests skating ponds illuminated by natural gas as among the possibilities of the future.

THE occurrence of a second period of very high barometric pressure in these islands during the month of January is noteworthy. The *Daily Weather Report* of the 28th showed that an anticyclonic area was spreading over the south-west of England, and at 11 p.m. on the 29th the high reading of 30·96 was recorded at Roche's Point, in the south of Ireland, and readings reached or exceeded 30·9 inches all over the south-western portions of England and Ireland. In London a maximum of 30·93 inches was reached, which corresponded with the reading there on the 9th of the same month. Such high readings have not occurred there since January 18, 1882 (when the barometer rose to 30·975 inches), and have been extremely rare during the last century. A peculiar feature of this high barometric pressure has been the

mildness and dampness of the weather; although some rather low temperatures were recorded by thermometers exposed to the sky, the maximum readings have reached 45° to 50° during the day-time. It will be remembered that this period last year was one of almost continuous, severe frost, which lasted until February 20.

IT was pointed out, in a recent article in the *Engineer*, that the introduction of warlike stores, and their final inspection and sentence, is entirely in the hands of naval and military men. The matter is again referred to in the current number of our contemporary as follows: "The actual manufacture only is under a civilian Director-General, but, with the exception of the Small Arms Factory at Enfield, the superintendents and their assistants were still all naval or military officers, and have remained so since the reorganisation carried out by an officer of the artillery in 1887. A colonel of artillery and two captains of the same arm manage the Royal Laboratory; a captain of the Navy and a lieutenant manage the Royal Gun Factory; a colonel of engineers is responsible for the Royal Carriage Department; a colonel of artillery, a captain, and a lieutenant, are responsible for the Royal Gunpowder Factory; and a colonel of artillery manages the factory in Birmingham. The Director-General has two military assistants, one a commander in the Navy, and one a captain in the artillery, and it would thus appear that he is assisted by no less than twelve officers of the Army and Navy, and therefore if the work turned out to be bad and dear—as it is alleged to be by the writers in the *Times*—that circumstance seems to us to be a strong argument in favour of the proposition that military and naval men are unfit, from want of technical knowledge and special training as manufacturers, to carry on manufacturing operations, and confirms the view which we have expressed of the imprudence of placing important factories under such management, and thus severely hampering a competent civilian Director-General. . . . In our judgment no substantial improvement in economical management is to be looked for till there is a complete separation between the military advisers of the Director-General and the civil assistants who are charged with the actual carrying out of the work and the keeping of the accounts."

THE question of the relation of psychology to physiology, and of the line of demarcation between the two sciences, is discussed by Prof. G. S. Fullerton in the *Psychological Review* for January. Psychologists are often charged with occupying themselves in doing work which is purely physiological, and they retort by stating that most text-books of physiology include matter which belongs to psychology. The fundamental assumption of psychology is, to state Prof. Fullerton's argument, the assumption of an external physical world, and of minds which mirror it. It is the task of the psychologist, with the aid of introspection, observation and experiment, to obtain a knowledge of such minds, and to reduce their phenomena to laws. Though little is known about the changes in a nerve during a passage of a nervous impulse, the methods employed in investigating physical and chemical problems may be expected to throw some light upon them. On the other hand, argues Prof. Fullerton, psychical facts—such as sensations, perceptions, volitions—have also to be reckoned with, and one would hardly expect to study them just as the changes in a muscle during contraction are studied. Therefore he thinks that while the task of the physiologist is to investigate, by directly objective methods, the physical series of causes and effects, the psychologist studies facts of another order by the method of introspection, observation and experiment, and interpretation.

IN a recent note we congratulated those interested in astronomy upon the fact that there would be soon a total solar eclipse visible almost at our doors, and that the Orient Company, Messrs. Cook, and Messrs. Gaze were advertising special steamers to go to Norway for the benefit of would-be observers. Then we went on to say: "We notice with some astonishment, in a circular issued by Messrs. Gaze and Son, the statement that 'an official party of observers, arranged by a joint committee of the Royal Society and of the Astronomical Society, are proceeding to Norway, and will travel by the s.s. *Norse King*.' We hardly think that this statement is authoritative, for scientific committees are not in the habit of advertising their intention to patronise any particular line of steamers; and, further, astronomers usually require more than five days to adjust and set up their instruments if any work of real use to science is to be done." We have received a letter from Messrs. Gaze and Son complaining that the above paragraph is "inaccurate," and assuring us that "an official party will travel by the *Norse King*." We willingly comply with their request, pointing out at the same time that we have been guilty of no inaccuracy, and that we did not deny their statement. We are not in a position to do so because, so far as we know, the Committee has published nothing on the subject. What we said was that it was not *authoritative*, and a statement of the kind made in an advertisement cannot surely be taken as authoritative even when it is used as a decoy. In any case we trust the "official party," whether singular or plural, will have a good time; but we still hold to our opinion as to the too short interval allowed for the preliminary arrangements on the spot.

MANY attacks have been made on the six zoological regions of Sclater and Wallace, and one of the most determined of these has been the proposal of an "Holarctic" region, to embrace the circumpolar districts and adjoining lands of both hemispheres. Dr. Scharff is a supporter of this view, which has likewise been maintained with great vigour by Dr. Merriam in America. But Dr. Wallace has shown that all the facts brought forward in its favour may easily be reconciled with the more orthodox view. An essay, entitled "Étude sur les Mammifères de la Région Holarctique et leurs relations avec ceux des Regions voisines," by Dr. R. F. Scharff, has just been published as an excerpt from the *Mémoires* of the French Zoological Society. In the essay, which has been rewarded by a prize founded at the International Zoological Congress held at Moscow, Dr. Scharff commences by a discussion of the Mammal-fauna of Ireland, and traces the species now existing and recently extinct in that country to their places of origin, so far as these can be settled by geological evidence. He proceeds to Southern Europe and Northern Africa, and shows how the Mammals that now inhabit these portions of the Palæarctic region may have reached their present quarters. There is much information to be gathered from the facts brought together by Dr. Scharff, but we cannot say that he has carried the case in favour of the "Holarctic" region much further than previous supporters of that theory.

THE number just issued of the *Arbeiten aus dem Kaiserlichen Gesundheitsamte* contains an official report by Regierungsrath Dr. Rahts, on the outbreak of influenza which occurred in Germany during the winter of 1893–94. In this epidemic, the country population suffered far more severely than that of the towns, and it is interesting to note that Hamburg experienced an exceptionally light visitation of the disease, this being doubtless partly attributable to the cholera epidemic of the previous year having eliminated to a certain extent the less vigorous lives. The period of incubation appears to have varied from two to five days, and the infectious nature of influenza was again amply verified. It is pointed out that the careful disinfection of all catarrhal expectoration is of great importance in preventing the

spread of the contagion, and the successful manner in which outbreaks were restricted is ascribed to such disinfection having been carried out on the same lines as those laid down in the case of tuberculous infectious material. On the whole the report does not throw any important fresh light on this mysterious disease, and its latest appearance in epidemic form does not appear to have differed very materially from that which has characterised previous outbreaks. No reference is made to the bacteriology of influenza.

AN important and most elaborately conducted inquiry has recently been made by Dr. Lösener on the opportunity for spreading disease offered by the burial instead of cremation of infected carcases. The actual conditions attending the process of burial were as far as possible faithfully followed, both as regards the depth of the hole and the enclosure of the carcase. The duration of vitality of the various pathogenic microbes under such circumstances was found to vary very considerably. Thus typhoid bacilli only on one occasion survived the processes of putrefaction 96 days, cholera vibrios could not be detected after 28 days, tubercle bacilli lived from 95 to 123 days. Tetanus bacilli were, however, still in a highly virulent condition even after 234 days, but after the lapse of 361 days they were no longer discoverable. The bacillus pyocyaneus lived up to 33 days, and Friedländer's pneumonia bacillus 28 days; whilst anthrax germs retained their full complement of virulence during the whole year over which the investigations extended. As regards infection of the surroundings, the information is so far satisfactory, inasmuch as only in the case of anthrax germs were they discovered to have found their way to the adjacent soil and water. So admirable a barrier, however, is provided by the soil, that the earth close beneath the bottom of the hole containing the infected carcase, was in every case found to be quite devoid of pathogenic germs. The bacterial purification effected by filtration through soil has been shown by the Massachusetts experiments on sewage in which five feet of garden soil and five feet of peat were respectively used. So few microbes found their way through, that they were not attributable to the filtration itself, but rather to post-filtration sources. Of course for practical filtration purposes these materials are not available, as they work so very slowly, but the results obtained with them help to support Dr. Lösener in his reassuring views as to the hygienic aspects of burial.

A PAPER of considerable interest, contributed by Dr. F. Ahlborn to the current number of one of our best-known contemporaries, contains a novel application of rowing to biology (*Zeit. f. wiss. Zool.*, lxi., December 1895). The main object of the paper is to explain the use and meaning of the asymmetrical types of tail-fin which are so commonly met with among fishes—*e.g.* the upturned tail of the shark and sturgeon, and the downwardly extended fin of the flying-fish. Dr. Ahlborn's explanation is founded on a recent suggestion of Prof. F. E. Schulze's in regard to the tail of Ichthyosaurus, and is illustrated by comparisons presumably drawn from the author's own experiences in the art of rowing. Every tyro knows the consequences which ensue if he holds his blade too obliquely in the water. If the upper edge is inclined too much towards the stern of the boat, a brisk pull upon the handle results in the blade jumping out of the water, and the oarsman falling backwards from his seat; if, on the other hand, the blade is inclined too much in the opposite direction, it digs into the water and the oarsman "catches a crab." The relevance of these illustrations is found in the fact that the skeletal support of the asymmetrical tails of fishes is generally such that either the upper or lower border of the fin is more resistant to the pressure of the water than the opposite border, a fact which causes the fin in action to assume an oblique, instead of a vertical position. The result of such a disposition is that in those cases where the upper part of the tail is stiffer than the lower the tail in locomotion is driven upwards, as the oar is driven out of the water (heterocercal tail of shark and sturgeon); while in cases where the lower part of the tail is firmer than the upper the tail tends, in action, to assume a lower position than the rest of the body (flying-fish). The body of the animal, in fact, is made to swing vertically about a horizontal axis running through the centre of gravity: in the first group the tail becomes elevated above the head, in the second group the head becomes raised above the tail. The utility of these types of organisation becomes obvious when we reflect, with Dr. Ahlborn, upon the habits of the creatures which exhibit them. The first group consists of bottom-haunting fish, which are thus enabled to give free play to their tails while scouring the sea-bottom in search of food; the second consists entirely of surface-swimming forms which are enabled, by this beautiful adaptation of structure, to swim swiftly beneath the surface of the water without the risk of their tails emerging, and so causing inconvenience and waste of force. The tails of many air-breathing aquatic animals, such as the crocodile, water-snake, and the extinct Ichthyosaurus, are constructed upon this latter principle.

THE number of the *Trinidad Field-Naturalists' Club* for October 1895, contains an elaborate paper by Mr. T. I. Potter, on four species of *Oncidium*, natives of the island.

THE Field Columbian Museum has commenced the issue of a series of botanical papers, with a contribution to the Flora of Yucatan, by Mr. C. F. Millspaugh, botanical curator, illustrated by several photographs. The orders which are most numerously represented in the Peninsula are the Leguminosæ and the Compositæ.

ATTRACTIVE, but somewhat belated, are the Brochures 3 and 4 of vol ii. of the *Proceedings* of the Rochester Academy of Science, just received by us. The papers contained in these publications were, for the most part, read before the Society in 1893. Among the subjects treated are: "The Evolution of the Ungulate Mammals," by Prof. H. L. Fairchild; "Solar Electrical Energy not transmitted by Radiation" by Dr. M. A. Veeder; and "The Pitch Lake of Trinidad," by Mr. A. Cronise.

THE editor of *Just's Botanischer Jahresbericht* has issued an appeal to all botanists for a prompt despatch of separate copies of their contributions to scientific journals, or other botanical treatises. The average number of such papers, an abstract of which is given in each year's *Bericht*, is about 5300; and of these the editor has never received, up to the present time, copies of more than 300. The papers should be addressed to the Editor, Prof. Dr. E. Koehne, Kirchstrasse 5, Friedenau-Berlin.

VOL. iii. No. 6 of the Contributions from the *U.S. National Herbarium* consists of an interesting account of the botany of Yakutat Bay, Alaska, by F. V. Coville, to which is prefixed a general report on the characteristics of the Flora, by F. Funston. Even in August the danger in crossing the bay in canoes is very great from the floating ice. The country is largely covered by impenetrable forests of the Sitka spruce, *Picea sitchensis*. The number of species of vascular plants gathered was 137, the predominant orders being Ranunculaceæ, Rosaceæ, Compositæ, and Gramineæ.

Bulletin No. 9 of the "Minnesota Botanical Studies" for 1895 contains an interesting article, by Mr. R. W. Squires, on Tree-temperatures. The observations were made between

January and June on a specimen of *Acer Negundo*. During the whole of this period the temperature of the tree was lower than that of the air in the morning and at noon, but higher in the evening. The lowest temperature of the tree recorded was in February, $-21^{\circ}\cdot1$ C. In the same part Miss H. G. Fox gives a monograph of the species of *Cypripedium* belonging to the Atlantic region of North America, six in number, with a scheme of the affinities of all the American species of the genus.

THE fourth volume of the *Transactions* of the Royal Society of Victoria (1895, pp. 166) is taken up with "A Monograph of the Tertiary Polyzoa of Victoria," by the late Dr. MacGillivray. The monograph is illustrated by twenty-two lithographed plates, all of which were prepared by Dr. MacGillivray, but only a few pages of the descriptive text had been written, and Prof. Baldwin Spencer and Mr. T. S. Hall are responsible for the descriptions required to complete it. In Victoria, as well as in South Australia, there are numerous Tertiary formations containing large deposits of Polyzoa, the accurate determination of which, especially in relation to the living species, is of great geological interest. Dr. MacGillivray's monograph, with its numerous fine illustrations of species, will prove of great assistance in working out this relation.

THE second volume on "Africa," in the new issue of Stanford's Compendium of Geography and Travel, deals with South Africa, and the author is Mr. A. H. Keane. The volume is not merely an enlarged edition of Keith Johnston's work, but practically a new publication, containing but a few passages of the original text, while only three of the old text-figures have been retained. Nnmerous new and carefully selected illustrations give attractiveness to the text, which is well abreast of the knowledge of African geography. How enormously the available information has increased may be gathered from the fact that the present volume, dealing with South Africa alone, runs into 671 pages; and we can quite believe Mr. Keane when he says: "Occurrences of far-reaching consequence have followed in such swift succession that in the preparation of this work the chief difficulty has been to keep pace with the shifting scenes." A broad view is taken of geography, attention being given to African history, political questions, and ethnology, as well as to the physical features, hydrography, and natural history of the continent. Altogether the volume is a valuable addition to the works dealing with Africa, and a desirable acquisition to every geographer's library.

THE first volume of what promises to be a very elaborate "Traité de Chirurgie clinique et opératoire," has come to us from MM. J. B. Baillière et Fils. The editors of the work, which will be completed in ten bulky volumes, are Profs. A. Le Dentu and P. Delbet; and if the first volume, dealing with general and special pathology, is followed by others of like fulness and quality, a valuable work of reference will have been added to the literature of surgery. The chief object of the editors—the object towards which the efforts of all physicians and surgeons tend—will be to make the publication the *livre de chevet* of those who are concerned with the origin and treatment of diseases. It is the surgery of to-day that will be expounded, not that of the past. The recent conquests in the domain of anatomy, bacteriology with all its applications to therapeutical surgery, and operative methods which have extended the field of action of surgery, will all be fully dealt with. Such a broad scope, when considered by the side of the distinguished men who have undertaken to write the various sections, is sufficient to establish the work in a high position.

IN a paper in the current number of the *Berichte* (January 13) by Lobry de Bruyn and A. van Ehenstein, further details are given of the properties of free hydrazine, NH_2—NH_2. In the first preliminary communication by M. Lobry de Bruyn, two methods of obtaining the anhydrous base were described, viz., by the action of barium oxide upon hydrazine hydrate, and by the reaction between sodium methylate and hydrazine hydrochloride in absolute methyl alcohol; in either case the hydrazine being separated by fractional distillation under reduced pressure. Free hydrazine is a liquid which at 23° has a density of 1·003, and on cooling with ice solidifies to a crystalline mass melting at $1^{\circ}\cdot4$ C. Unlike free hydroxylamine, which is explosive, hydrazine is a very stable body, boiling unchanged under ordinary atmospheric pressure at $113^{\circ}\cdot5$ C., and not decomposing at a temperature of 300°. In its chemical behaviour the free base resembles the hydrate, being oxidised to nitrogen by oxygen or air, and converting solid sulphur into hydrogen sulphide on warming. In a subsequent note in the same journal, by M. Lobry de Bruyn, an improved method is given for the preparation of hydrazine hydrate in quantity, advantage being taken of the fact that glass is not attacked by this substance at temperatures under 50° C. Since the hydrate boils at 47° under a pressure of 26 mm., the fractional distillation, if conducted at pressures below this, may be carried out in glass vessels.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, presented by Mr. Edmund Sheriff; a Common Boa (*Boa constrictor*) from Trinidad, presented by Mr. S. A. Cumberland; a —— Antelope (*Cervicapra*) from Africa, a Kinkajou (*Cercoleptes caudivolvulus*) from South America, a Cormorant (*Phalacrocorax carbo*), British, two Samoan Fruit Pigeons (*Ptilonopus apicalis*) from Samoa, deposited; a Sharp-nosed Snake (*Passerita mycterizans*) from India, purchased.

OUR ASTRONOMICAL COLUMN.

ECLIPSES IN FEBRUARY.—During the present month there will be an annular eclipse of the sun and a partial eclipse of the moon. The former will occur on February 13, but as the path of the annulus lies wholly in the South Atlantic and Antarctic Oceans, it is of little interest. At the Cape of Good Hope it will be visible as a partial eclipse, magnitude 0·849, the greatest phase occurring at 6h. 38m. Cape mean time, that is, sixteen minutes before sunset.

The more important phases of the partial eclipse of the moon on February 28 will be visible in this country, provided the weather be favourable. The following particulars for Greenwich are from the *Companion to the Observatory*:—

	h. m.			h. m.
First contact with penumbra	5 15·5	...	With shadow	6 16·3
Last ,, ,,	10 15·9	...	,, ,,	9 15·1

First contact with shadow takes place at an angle of 85° from the north point towards the east, and the last contact at 30° towards the west. The magnitude of the eclipse (moon's diameter = 1) will be 0·870. The moon will rise at 5h. 27m.

During the partial eclipse the following stars will be occulted:

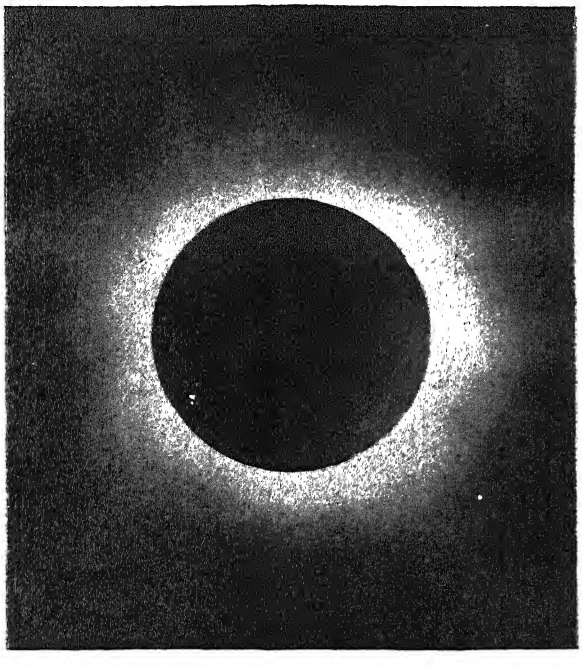
Star.	Mag.	Disappearance or Reappearance.	G.M.T.	Angle E. of N.
			h. m.	
B.D. +7·2373	9·3	D	6 42	81
+6·2364	8·8	D	7 6	147
+7·2370	9·5	R	7 7	325
+7·2373	9·3	R	7 28	334
+7·2364	8·8	R	7 56	270

ASTROPHYSICAL STANDARDS.—The need for greater uniformity in standards, &c., has long been felt by all engaged in astrophysical researches, and we learn with pleasure that the Editorial Board of the *Astrophysical Journal* has taken up the matter. As the result of a circular addressed to the Associate Editors, the following decisions have been arrived at, and an

appeal is made for their general adoption. Rowland's scale of wave-lengths, as represented by the tables in course of publication in the journal above named, is to be employed, and the unit of wave-length is to be the ten-millionth of a millimetre, or "tenth-metre." For measurements of velocity in the line of sight, the kilometre is to be taken as the unit. To distinguish the lines of hydrogen, the nomenclature starting with H_α in the red and continuing in alphabetical order through the entire series is agreed upon. Maps of spectra are to be drawn with the red end to the right, and tables of wave-length are to be printed with the shorter wave-lengths at the top.

Although some of the leading workers in astrophysics have not been consulted, it is probable that these arrangements, so far as they go, will meet with general approbation. It is to be regretted, however, that the representation of intensities of spectrum lines was not considered, as a scale which every one might be willing to adopt is, perhaps, even more urgently required than any general agreement on the points to which reference is made above.

REPRODUCTION OF ASTRONOMICAL PHOTOGRAPHS.—The Council of the Royal Astronomical Society has lately undertaken the reproduction (by paper prints and lantern slides) of a selection of the instructive astronomical photographs in the possession of the Society. The prints and lantern slides are sold to Fellows of the Society at approximately cost-price, and full details as regard subject, instrumental data, exposure, &c., are given upon each. Among the celestial pictures which have been thus rendered available to a wider circle of astronomers, are



photographs of total solar eclipses of 1886, 1889, and 1893, Dr. Roberts' photographs of the Pleiades and the Great Nebula in Orion, Prof. Barnard's photographs of the Milky Way, and of Brooks' and Swift's comets, Dr. Gill's photograph of the nebula about η Argûs, and MM. Loewy and Puiseux's lunar photographs. The accompanying illustration of the eclipse of April 16, 1893, has been reduced by one-third from a print sold by the Society. The original was taken by Sergt.-Major Kearney, R.E., at Fiundium, West Africa, with a Dallmeyer photoheliograph, the exposure being twenty seconds.

HOLMES' COMET.—Prof. Barnard has just published an account of his observations and photographs of this comet, made during its appearance in 1892 and 1893 (*Astrophysical Journal*, vol. iii. No. 1). Some of the telescopic features appear to have been quite unique. On January 4, 1893, only a feeble glow was visible; twelve days later it seemed like a hazy star, and the nucleus was actually seen to brighten in the few hours of observation, while the body itself expanded; six days afterwards, the nucleus had almost disappeared again. A photograph taken on November 10, 1892, is chiefly remarkable as showing a large irregular mass of nebulosity covering an area of at least a square degree, and connected with the comet by a short hazy tail. This curious appendage, which certainly belonged to the comet, seems to have been overlooked by most observers, but its recognition may possibly at some time or other prove to be of importance. The facts seem to be in favour of the comet having suddenly become bright just before the time of its discovery. It differed from the average comet in having a nearly circular orbit, and unless there had been some great change in its path, or some internal change, it should have been discovered long before. As the comet could not be seen with the Lick telescope during the succeeding opposition, Prof. Barnard thinks that it no longer exists in the cometary form, and will never be seen again.

THE LIQUEFACTION OF AIR AND RESEARCH AT LOW TEMPERATURES.[1]

THE best and most economical plant for the production of liquid air or oxygen is one based on the general principle of that used by Pictet in 1878, for liquefying oxygen; instead, however, of using Pictet's combined circuits of liquid sulphur dioxide and carbon dioxide kept in circulation by compression, liquefaction and exhaustion, it is better to employ ethylene in one circuit, as Cailletet and Wroblewski did, and to use nitrous oxide, or preferably carbon dioxide, in another. Further, instead of causing the oxygen to compress itself during its formation from potassium chlorate heated in an iron bomb connected with the refrigerator, it is found convenient to use gas previously compressed in steel cylinders.

A very convenient laboratory apparatus, the arrangements of the circuits of which will be easily understood from the sectional view shown in Fig. 1, has been devised for the liquefaction of small quantities of oxygen or other gases; with this simple arrangement, 100 c.c. of liquid oxygen can readily be obtained, using liquid carbon dioxide at − 79° C. for cooling and employing no exhaustion. The gaseous oxygen, cooled before expansion by passing through a spiral of copper tube immersed in solid carbon dioxide, passes through a fine screw stopcock under a pressure of 100 atmos., and thence backwards over the coils of pipe. The liquid oxygen begins to drop in about a quarter of an hour from starting. The pressure in the oxygen cylinders at starting is generally about 150 atmos., and the best results are got by working down to about 100. This little apparatus will enable liquid oxygen to be used for demonstration and research in all laboratories.

By employing jacketed glass vessels, of which the annular space is highly exhausted, for storing liquefied gases, the influx of heat is reduced to one-fifth of that which occurs when the jacket contains air; if the interior walls are silvered, or excess of mercury vapour is left in the jacket, the influx of heat is again reduced to one-sixth, so that the total effect of the high vacuum and the silvering is to reduce the ingoing heat to about 3½ per cent. of that which enters when these precautions are neglected. The suggestion that the metallic coating is useless, because Pictet has found that all kinds of matter are transparent to heat at low temperatures, is thus disposed of; further, no increase in the transparency of glass to thermal radiation occurs on cooling to the boiling point of air.

In order to test Olszewski's statement that air cannot be solidified at the lowest pressures (*Phil. Mag.*, February 1895), the author's former experiments have been repeated on a larger scale. If a litre of liquid air be exhausted in a silvered vacuum vessel, half a litre of solid air may be obtained and kept solid for half an hour. The solid is at first a stiff transparent jelly, which, when placed in a magnetic field, has the still liquid oxygen drawn out to the poles, showing that solid air is a nitrogen-jelly containing liquid oxygen. Solid air can only be examined in a vacuum or an atmosphere of hydrogen, because it instantly melts on exposure to the air, causing an additional quantity of air to liquefy; it is strange to see a mass of solid air melting in contact with the atmosphere, and all the time welling up like a fountain.

On causing dry air, contained in sealed flasks, to solidify by

[1] A paper read before the Chemical Society on December 19, 1895, by Prof. J. Dewar, F.R.S. (Abridged from the *Proceedings* of the Society issued January 14.)

immersing the side arms attached to the flasks in liquid air boiling under a low pressure, and subsequently hermetically sealing off the side arms containing the solid, the residual air left in the flasks may be preserved for analysis; it is then ascertained that the residual air still contains oxygen and nitrogen in the usual proportion. In the earlier experiments, the argon solidified before the nitrogen, but chemical nitrogen and air nitrogen with

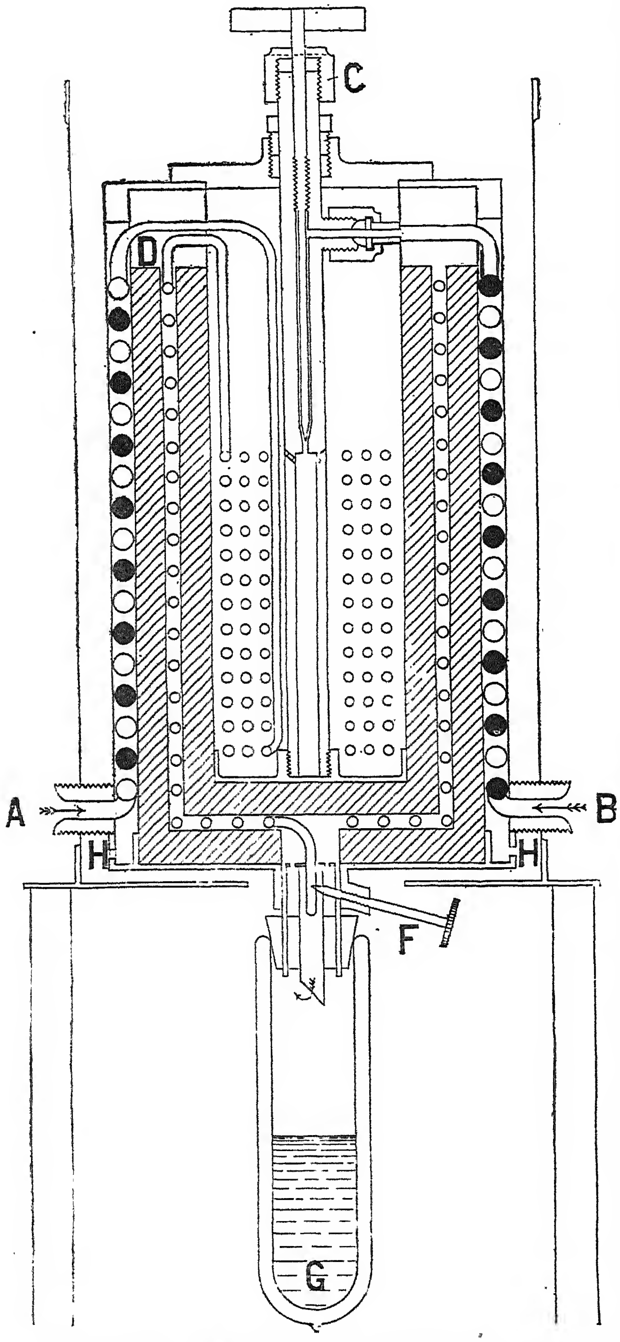


FIG. 1.—A, air or oxygen inlet. B, carbon dioxide valve. D, regenerator coils. F, air or oxygen expansion valve. G, vacuum vessel with liquid oxygen. H, carbon dioxide and air outlet. ○, air coil. ● carbon dioxide coil.

its 1·1 per cent. of argon behaved in substantially the same way on liquefaction.

Olszewski has examined liquid nitric oxide, and describes it as colourless, but on strongly cooling several carefully purified samples of this gas, which had been prepared by different methods, the author obtained in each case a nearly white solid melting to a blue liquid. The colour is more marked at the melting than at the boiling point, and the liquid is not magnetic. Solid nitric oxide is not phosphorescent, nor does it show any chemical action in liquid oxygen, provided the tube containing it is completely immersed; but if the tube full of liquid oxygen be lifted into the air, a violent explosion almost instantly occurs.

In a good vacuum vessel, specific gravities may be taken in liquid oxygen as easily as in water. Some twenty substances were weighed in liquid oxygen, and the apparent density of the liquid calculated; the results were then corrected, using Fizeau's values for the variation of the coefficients of expansion of the solids employed, and the real density of liquid oxygen was thus calculated as 1·1375 under a pressure of 766·5 m.m. The variation of density is about $\pm$ 0·0012 for 20 m.m. pressure. Wroblewski found the density of liquid oxygen at the boiling point to be 1·168, whilst Olszewski found 1·124. Fizeau's parabolic law for the variation of the coefficient of expansion holds down to $-183°$; the solid which contracted least during cooling was a compressed cylinder of silver iodide, that which contracted most a block of compressed iodine.

Similarly the density of liquid air was found to be 0·910 and that of nitrogen at its boiling point 0·850. No great accuracy attaches to the density of liquid air as thus determined, for liquid air kept in a silvered vacuum vessel rises 1° in boiling point every ten minutes during the first hour; the density of

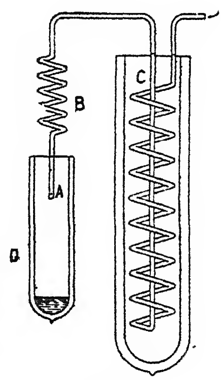

FIG. 2.

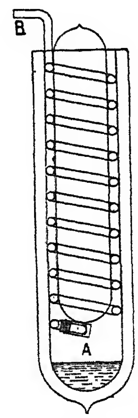

FIG. 3.

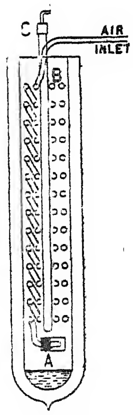

FIG. 4.

liquid air, however, does not reach that of pure oxygen even after thirty hours' storage.

A small ignited jet of hydrogen burns continuously below the surface of liquid oxygen, all the water produced being carried away as snow. There is a considerable amount of ozone formed, which concentrates as the liquid oxygen evaporates. In the same way graphite, or diamond, when properly ignited, burns continuously on the surface of liquid oxygen, producing solid carbonic acid and generating ozone. If liquid oxygen is absorbed in wood charcoal, or cotton wool, and a part of the body heated to redness, combustion can start with explosive violence.

The experiments of Joule and Thomson and Regnault on the temperature of gas jets issuing under low pressures are well known; the following observations refer to the pressure required to produce a lowering of temperature sufficient to yield liquid in the gas jet. The apparatus used in the study of highly compressed gas jets is sketched in Fig. 2; C is a vacuum tube holding a coil of pipe about 5 mm. in diameter along with carbon dioxide or liquid air for cooling the gas before expansion, and A is a small hole in the silver or copper tube about $\frac{1}{5}$ mm. in diameter, which takes the place of a stopcock. When carbon dioxide gas, at a pressure of 30 or 40 atmos., is expanded through such an aperture, liquid can be seen where the jet impinges on the wall of the vacuum tube along with a considerable amount of solid. If oxygen gas escapes from the small hole at the pressure of 100 atmos., having been cooled previously to $-79°$ in the vessel C, a liquid jet is just visible. It is interesting to note in passing that Pictet could get no liquid oxygen just below 270 atmos., owing to his stopcock being massive and outside the re-

frigerator. If the oxygen is replaced by air, no liquid jet can be seen unless the pressure is raised to 180 atmos. If the carbon dioxide is cooled by exhaustion (to about 1 in. pressure) or $-115°$, liquid air can easily be collected in the small vacuum vessel D, or if the air pressure is raised above 200 atmos., keeping the cooling at $-79°$ as before. The chief difficulty is in collecting the liquid, owing to the rapid current of gas. The amount of liquid in the gas jet is small, and its collection is greatly facilitated by directing the spray on to a part of the metallic tube above the little hole, or by increasing resistance to the escaping gas by placing some few turns of the tube, like B in the figure, in the upper part of the vacuum tube, or generally by pushing in more tube in any form. For better isolation, the pipe can be rolled between two vacuum tubes, the outer one being about nine inches long and one and a half inches diameter, as shown in Fig. 3; the aperture in the metal pipe has a small piece of glass tube over it, to help the collection of the liquid. Using this apparatus and an air supply at 200 atmos. with no previous cooling, liquid air begins to collect in about five minutes, but the liquid jet can be seen in two to three minutes. In Fig. 4 the metallic tube in the vacuum vessel is placed in horizontal rings, leaving a central tube for the passage of the glass tube C, which is used to cool bodies or examine gases under compression; the inner tube can be filled for an inch with liquid air at 60 atmos. pressure, in about three minutes. A double coil of pipe may be advantageously used in some experiments; the efficiency is low, but it affords a quick method of reaching low temperatures and collecting a few hundred cubic centimetres of liquid air. By the use of this apparatus air at the ordinary temperature can be simply converted into liquid air at the boiling point, $-194°$, in less than ten minutes; a fall of 200° is effected in this short period of time.

The author, after giving a sketch of the results up to the present achieved in connection with the liquefaction of hydrogen, remarks that hydrogen, cooled to $-194°$ (80° abs. t), the boiling point of air, is still at a temperature which is two and a half times its critical temperature, and its direct liquefaction at this point would be comparable to that of air taken at 60°, and liquefied by the apparatus just described. Now, air supplied at such a high temperature greatly increases the difficulty and the time required for liquefaction. Still, it can be done, even with the air supply at 100°, in the course of seven minutes; and this is the best proof that hydrogen, if placed under really analogous conditions, at $-194°$ must also liquefy with the same form of apparatus. Hydrogen, cooled to $-200°$, was forced through a fine nozzle under 140 atmos. pressure, and yet no liquid jet could be seen. If the hydrogen contained a few per cent. of oxygen the gas jet was visible, and the liquid collected, which was chiefly oxygen, contained hydrogen in solution, the gas given off for some time being explosive.

If, however, hydrogen, previously cooled by a bath of boiling air, is allowed to expand at 200 atmos. over a regenerative coil similar to that shown in Fig. 2, but longer, a liquid jet can be seen after the circulation has continued for a few minutes along with a liquid which is in rapid rotation in the lower part of the vacuum vessel. The liquid did not accumulate, owing to its low specific gravity and the rapid current of gas. These difficulties will doubtless be overcome by the use of a differently shaped vacuum vessel and by better isolation. The liquid jet can, however, be used as a cooling agent, like the spray of liquid air obtained under similar circumstances, and, this being practicable, the only difficulty is one of expense. In order to test in the first instance what the hydrogen jet could do in the production of lower temperatures, liquid air and oxygen were placed in the lower part of the vacuum tube just covering the jet. The result was that in a few minutes about 50 c.c. of the respective liquids were transformed into hard white solids resembling avalanche snow, quite different in appearance from the jelly-like mass of solid air got by the use of the air pump. The solid oxygen had a pale, bluish colour, showing by reflection all the absorption bands of the liquid. There is no reason, apart from that of cost, why a spray of liquid hydrogen, at its boiling point in an open vacuum vessel, should not be used as a cooling agent in order to study the properties of matter at some 20° or 30° above the absolute zero.

The only widely distributed element which has not yet been liquefied is fluorine; and it would seem that, although the atomic weight of fluorine is nineteen times that of hydrogen, it must in the free state approach hydrogen in volatility. If the chemical energy of fluorine is abolished at low temperatures, like that of other active substances, some kind of glass or transparent substance, less brittle than calcium fluoride, could be employed in the form of a tube, and the liquefaction of fluorine achieved by the use of hydrogen as a cooling agent.

SCIENCE IN THE MAGAZINES.

POLITICS saturates the February magazines, but science is not altogether drowned in this plethora of diplomatic diatribes. There are four articles in the *Contemporary* of interest to scientific readers. Mr. Herbert Spencer traces the development of the sculptor, and shows how, in its primitive character, sculpture was an auxiliary to ancestor-worship. "The tomb and the temple are," he shows, "developed out of the shelter for the grave—rude and transitory at first, but eventually becoming refined and permanent; while the statue, which is the nucleus of the temple, is an elaborated and finished form of the original effigy placed on the grave. The implication is that, as with the temple so with the statue, the priest, when not himself the executant, as he is among savages, remains always the director of the executant—the man whose injunctions the sculptor carries out." Mr. W. H. Hudson writes pleasantly, if somewhat aimlessly, about the village of Selborne and of the simple naturalist whose observations have made it famous. Mr. W. H. Mallock continues his study of "Physics and Sociology." The argument of the two articles which preceded the present one may be thus summarised: Great men are analogous to atoms of superior size, on whose presence the aggregation of all the other atoms depend, therefore they should form the first study of the sociologist. Two propositions (among others) which follow from this conclusion are now stated by Mr. Mallock; the first of them being more or less of a heresy, so far as scientific opinion is concerned. The propositions are as follows. (1) Other things being equal, communities progress and become civilised not in proportion to the talents of the mass of the individuals who compose them, but in proportion to the percentage which occurs in each of the individuals whose talents are superior to those of the mass. (2) Other things being equal, communities progress and become civilised in proportion to the desirability of the rewards which are practically attainable in each by the exercise of superior talents, and which thus stimulate the possessors of these talents to develop them, and make them actual instead of merely potential. Mr. D. C. Boulger having suffered from diphtheria, and been made a victim of the anti-toxin treatment, survived, and now records his experience of the disagreeable character of the disease and its sequelæ, all of which unpleasantness was aggravated, in his opinion, by the employment of antitoxic serum. From his particular case, he passes to a general discussion of diphtheria and antitoxin, which he condemns. So few are the gifts to science and education in England, that we rejoice to find Mr. Bernard Shaw commending in the *Contemporary* such benefactions to the attention of millionaires. The questions which a millionaire, moved by a generous spirit to benefit any locality, should ask himself are: "Has it a school, with scholarships for the endowment of research, and the attraction of rising talent at the universities? Has it a library, or a museum? If not, then he has an opening at once for his ten thousand or hundred thousand pounds."

"Reflex Action, Instinct, and Reason" are discussed from the point of view of their development in the *Fortnightly* by Mr. G. A. Reid. It suffices here to call attention to the article, which is a chapter from a forthcoming book on "The Present Evolution of Man," and to state the definitions of instinct and reason given in it. Instinct is defined as "the faculty which is concerned in the conscious adaptation of means to ends," by virtue of inborn inherited knowledge and ways of thinking and acting. Reason is defined as "the faculty which is concerned in the conscious adaptation of means to ends" by virtue of acquired non-inherited knowledge and ways of thinking and acting. An admirable article on "Plant Names" appears in the *Quarterly Review* (January), being a review of the "Index Kewensis" and of four other recent publications upon the names of plants. In the *National*, Mr. Walter B. Harris describes Tiflis, the capital of Transcaucasia, and in *Scribner* an interesting account is given of an ascent of Mount Ararat, the paper being illustrated by several of the finest specimens of process-work we have ever seen.

Knowledge contains articles on curious facts in plant distribution, by Mr. W. B. Hemsley, F.R.S.; waves, by Mr. Vaughan Cornish; Antarctic exploration, by Mr. W. S. Bruce; and comets of short period, by Mr. W. E. Plummer. There is also a full-page reproduction of Dr. Roberts' photograph of the nebula near 15 Monocerotis. We omitted to mention that in the January number, Dr. H. R. Mill had an article on "Geography as a Science in England," in which he pleaded for a more scientific study of geography.

Longman's Magazine has an excellent short article on the Pasteur Institute, by Mrs. Frankland. Mr. H. M. Stanley tells "The Story of the Development of Africa" in the *Century*. Among the subjects lightly and brightly treated in *Chambers's Journal* are left-handedness, by Dr. R. A. Lundie; turpentine farms in Georgia; Bath brick; new work on the filtration of water; and flint-knapping. Dr. Andrew Wilson writes on Medusæ in the *English Illustrated*. A description of the fantastic forms taken by lycopodium powder or a semi-liquid substance, when placed upon a flexible membrane set vibrating by the voice, is given by Margaret W. Hughes in *Good Words*, under the title of "Voice Figures." The article is illustrated by reproductions of some of the beautiful patterns thus produced. An article entitled "The Romance of the Museums," in the *Strand Magazine*, contains a short description, with illustration, of the Cranborne meteorite, in the British Museum Collection. The same magazine has in it a short story of adventure, founded upon the action of the "Souffleur" at Port Gorey, Sark. The scientific interest of the story lies in the section which is given of the Gouliot Caves, in order to explain how "Souffleurs" are caused.

THE CONSTITUTION OF SCIENTIFIC SOCIETIES.[1]

SOME cultivators of the sciences occasionally complain that the meetings of scientific bodies are not well attended, and that they read papers to too many empty benches. Moreover, even when they have a scientific audience they allege that very few of those present understand what they have to say. And they speculate on measures to be adopted to remedy this state of affairs.

As the scientific investigator acquires years and experience, he recognises that in the present state of human society he has no right to expect that the situation can be very different. The number of serious cultivators of science in any community is not large, and the number of men engaged in original research in any given field is still smaller. Like the landed aristocracy of the old nations, the producers in each department of science are well scattered over a country, and it is only on national occasions that they gather in any considerable force. The situation as to the audiences who assemble to listen to papers of original value in pure science is therefore not likely to change for some years. In fact, the size of audiences may be set down as inversely as the rationality, and directly as the emotionality of the matter set before them. Such is the present state of the civilised nations of the earth, and it is not peculiar to any one of them.

Most of the large cities of the United States have an "Academy of Sciences," or its equivalent, and it is largely with reference to the prosperity of those bodies that discussions such as we have referred to above is heard. Many of the members want them to be what they call popular, which, in its best sense, means that they wish for large audiences at the meetings. Now, if what we have said above is true, this object cannot be attained unless the academy abandons its real object, the advancement of scientific knowledge by original research. This is the primary object of academies of science in all countries, and if they neglect it, they lose their identity, since the facilities for the distribution of knowledge are everywhere relatively abundant. When the academy of science becomes a distributor of knowledge only, it abandons its important proper function, and becomes comparatively a nonentity. Let us hope that academies of science in America will not follow the course of the academies of music, which are, in Europe, educational and critical, in America, mere theatres.

The measures adopted by academies of science in the United States to make themselves popular and therefore "successful," are often highly amusing. The usual method is to elect some man president who is rich but unknown to science; since, in the minds of some people, money is the source of the sciences and the arts. Men of the same type are also often elected to other responsible positions in these societies for similar reasons. We have watched this mode of attacking the problem for many years, and have never known it to be successful. In the case of the Philadelphia Academy, it did, on one occasion, entail a loss of over $12,000 cash capital to the Society. In fact, the reasons why this method should not prove successful are not far to seek. The only way to make it successful would be to have a bill of sale of the office legally executed, so that the sum agreed on could be collected by process of law in case of failure to produce the "consideration" after the election. This the business world understands, whereas it does not perceive the cash value of original research. In fact, the election of an outsider to rule over them by a body of experts for a supposed financial equivalent, is a proceeding not calculated to excite the respect of a rich man or any other kind of man.

A society is, however, fortunate if it escapes without more serious injury than a financial disappointment. Men not habituated to the ways and means of research frequently apply nostrums which do more harm than good, and bring the society into deserved contempt. Thus in one city the president, who was of the type mentioned, succeeded in incorporating into the society a body of photographers, with the result of simply developing the photographic society. The men by whom the original society was known to the world were locally quite lost sight of. In another city a number of local amateur astronomical clubs were taken into the academy. These consisted of ladies and gentlemen whose devotion to science consisted in viewing the stars in each others pleasant society. Another academy adopted popular lectures as a device for filling empty benches. The selection of the lectures being in the hands of incompetent officers, cranky and ignorant persons, and those who had apparatus to sell, occupied the time of the academy, to the great scandal of the really scientific men of the city.

The appointment of amateurs and unscientific persons to positions in scientific bodies, often has ludicrous results. One academy of science discussed an ancient bone dredged up in salt water. It was perforated with fossæ in series, and it was concluded that it was a mouth bone of a fossil fish. It turned out to be the head of an ancient tooth-brush. An exhibition of foot-tracks on ancient rocks before the same academy, brought to his feet a dancing-master, who illustrated the formation of the impressions terpsichorean fashion.

Another plan for promoting the prosperity of scientific bodies is to have dinners and social receptions. These methods are always successful in drawing together numbers, and if persons are to be elected members of such societies in proportion to their gastronomic capacities, such a system must be eminently successful. To be serious, however, and to repeat what should be self-evident to every person, this plan tends only to an increase of non-expert membership, which is really at the bottom of all the evils which have befallen scientific societies. Hence, unless some measures to protect the membership be adopted, this method of "promotion" should be always rejected.

The result, both of our observations and cogitations on this subject, is that the only method by which academies of science can advance themselves in the public esteem, is to continue in their work of original research. If they cannot acquire public confidence in this way, they cannot acquire it at all. There is no short-cut to this so-called "success." As in all other human endeavours to wrest advantage from nature, labour and labour only "omnia vincit." As with the agriculturist, the machinist, or the accumulator of money, devotion to work, and this only, brings the rewards which we seek. The visible products of labour are what men respect, and if the scientific man wishes to inspire the respect of wealth, he must show results, rather than bestow on men of wealth what are to them empty honours.

[1] Reprinted from the *American Naturalist*, December 1895.

SCHOLARSHIP SCHEMES OF TECHNICAL EDUCATION COMMITTEES.

ONE of the chief ways in which Technical Education Committees all over the country spend the funds entrusted to them is in the award of scholarships; and if this branch of their work is wisely organised and carried out, there is no better method of securing the proper education of promising boys and girls. The scholarships awarded can be divided into four classes, namely, those tenable at (1) Technical Schools and Science and Art Schools; (2) Secondary Schools; (3) Universities or institutions of University rank; (4) short courses of instruction. Full information

with reference to these scholarships has appeared at various times in the *Record* of Technical and Secondary Education. An examination of the particulars there given reveals several interesting facts, not the least among which is the diversity of opinion as to what the candidates for such exhibitions and scholarships should be examined in. At Plymouth, boys are expected only to have a knowledge of sixth and seventh standard work when they enter for scholarships of the first of the above divisions, while those of Bristol are set papers not only in elementary subjects, but also in algebra, Euclid, French, German, chemistry, botany, &c. Candidates in Blackburn and Stockport, amongst numerous other places, are set papers in the subjects of the "Science and Art Directory," though in the former place any commercial knowledge proves useful, and at Stockport boys may enter themselves for any branch of technology mentioned in the City and Guilds' programme. Such facts as these show that we are yet far removed from any definite and uniform course of education graduating from the elementary school upwards. The complaints, which are published in most of the County Council reports, of the hopelessness of looking for any satisfactory progress in technical instruction until the students entering technical or science and art schools are better prepared to benefit by their teaching, are likely to be often repeated unless it is made compulsory upon all scholarship holders to give satisfactory evidence of their acquaintance with, at least, the work of the elementary schools. In some cases, authorities have tried to avoid this difficulty by stipulating that candidates shall have been pupils in elementary schools; but it is notorious that a year or two after leaving school most boys have completely lost any knowledge they may have had. Means by which the continuity of a boy's education may be ensured have yet to be taken. No permanent gain can result if technical work is built on insecure foundations, and we imagine that the foundations of scientific knowledge can be very properly begun in the elementary school. This knowledge should be carried on in evening continuation schools, and attendance at such schools should be made compulsory, as it is in Germany. If that were done, a boy at the age of seventeen would be in fit condition to enter the true technical school, whereas, under the present system of elementary education, he is not. The want of agreement to which we have referred obtains also when we come to consider the conditions under which scholarships to secondary schools are awarded. The most striking feature here is perhaps the countenance which is given to dabbling in all sorts of subjects. Since the secondary school is, as a rule, intended for boys from about thirteen to sixteen or seventeen years, and is, or should be, entered at, or about, the lower age, it seems unreasonable to expect any candidate to have done anything of importance at such subjects as botany and physiology, and yet such subjects are continually asked for. At every point one is struck with the want of coordination in the various grades of English education. If we could once get something like a consensus of opinion as to the proper work of the elementary, the secondary, the technical school, and finally of the college, this continual difficulty of what to examine in would not arise. When we come to look into the regulations affecting the scholarships offered by the technical instruction committees at universities or institutions of university rank, it becomes painfully evident that such committees are by no means clear what their work properly is. Several county authorities consider a knowledge of Latin, and one at least recognises familiarity with Greek, as being desirable for technical students. It is not our desire to decry the study of the classics, but we maintain that neither Greek nor Latin gives any claim to a technical scholarship, and, further, that the grant for technical education is being wrongly used if it is awarded for proficiency in such subjects. It cannot be too much insisted upon that one of the points which the advisers and directors of the various committees need yet to consider, refers to the requirements and capacities of the different classes of the community, and how these can best be met.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The lecture list for the current Term contains a few features of interest. In the Department of Medicine Dr. J. Ritchie gives a practical course of Elementary Morbid Histology, making use for the first time of the pathological laboratory which has recently been fitted up in the Department of the Regius Professor of Medicine.

Mr. J. C. Alsop is assisting the Professor of Experimental Philosophy in practical instruction, and Mr. E. W. A. Walker is assisting in the practical course of Physiology in the Department of Physiology. Otherwise the courses of lectures in the Faculties of Medicine and of Natural Science are unchanged.

An examination for a Radcliffe Travelling Fellowship will be held during the present term, commencing on March 3. Intending candidates, who must declare that they intend to devote themselves to the study of Medical Science during the tenure of the Fellowship, and travel abroad with a view to that study, are required to send their names and qualifications to the Radcliffe Examiners, the Radcliffe Library, Oxford, on or before February 3.

Mr. W. Warde Fowler, Fellow of Lincoln College, has been appointed a Curator of the Botanic Garden, in place of Mr. Edward Chapman, Fellow of Magdalen College, resigned.

The Delegacy of Non-Collegiate Students announce that a Shute Scholarship of an annual value of £50 will be awarded on Saturday, June 20. The examination will be in Chemistry, and will commence on Tuesday, June 2. The Scholarship is open, and there is no limitation of age; but no member of the University will be eligible, who shall have completed eight Terms from the date of matriculation.

CAMBRIDGE.—The Council of the Senate have appointed Mr. Charles Smith, Master of Sidney Sussex College, Vice-Chancellor, a Governor of Eton College, in the room of Dr. Forsyth, F.R.S., who has resigned.

The subscribers to the Robertson Smith Memorial have paid over to the University £335 for the purchase of Oriental manuscripts, after investing some £1100 for the maintenance in Christ's College of the late Professor's library.

The memorial respecting degrees for women, signed by over 2000 members of the Senate, has been presented to the Council. The discussion of the subject by means of fly-sheets and pamphlets has already begun, and promises to be unusually keen.

At the matriculation on January 28, twenty-seven new names were added to the list of freshmen; this raises the total entry up to the present to 938.

ON Friday, January 31, the Duke of Devonshire distributed certificates to the scholars and exhibitioners elected last year by the Technical Education Board of the London County Council. There were 5 senior county scholars, 60 intermediate county scholars, 600 junior county scholars, 135 art scholars and exhibitioners, and 73 evening science exhibitioners, making a total of 882. What the scholarship scheme of the Board is, and what it aims at doing, will be gathered from the following remarks made by the Duke of Devonshire. In the first place there are the junior county scholarships, open to boys and girls under thirteen years of age, by competition. These scholarships carry with them free education in a secondary selected school for two years, and a money payment divided between the two years of £20. The examination by which they are gained is an examination in the subjects taught in elementary schools. Thus, the advantage of two years of education beyond the age of thirteen in a higher school is opened up to a large number without any cost to themselves or to their parents. It is the first step upon the educational ladder which has been set up by the County Council, and whether that step is taken as a preliminary to an attempt to rise to higher rungs of that ladder, or whether it is taken with no object of prosecuting the ascent higher, yet the advantage of these two added years of education in an efficient selected school may prove and ought to prove of immense value to the student. The next step in this ladder is a grant of a smaller number of intermediate county scholarships, which enable boys and girls under the age of sixteen to continue their education further in secondary schools up to nineteen, and of course carrying with them a higher money payment to compensate for the higher value of the labour which it is the object of this scheme to make during the period of education necessary; and, finally, the County Council offer a limited number of still higher scholarships which will enable the fittest of those who have distinguished themselves in previous competitions to continue their education for three years in either a college or some other institution of University rank. What, in fact, the County Council, through its Technical Board, has been able to do has been to establish something in the nature of a technical

University for the county of London, although the County Council itself has not assumed any such ambitious denomination for its work. On the contrary, continued the Duke, the Technical Education Board is fully aware of the need of our great metropolis for a teaching University, and it has promised to that new University a contribution of £10,000 a year, contingent upon the organisation of that body being such as will secure the advantages of a new University to all classes of the inhabitants of London, including the artisan and the labouring classes. The Council has thus shown the most practical proof that in its opinion the great work which it has already undertaken still requires to be supplemented by something more thoroughly and more completely deserving the name of University education for the county of London.

WE learn from the *Times* that Mr. T. H. Ismay has written to the President of the Liverpool Engineering Society, offering on behalf of the White Star Line Company the sum of £2000, to be used in founding and maintaining in connection with University College a scholarship intended to perpetuate the memory of the late Sir Edward Harland and his association with the shipping life and engineering profession of Liverpool. It is proposed that the scholarship shall be awarded for nautical engineering and marine architecture, and called the "Sir Edward Harland Memorial Scholarship."

THE following new announcements of gifts to educational institutions in America are noted in *Science*. Mr. J. H. Armstrong, of Plattsburg, deeded a considerable property to Union College, but retained a life interest in it. On January 2 of this year he died, and by his will added to the gift, which now amounts to 100,000 dols. The Legislature of Massachusetts has passed the Bill granting 25,000 dols. to the Massachusetts Institute of Technology. Mrs. Josiah N. Fiske has given Barnard College 5000 dols. for the foundation of a scholarship which will be open to competition.

SCIENTIFIC SERIALS.

THE *Quarterly Journal of Microscopical Science* for January 1896, contains but one article—on the development of *Asterina gibbosa*, by E. W. MacBride, Fellow of St. John's College, with plates 18-29. The investigations forming the subject of this memoir were commenced some years ago; the author at first intended to work out the development of the so-called heart, with its accompanying sinuses, in the Asterids, as he had previously done in the case of the Ophiurids. Coming to the conclusion, however, that our knowledge of the development of most of the organs in the Asterid body was very defective, he determined to thoroughly revise their whole history, embryonic and larval. This work has occupied his attention for the last two years, and as a result we have this carefully written memoir, which the author hopes may be found to place our knowledge of Asterid development on the same level as that to which our acquaintance with Crinoid ontogeny has been raised by the researches, among others, of Bury and Seeliger. The material was chiefly collected at the Naples Station. The memoir is prefixed by a statement of the methods of research adopted, and concludes with a chapter entitled "General Considerations," in which two questions are asked: (1) What light does this history throw on the affinities of the Asterids with the other Echinoderms? and (2) Does it suggest any direction in which we may look to find the origin of the group Echinodermata? The answer given to the former is that the Asterids have an affinity with the Crinoids, and that they had a fixed ancestor; and to the latter, that assuming a free-swimming ancestor of Echinoderms (provisionally called Dipleurula), it and the Tornaria ancestor of Balanoglossus must have been closely allied. This further involves the assumption that the Asterids were thus allied to the Protochordata.

THE number of the *Nuovo Giornale Botanico Italiano* for January contains, among others, the following papers:—Botanical results of a journey to the Lower Obi, by S. Sommier.—A paper by A. Pizzigoni on the dry and moist cancer of the potato, which he regards as two distinct diseases; the former due to the attacks of *Fusisporium solani* alone, the latter to this fungus, together with bacteria.—Sig. G. Del Guercio describes the changes produced in the cortex of the oak by the attacks of the larva of *Gracilaria simploniella*.—Prof. A. Borzì has a paper on the hydrophorous apparatus of xerophilous plants belonging to the Mediterranean flora; those specially described are the nodal sheath and cushion of many Caryophylleæ, the leaf-sheath of Gramineæ and Umbelliferæ, and the ochrea of Polygonaceæ.—Sig. A. Lenticchia contributes a useful list of the flowering plants of Italian Switzerland.

IN the *Bullettino* of the Italian Botanical Society for December 1895 and January 1896, are papers on the dimorphism in the flowers of *Convolvulus arvensis*, caused by the attacks of *Thecaphora hyalina*.—On the meteorology of the year 1895, and its effects on the plants in the Botanic Garden at Florence. The lowest temperature recorded during the severe winter 1894-95 was -7° C.—On the biology of the flowers of *Oxalis cernua*, with especial reference to the occurrence of fertile flowers intermediate between the normal and the true cleistogamous flowers.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 5, 1895.—"The Measurement of High Potential Difference." By H. C. Leake, R. Leventhorpe, and C. S. Whitehead.

This paper describes firstly the method adopted by Prof. Ayrton and Mr. Mather for the accurate calibration of electrostatic voltmeters in electro-magnetic units. For this purpose a high alternating potential difference is employed, which can be measured by the apparatus in several ways, each of which is a check on the others. By means of a divided resistance and a new type of low-reading idiostatic electrometer, the high alternating potential difference can be measured without involving determinations of either current or resistance. It is probable that the measurements of 2000 volts are correct to about $\frac{1}{10}$ per cent. in terms of the Clark cell.

With the aid of this apparatus, and the most probable value of "v," the authors determined the accuracy with which measurements of steady potential differences of about 2000 volts could be made in terms of the absolute electrostatic unit by means of the Kelvin absolute electrometer, when used in the ordinary way, and they found that measurements made with this instrument were always too large by, on the average, $1\frac{1}{2}$ per cent.

They traced this error to imperfection in the action of the coach-springs, the greater part of which could be eliminated by keeping the springs constantly loaded.

The remaining error, which was due to change of temperature of the coach-springs, was reduced by very carefully shielding the instrument from heat when in use, and was finally eliminated by the use of a simple correction formula. This method of correction had the great advantage of not depending on thermometer readings, as the coach-springs themselves were virtually used as a metallic thermometer to indicate their own temperature.

With these precautions it was found possible on some occasions to make measurements with the absolute electrometer accurate in absolute electrostatic units to about $\frac{1}{10}$ per cent., in so far as the authors were able to judge; but it was found that on many days there was an error of about $\frac{1}{2}$ per cent. in the constant of the instrument, due to some inherent defect, intermittent in its action, which could not be satisfactorily explained.

A theoretical investigation is given to determine the most suitable values of the mass to be used for the initial adjustment of the coach-springs, and of the potential difference to which the electrometer should be charged, for the heterostatic measurement of a given potential difference, with the result that the former should be proportional to the $\frac{3}{2}$ power, and the latter to the first power of the potential difference to be measured. It is also shown that, in addition to the well-known advantages of the heterostatic over the idiostatic method, there is the additional advantage that the error in the ordinary assumption as to the value of the effective area of the attracted disk is of far less importance in the former than in the latter method.

Finally an investigation is given in which Schwarz's method is applied to determine the error in the ordinary assumption as to the value of the effective area, for the case when the disk and guard-ring are not quite in the same plane.

Geological Society, January 8.—Dr. Henry Woodward, F.R.S., President, in the chair.—A delimitation of the Cenomanian, being a comparison of the corresponding beds in Southern England and Western France, by A. J. Jukes-Browne and William Hill. The object of the authors has been to compare the beds which form the lower part of the Upper Cre-

taceous series in those parts of Southern England and Western France which are nearest to one another. They claim to have defined the limits of the Cenomanian stage in Western France, and to have shown that this group of beds is simply a southern extension of our Lower Chalk, formed in a shallower part of the Cretaceous Sea and nearer to a coast-line.—The Llandovery and associated rocks of Conway, by G. L. Elles and E. M. R. Wood, Newnham College. In the paper a full description of the representatives of the Birkhill, Gala (Tarannon), and Wenlock beds was given, and the distribution of the fossils (chiefly graptolites) in the various subdivisions was recorded. Many of the graptolites are forms which had been described from Swedish deposits, but had hitherto been unrecorded in this country.—The gypsum deposits of Nottinghamshire and Derbyshire, by A. T. Metcalfe. The gypsum deposits of these counties occur in the Upper Marls of the Keuper division of the Triassic system. The author described their occurrence in thick nodular irregular beds, large spheroidal masses, and lenticular intercalations, and their association with satin-spar, alabaster, selenite, and anhydrite.

EDINBURGH.

Royal Society, January 6.—The Hon. Lord M'Laren in the chair.—Dr. Buchan submitted a paper on the high temperatures of September, and the Ben Nevis observatories. He described briefly the weather of September generally, which was markedly anticyclonic, and selected for consideration the 28th, 29th, and 30th of the month, as being characteristic in an intensified degree. On these days, the state of the atmosphere at Fort William, and low levels in Scotland generally, was one of great humidity. On the top of the mountain, on the other hand, there was great dryness. It was the opinion of Prof. Tait, and other physicists whom he had asked, that when the vapour in the atmosphere existed as pure vapour, it was practically diatherminous to the sun's rays. Between the (reduced) barometer at the top of the mountain, and the barometer at Fort William with a temperature difference of four degrees, there was only a difference of half a tenth, while the calculated difference for such a difference in temperature should have been a hundredth. He considered this inquiry to be of value in the prediction of storms. —Dr. Knott read a paper on the strain produced in iron and nickel tubes in the magnetic field. He described the apparatus used, and the numerous difficulties to be overcome, and exhibited graphs of the volume-changes of the tubes. He had found the behaviour of steel tubes so extraordinary that he reserved it for further treatment.—Prof. Tait described some further work he had done in the study of the path of a rotating spherical projectile. From the equations involved he had deduced the paths which such a moving body should follow, and, though some of these looked extraordinary, being concave *upwards*, and even looped, he was not without hopes of reaching them in practice. He had already succeeded in the case of some of them, with a teetotum.

DUBLIN.

Royal Dublin Society, December 18, 1895.—Prof. A. C. Haddon in the chair.—Mr. A. Francis Dixon read a paper on the development of the branches of the fifth cranial nerve in man. The paper was illustrated by models of the fifth cranial nerve in five different stages of the human embryo.—Prof. Grenville A. J. Cole read a paper on the rhyolites of County Antrim, with a note on bauxite. These rocks, often spoken of as "trachytes," occur as isolated exposures among basalts. At Templepatrick, rhyolite is seen to be intrusive in the Lower Basalts; but elsewhere the junctions are quite obscure. The author believes that there is not justification for the construction of sections showing the supposed relations of the rocks; but he urges that the mass at Tardree Mountain is very complex, and he calls special attention to the extensive flows of fluidal, perlitic, and spherulitic lavas at Sandy Braes. The various rocks are described in detail, and a survey of this area suggests that the pale bauxites of Co. Antrim have been derived from the decomposition of the rhyolites. Soluble salts of aluminium may have been formed throughout the lavas by the action of solfataras, &c.; waters containing alkali-carbonates may have acted on these, causing the precipitation of the basic aluminium carbonate studied by MM. Urbain and Renoul; and the extreme instability of this compound may have given rise to aluminium hydrate, which would be washed down into lakes during the interval between the outpouring of the Lower and Upper Basalts, together with the iron oxide also found in bauxite. At Ballycloughan, north of Ballymena, a distinctly biotitic rhyolite occurs as an intrusive neck; and at Cloughwater there is a patch of most delicately fluidal character; both these have vertical flow-planes. The rhyolites of Co. Antrim are often poor in ferro-magnesian minerals, but soda-pyroxene is common at Carnearny and on Sandy Braes.—Prof. James Lyon described a system of hot-water supply for domestic purposes. In the case of hot-water supply by means of domestic boiler and circulating cylinder, in order to obviate the necessity for drawing off a quantity of cold water from the rising pipe before the hot water can be obtained, the rising pipe is often returned near the bottom of cylinder to produce circulation. When this is done a flap valve of special construction should be placed at the latter point, to prevent cold water supply from flowing from bottom of cylinder, and thus mingling with the hot water which is being drawn.

PARIS.

Academy of Sciences, January 27.—M. Cornu in the chair.—On the equilibrium of an elastic body, by M. H. Poincaré.—Of the utility of photography by the X-rays in human pathology, by MM. Lannelongue, Barthélemy, and Oudin. In diseases in which there is an actual loss of substance of the bone, or an abnormal growth of bony tissue, the photographs taken by the Röntgen method confirm the previous diagnosis.—On a non-linear differential equation of the second order with doubly periodic coefficients, by M. Hugo-Gyldén. A particular solution of an equation of importance in astronomy. Application is made of the solution to the planet Hilda (153) with a satisfactory result.—Biological studies on some Hirudinia, by M. A. Kowalevsky.—On the linear equations and the method of Laplace, by M. E. Goursat.—On the addition of the arguments in the periodic functions of the second order, by M. G. Fontené.—On the complete solutions of the equation

$$x_1 \tan^{-1}\frac{1}{\kappa} + x_2 \tan^{-1}\frac{1}{\kappa_2} + \ldots + x_n \tan^{-1}\frac{1}{\kappa_n} = k \cdot \frac{\pi}{4},$$

by M. Carl Stormer.—On certain invariants relating to a group of Hesse, by M. Boulanger.—On groups of operations, by M. Levasseur.—Theory of pitching on a rolling sea, by M. A. Kriloff.—Some properties of the Röntgen rays, by M. Jean Perrin. The conclusion is drawn that these rays are not identical with the kathodic rays, since the latter cannot pass out through vacuum tube walls of 1 mm. in thickness. The propagation of the Röntgen rays is shown experimentally to be linear; they are not reflected either by a mirror of polished steel or of glass, neither are they refracted by prisms of paraffin or wax. Unsuccessful attempts to form diffraction fringes showed that if the phenomenon is periodic, the period is much below that of green light.—Observations on the preceding communication by M. Poincaré, pointing out that Prof. Röntgen has already shown that the X-rays are not refracted.—Dark light, by M. Gustave Le Bon. An ordinary photographic dry plate, placed under a negative in a printing-frame, and the negative closely covered with a thin plate of iron, was exposed to the light of a paraffin lamp for three hours. Vigorous and prolonged development brought out a faint but well-defined image. If a plate of lead was wrapped round the back of the frame, and bent over the edges of the iron plate so as to enclose the printing-frame in a metallic box, after three hours' exposure to the same source of light an image was obtained "which was nearly as vigorous as if no obstacle had been interposed between the light and the plate." M. Le Bon proposes to continue the study of the properties of light after its passage through opaque bodies.—Action of heat on mercurous iodide, by M. Maurice François. To avoid the complications introduced by the presence of air, the mercurous iodide was heated *in vacuo*. The reaction is a limited one, equilibrium resulting when a fixed amount (depending on the temperature) of mercurous iodide has been broken up into mercury and mercuric iodide. Hence the reaction is reversible, and the same state of equilibrium results if mercury and mercuric iodide are taken and heated together.—The absorption of light by solutions of indophenols, by MM. Bayrac and Ch. Camichel. A quantitative study of the absorption spectra of homologous indophenols in various solvents. Relations are indicated between the positions of the absorption bands, concentrations, and molecular weights. One compound, obtained by the general method of preparation of indophenols from mono-methyl-resorcinol and *p*-nitroso-dimethyl-aniline hydrochloride, gives quite anomalous results, and hence the conclusion is drawn that this body is not an indophenol.—Combinations of aluminium chloride with phenols and

their derivatives, by M. G. Perrier.—On Russian essence of aniseed, by MM. G. Bouchardat and Tardy.—On the production of pure gaseous formic aldehyde, by M. A. Brochet. For the purposes of disinfection by gaseous formic aldehyde, free from water vapour, a current of a warm indifferent gas (nitrogen or carbon dioxide) is passed through a tube containing fragments of trioxymethylene. The quantity can be regulated by altering the temperature.—On antivenomous serum, by MM. Calmette, Hankin, and Lépinay. An account of some experiments with a serum, the injection of which protects the animal from snake venom.—On some points in the anatomy of *Tetraclita porosa*, by M. A. Gruvel.—New form of negative reaction on the retina, by M. Aug. Charpentier.—Proofs of the submarine extension to the south of Marseilles of the Maures and Esterel group, by MM. Vasseur and Fournier.

BERLIN.

Physical Society, December 13, 1895.—Prof. Warburg, President, in the chair.—The President referred to the deaths of Prof. Knoblauch, of Halle, and Prof. Spörer, of Potsdam.—Prof. Des Coudres spoke on kathodic radiation, and demonstrated its sensitiveness to magnetic lines of force.—Prof. Neesen described two interesting strokes of lightning, of which one pierced the roof of a church-tower unprovided with a conductor, and stopped short at the organ. Its effects were characterised by the rents it made in the inside of the church above the organ, similar to those observed in a tree when struck. The second struck a petroleum store, whose four tanks were each protected by five-pointed conductors adequately put to earth. Two of the tanks were completely shattered by a violent explosion, the other two burnt out by fire. The speaker was of opinion that the petroleum vapours above the tanks had been ignited by small sparks during the discharge, and he had verified this view by experiment; he therefore proposed that for the purpose of adequate protection all openings, more particularly manholes, should be guarded by wire netting, on the principle of the Davy lamp.—A small instrument was exhibited by Mr. von Hefner-Alteneck for demonstrating minute variations of atmospheric pressure. It consists of a flask, whose neck communicates with a horizontal glass tube, whose central portion is bent slightly downwards; in this tube there is an extremely mobile index of coloured petroleum, which follows the least change of external pressure. The apparatus is one hundred and fifty times more sensitive than a mercurial barometer.—Prof. Neesen criticised a recently published method of measuring the velocity of projectiles. It consists in making the projectile close and open a current which passes spirally round a tube containing carbon bisulphide; the plane of polarisation of this fluid is rotated during the time of flight, and hence a beam of light previously extinguished by crossed Nicols can now pass through, and make a record on photographic paper.

Physiological Society, December 6, 1895.—Prof. H. Munk, President, in the chair.—Prof. I. Munk reported on further experiments as to the minimal proteid requirements of a dog during nitrogenous equilibrium.

December 20.—Prof. H. Munk, President, in the chair.—Dr. Cohnstein reviewed the laws of osmotic pressure from the existing point of view of physical chemistry.—Dr. Rosenberg spoke on reported cases of presumed regeneration of the bile duct some twenty days after its extirpation. He reported a case of a lateral branch from the duct recently observed in a dog and leading into the intestine, and urged that the possible existence of such a branch should have been in every case disproved before concluding that a regeneration of the duct had taken place.—The President exhibited a section of an elephant's tooth, which showed a circular green streak round the outer border of the pulp cavity.

POPULAR GEOLOGY.

Open-Air Studies: an Introduction to Geology Out-of-doors. With illustrations. By Prof. Grenville A. J. Cole, M.R.I.A., F.G.S., &c. Pp. viii + 322. (London: Griffin and Co., Limited, 1895.)

PROF. GRENVILLE COLE has already won himself wide repute as a writer on geological science by his book, entitled "Aids in Practical Geology" (Griffin and Co.). There Prof. Cole treated the branches of mineralogy, petrology, and palæontology, dwelling more particularly on methods of work in laboratory and museum. This recent publication, "Open-Air Studies," breathes another atmosphere, lighter, gayer, and for the popular mind more enticing. The Professor leads his readers, like a class of students, into one countryside after another, makes use in imagination of bicycle and railway on the low ground, ascends boldly into glacier-swept regions, and roams at will across moorland and highland Everywhere he directs their powers of observation, drills great facts into them by presenting particular aspects again and again as occasion offers. Now and then the Professor calls a halt to recapitulate, set in order, or give more careful demonstration of stratigraphical difficulties.

The "Open-Air Studies" are ten in number. The author gives the key-note in his preface: "In our walks abroad we may be struck by this or that detail, seemingly trivial in itself, which finally leads up to some one of the vexed problems of the globe." The first chapter gives some preliminary teaching on "The Materials of the Earth," the rock-forming minerals being carefully examined. It is not until chapter ii. that the author takes his pen into the "Open Air." We are told: "We must imagine that we wake up on a fine clear morning at the foot of some of our wild mountain-masses in the British Isles" (p. 28), and we are guided up a swirling stream, past pools and waterfalls, to "a mountain hollow." On our way, our professorial guide bids us do many simple things. We have to "dig for a little while with a walking-stick," that "we may be able to see the tiny streamlet flowing"; we have to note that the "loose blocks, half buried in the grass, are made of the same materials as the cliffs"; to watch how, if some one kicks a stone, "it goes bounding down across the grass, it leaps over one or two of the little cliffs, and so descends until it rests on some lower ledge of the hill-side" (p. 30). Then we put our fingers into pot-holes, and move the pebbles in them, and we watch the stream washing down its load of mud and pebble, and listen to its rattling stones.

In this manner the pleasant little object-lesson is continued, and the attentive follower is made to observe for himself the forces of denudation at work on a mountain-side. Arrived at the mountain-tarn, the Professor is beguiled by the endless questions which rise to our lips into delivering quite a learned lecture on nature's tools—cloudland; wind, dew, and rain; frost, ice, and snow; stream, glacier, and avalanche. In the midst of it, we find ourselves frequently transported to glaciated Alpine valleys. Cirques are described and explained, an illustration is given of a snow-filled cirque on the Matterhorn, and applied to the past history of our own mountain-hollows.

From the tenour of this chapter, which is a fair type, it will be seen that Prof. Cole limits the subject-matter of his new book to that contained in any ordinary elementary text-book of geology. Familiar truths are re-set, and any claim to originality or success rests entirely upon the workmanship and brilliancy of that re-setting.

If we rightly understand Prof. Cole's method, it is the antithesis of the analytic method practised by a text-book writer. The latter passes, as it were, the diffuse light of knowledge through his own prism-acting mind, and it appears on his manuscript as a fully-resolved spectrum in which every band of colour is clearly presented to the student. Prof. Cole's method, on the other hand, is to call upon each student to make his own mind the prism. Observations, massed together with all the local details of nature, are thrown upon the student's mind, which may or may not be fit to act on its own account as a clear prism. Theoretically the system is laudable, but decidedly unstable. The author himself succeeds in carrying it out only through about one-half of the 313 pages of "Open-Air Studies." Certainly half the chapters—i., vi., vii., viii., and x.—are really text-book studies, and these are, moreover, the most concise and complete in their treatment.

To proceed with the actual contents, chap. iii. is called "Down the Valley." Its central theme may be thus expressed, in the words of the author: "The story of all streams is alike—excavation at one end and deposition at the other; and the area of deposition extends slowly back up the valley as time goes on" (p. 80). A typical Tyrolese valley is made the main basis of observation. The cutting of deep gorges by torrential side-streams, the spreading-out of talus-cones at the mouth of tributary valleys, the "creep" of a hillside downwards, landslips, the occasional damming up of the stream and formation of a lake, the resulting wide agricultural flats where these become later silted up or drained—these and other features are described with copious reference to famous scenes and incidents in the Alps.

The river Rhine is studied between Chur and the Lake of Constance, to illustrate alluvial deposits and the variations which take place in the course of a river. A "delta" is defined, examples given, and brought home to us by the remark that "an enterprising child with a spade can soon produce a shallow lake, and can observe how it becomes filled and obliterated by the encroachment of a delta at its upper end" (p. 86).

The main discussion of deltas, however, falls into the following chapter, "Along the Shore." There, too, the first lessons on sedimentary deposits are given. The abrasion of a coast-line by the action of the waves, leads up to an explanation of Sir Andrew Ramsay's term "plain of marine denudation." The author then goes on to show how the worn-away material is reconstructed into different kinds of strata bedded beneath sea, lake, and river. Even deep-sea deposits of siliceous organisms, the growth of coral-reefs, and the formation of oolites find a place here, although the chapter begins and ends

with the description of a pretty fishing-village, low cliffs, and a coastguard station!

Chapter v., "Across the Plains," is probably the most successful in the book. Written in the same style as those just described, it is distinctly more realistic and dignified in its tone. The subject-matter is also more coherent, and its treatment—for the scope of the book—exhaustive. Were all ten chapters equal to this one, we would say Prof. Cole had been most successful in carrying out a set purpose pleasantly and beneficially for cultured readers who travel at home and abroad. But unfortunately the high-water level is seldom reached in the book.

Chap. vi. dips into the lore of "Dead Volcanoes," starting with the highland of Auvergne, and returning to our own islands. Chap. vii. is a careful study of "A Granite Highland," and generally of igneous rocks. "The Annals of the Earth" (chap. viii.) gives a general account of the stratigraphical succession. Chap. ix., "The Surrey Hills," is a very happy combination of the art of seeing and describing beauty of landscape, along with the practical demonstration of the principles of stratigraphy. It resounds with the stroke of the geologist's hammer, and the enthusiasm of a true guide and teacher. Chap. x., "The Folds of the Mountains," will be to most readers difficult, as it deals with the hard subject of the making of mountain-chains. The Alps are mainly considered, the writing is admirably clear, and the doctrines taught are in accord with all the newest researches.

It remains to add how often passages occur throughout the book which remind us of the artistic feeling for nature displayed by the author in a previous publication, "The Gypsy Road." Every small detail in a scene is touched with a sympathetic, kindly pen, that reminds one of the lingering brush of a Constable. Take his description of Fenland:

"From Cambridge northward to the estuary of the Wash, there are forty-five miles of level ground. . . . Between the scattered villages lie areas of black peat, covered with coarse grass, and dug into here and there for fuel. The roads are carried along the crests of broad embankments, with dark, little drainage-cuts on either side of them, crossed by bridges to the fields. A few trees cluster round the old farm-houses, protecting them from the winds that sweep across the fenland steadily for weeks together. . . . The sky is usually full of great cumulus-clouds, dark grey below and silvery white above, where the sunlight strikes through them in long shafts across the grey-green plain. A church-tower or a windmill is visible ten miles away, when touched on by these sudden gleams; then it sinks back again into the great gloom of the horizon" (p. 121).

Taken as a whole, the book fails, in so far as it constantly mixes together two distinct styles of writing, the picturesque and the didactic. It is at the same time eminently readable, and will be warmly hailed by many lovers of geology out-of-doors. A solid groundwork is formed by the five chapters referred to above as partaking of the text-book method. The others are somewhat of a skim-swallow type, too rapid in their course, too overladen with detail and local colouring, to be adapted either to the serious wants of a student or to the slow apprehension of a complete novice in nature's fields. The book will appeal most to the dilettante student, or to the tourist who has already had abundant opportunity of observing, who delights in finding his own dim perceptions vividly mirrored by a trained scientific mind, and in seeing them marshalled towards the solution of "vexed problems of the globe."

Maria M. Ogilvie.

PRIMITIVE PICTURE-WRITING.

The Beginnings of Writing. By Walter James Hoffman, M.D. With an Introduction by Prof. Frederick Starr. Pp. xiv + 209. (London: Macmillan and Co., 1895.)

THERE is no more fascinating subject for study than the development of the art of writing through its various stages, from the first rough pictures drawn by primitive man to the alphabets in use among the civilised nations of the present day. But the historic systems of writing go back to a remote antiquity, and although we can trace some of them back many hundreds of years, the question of their first origin is one that is beset with many difficulties. It is at this point, however, that the anthropologist comes to the antiquary's help, for he shows that the mind of savage man always works along the same general lines of development. All primitive races, whether in China, Central India, Western Asia, Europe, North Africa, or North America, have used the same rude means to record their thoughts and actions, scratching on their rocks or weapons rough pictures of their possessions and pursuits. The methods used by hunters of the Palæolithic age to record a successful hunting expedition resemble those which the North American Indian now employs. From these rude pictures the savage passes, by a natural law of development, to the representation of ideas, expressing motion or condition by means of gesture-signs. Then, after certain pictures have become associated with certain words, he begins to use them to express their sound but not their meaning; in fact, he begins to write phonetically. His pictures, as he writes more rapidly, change to signs, which become more and more simplified, and finally his system of syllabic writing he develops still further till he reaches the most perfect phonetic system of writing, the alphabet.

Such in brief are the main lines of development which all races follow who work out for themselves the art of writing, and it is this attractive subject that Mr. Hoffman has selected for his book. In the brief preface in which Prof. Starr introduces him and his book to the reader, we learn that he has for some years been engaged both in field-work and study among the Indian tribes of North America, and from his book itself we find that his studies have resulted in a most interesting collection of the various methods of writing employed by these primitive races. It is true that many of his examples are already well known from other publications, but the collection does not aim at being original, for the book belongs to an educational series, where original work would be out of place. What was wanted, and what in the main Mr. Hoffman has given us, was a representative collection of the various methods of writing employed by the North American Indians. These are here classified, described clearly and illustrated with numerous small cuts; and for this part of his work we have nothing but praise. But why did not Mr. Hoffman confine his book to the subject in which he is in a sense a specialist? Why did he seek

to extend the aim of his volume so that it might apply to the beginnings of writing all the world over?

Yet such an extension Mr. Hoffman has attempted in the course of about 200 *octavo* pages printed in large type. The result was inevitable. The lion's share of the little space at his disposal falls naturally enough to the North American Indians with whose pictographs and writing he is most familiar; but, in consequence of this mistaken aim at universality, the book is peppered here and there with Egyptian hieroglyphs, once or twice a cuneiform character crops up, and we have even come across a Christian symbol. In many places, therefore, the work is patchy, and the reader is in some danger of bewilderment. Moreover, this is not the only danger to which Mr. Hoffman exposes his readers, by rashly leaving the ground he knows; for his studies have not been sufficiently extended to enable him to act as a trustworthy guide elsewhere. He is certainly wise in making considerable use of "The Alphabet," by Isaac Taylor, but some statements made twelve years ago naturally now-a-days need revision. For instance, the dates he quotes at the beginning of p. 184 must now be considerably altered in view of M. de Sarzec's recent discoveries at Telloh in Southern Babylonia. But perhaps the most misleading portions of the book are those passages in which he refers to the so-called "Hittite" inscriptions. Here Mr. Hoffman's authorities are not so trustworthy as Mr. Taylor, and the result is disastrous. From his description of these hieroglyphs, the reader would certainly infer that no doubt existed as to their interpretation, but no impression could be more erroneous. The four or five systems of interpretation that have been proposed, and the last of which appeared less than two years ago in the *Zeitschrift* of the German Oriental Society, differ totally from one another, and are mutually exclusive; that is to say, each interpreter has employed a different method and system of interpretation, and, although they all work on the same inscriptions, the translations they have produced do not agree at all. Of course Mr. Hoffman is at liberty to select one of these systems and to say it appears to him to be correct, but to take the results of one of them, and to describe them as though they were universally adopted without reference to the controversy which still rages, is surely misleading in the highest degree. Moreover, on p. 158 occurs this rather puzzling sentence: "In the Akkadian, *a* signifies 'water' . . . and is represented by the inverted triangle, the prototype in Hittite being the vase or *olla*." If we take this sentence literally, we can only infer that Mr. Hoffman considers the earliest cuneiform character to be the descendant of the Hittite hieroglyphs. We think, however, that he cannot seriously hold this view, and that the sentence referred to does not rightly express his meaning.

It is not necessary, however, to dwell at greater length on the blemishes which mar an otherwise excellent book. They might, indeed, have been avoided by the exercise of a little discretion, and the book would have been none the less interesting if its contents had been confined to the beginnings of writing among the tribes of North America. Even as it is, the greater part is both interesting and instructive, and the excellent print and numerous diagrams add considerably to its attractiveness.

OUR BOOK SHELF.

Elements of Geometry. By Prof. George C. Edwards. Pp. vii + 293. (London: Macmillan and Co., 1895.)

PROF. EDWARDS has forsaken the general sequence of parts in the study of the elements of geometry as propounded by Euclid, and has given us a book almost on a new plan. It must have been felt by most people, when in their early school-days they commenced to read Euclid's Elements, that much of the first few pages was almost unintelligible; and while no one would take exception to the rigidity of the methods there used, yet it would be exceedingly difficult for the average beginner to comprehend many of the definitions from the text alone without further *viva voce* explanation.

The substance of Euclid's Elements may be condensed into a very small fraction of its present dimensions for all practical purposes without losing any of the rigidity of argument or usefulness in application, and in this way a student may understand the proportionality of the sides of similar triangles without previously wading through four or five books. Prof. Edwards has arranged his book in this condensed form, and at the same time has presented his subject in a manner which attracts the attention of the reader by its simplicity and usefulness. One feature of this book is the great number of diagrams and figures which it contains; and where more than one figure is required with any one proposition, they are all carefully and separately given. The author does not overload the student with a mass of definitions at the commencement, but introduces them with explanations, when required, in the context. The usual mathematical conventions are introduced very early into the subject-matter, such as signs to denote directions; and the usual contractions are freely used, a table of them being given at the beginning for reference.

The first three chapters deal with propositions which relate to triangles and parallel lines; chapter iv. deals with the properties of circles; and chapter v. with areas, and the proportional relations of similar figures. This is one of the most important sections of the book, and includes some useful results which are generally obtained from books on trigonometry. Immediately following we find a chapter devoted to chords and tangents, and another to polygons and limits, including finding the value of π. Then follow over thirty pages of problem questions, with hints to some of their solutions, and innumerable figures to illustrate them where necessary. No pains appear to have been spared to make the whole as clear and intelligible as possible.

We then find a few chapters on solid geometry, which include matter dealing with surfaces, volumes, intersection of surfaces, and spherical triangles. The last chapter contains some useful propositions in conic sections.

Throughout the book there are a great number of examples, notes, suggestions and warnings to the reader, which should be of especial value to those who have not pursued the study of geometry to any extent previously. Altogether the book is a valuable one for any educational institution, and exceptionally so to technical students.

Elementary Mensuration. By F. H. Stevens, M.A. Pp. xii + 243. (London: Macmillan and Co., 1895.)

Mensuration. By the Rev. A. Dawson Clarke, M.A. Pp. vi + 88. (London: Rivington, Percival, and Co., 1895.)

MR. STEVENS' book is divided into two parts, the first only requiring a knowledge of Euclid's first book, and the use of algebraic symbols, in order to understand it; while the second part necessitates a much fuller acquaintance with geometry and algebra, and a slight knowledge of trigonometry. The book is not technical, but contains a thorough treatment of those principles upon which

all calculations of dimensions depend, and therefore it will be valuable as an introduction to works concerned with special practical applications of the rules described and exemplified. Moreover, it should play a useful part in schools, by illustrating the concrete applications of abstract geometrical principles. The large number of original examples will be found of great assistance by teachers, and the questions, selected from papers set by the principal examining bodies, will prove of service as tests of the students' capabilities in working out mensuration problems.

Of a less detailed character is the Rev. Dawson Clarke's primer, intended "for the use of schools, and Woolwich, Sandhurst, and Home Civil Service candidates." The book is a collection of rules and formulæ, with examples to explain their use, and numerous exercises selected from various examination papers. It particularly appeals to students who learn the rules of mensuration in order to utilise their knowledge in the examination-rooms of the Civil Service Commissioners; but it is, also, a concise text-book which other students will find serviceable.

Physical Measurements. By Frank C. Weedon. Pp. 232. (London: G. Gill and Sons, 1895.)

This volume is another help towards the establishment of rational methods of instruction in elementary science. It is a laboratory manual of practical physics for organised science schools under the Department of Science and Art, and other secondary schools. Of the educational value of the course contained in the book, there can be no doubt; for the experiments (which are of a character suited to beginners) follow a natural order, and are such as will develop the faculties of observation, investigation, and common sense; in fact, they will lead the student to think as well as learn. The book is divided into three sections, dealing respectively with measuring and weighing, relative densities, and experimental mechanics. Experiments on these matters elucidate the fundamental principles which form the basis of a scientific education. The knowledge cannot be labelled "Sound, Light and Heat," or "Magnetism and Electricity," and therefore superficial critics, and syllabus-bound teachers, think it is not Physics. We are of the opinion, however, that experimental work in measuring and weighing, constitutes the foundations of physics. The student who is able to weigh and measure carefully, and to observe and think accurately, knows more of the realities of physical investigation than if he had spent a dozen years in learning scraps of information about other people's contributions to knowledge.

LETTERS TO THE EDITOR.

The New Actinic Rays.

A brief account of some experiments which I have been making in my laboratory at Blythswood, in connection with the new photographic rays, may, I hope, be of interest to the readers of Nature.

Three or four years ago I constructed a very powerful Wimshurst electrical machine. It has 128 plates, three feet in diameter, and is driven by an electric motor of about 1½ horse-power. With this machine, which was specially built for quantity, I can obtain a torrent of sparks a foot and a half or two feet long: and it occurred to me to try to obtain photographs, after the manner of Röntgen, but without the intervention of a vacuum tube.

A thick sheet of lead was placed upright between the poles of the electric machine, as a screen, and was connected to the ground, the two poles being insulated. A sensitive dry plate was put into the camera dark slide, with a metallic object to be photographed (a steel washer with holes in it), and this was connected, by a wire which passed out of the dark slide, to the ground. The whole was wrapped up in four folds of a black velvet focussing cloth, and was put, in some cases between the negative pole and the lead screen, and in other cases between the positive pole and the lead screen, the plane of the slide being perpendicular to the line of discharge. In all cases good strong negatives were obtained with exposures of about twenty minutes. The machine was arranged to give a silent brush discharge during the experiments.

I next tried similar experiments with the dark slide containing the sensitive plate quite out of the line of discharge, and with the plane of the plate parallel to the line of discharge, and obtained equally good results. It seems, therefore, that the vacuum tube is not essential to the production of the Röntgen rays. With reference to this, however, I am not so sure, as I think I may have been deceived by using isochromatic plates—at all events I am engaged in further experiments either to confirm or the contrary. Blythswood.

Blythswood, Renfrew, February 10.

With reference to Mr. Porter's letter regarding the amount of electric energy and exposure required for obtaining photographs by the Röntgen method, I may mention that against his photograph taken with a 3-inch coil and four minutes' exposure, I can instance a successful human foot that shows the bones very distinctly almost up to the ankle-joint, in taking which I used a 10-inch coil working at about half power without Leyden jars, and for which fifty-five seconds' exposure proved ample.

For living physiological subjects, it is very important to shorten the exposure as much as possible, and to attain a minimum in this respect, very high vacua and considerable E.M.F. are requisite.

Again, for an extensive subject, a large tube placed at a considerable distance from the subject is required, and more electric energy is needed for this than for a small subject, for which a smaller tube in closer proximity will suffice.

66 Victoria Street, S.W. A. A. C. Swinton.

Having made some experiments on the lines laid down by Mr. Gifford, of Chard, I think the two enclosed photographs will prove of interest, as showing perhaps that Mr. Gifford's method of dispensing with a Crookes' tube introduces elements of another character. Both these negatives were taken without a tube, using the discharge from the terminal of a small Tesla transformer. In each case a metal plate was placed behind the film in communication with the other terminal of the coil. Under these conditions a stream of "discharge" passes from one terminal through the photographic film.

The interesting point is that not only does the outline of the coin come out, but also the impression. And that in the case of the florin the coin was placed *behind* the film. The same sparking appearance as described by Mr. Gifford is evident.

From the fact that it is immaterial on which side of the photographic film the coin is placed, it is evident, I think, that we have here to do with a "contact" phenomenon, and not with Röntgen's rays at all. Sydney D. Rowland.

"The Astronomical Theory of the Glacial Period."

As it was my two letters which initiated the interesting and not unfruitful discussion now going on in your pages on the above subject, I think it right to say a few words in reply.

The object of my letters was to point out (perhaps I did it in somewhat too heated language) that Sir Robert Ball, whose personal and official distinction give his words exceptional weight, had in his work entitled "The Cause of an Ice Age" given fresh currency to a discredited theory, and further that when this had been pointed out, he had refused to take any notice of his critics, and continued to publish his book.

In his letter to you, Sir R. Ball (if I do not misunderstand him) entirely breaks away from the position maintained in his book, and gives up the case there argued, definitely and completely. While Prof. Darwin, who had given the book the advantage of his friendly recommendation and countenance, tells us he is now reluctantly compelled to take the other side.

So far as I know, there does not now remain a single mathematician or astronomer who favours a purely astronomical theory of an Ice Age; a theory which, as Arago, Humboldt and Croll, all urged long ago, is quite inadequate to explain the climatic effects required. Every one, as far as I know, now agrees with the American astronomer Meech, who subjected the astronomical theory to a most searching analysis, as far back as 1857, that "the causes of notable geological changes must be other than the relative position of the sun and earth under their present laws of motion." It is with this sentence that I close my own analysis of the problem in chapter ix. of my "Glacial Nightmare."

As I understand, Sir R. Ball in surrendering his old view, which was *that astronomical causes by themselves* are sufficient to produce an Ice Age, falls back upon a modification of Croll's meteorological argument. While, however, he no longer relies on the adequacy of astronomical causes alone as competent to produce an Ice Age, he does not admit the conclusiveness of Mr. Culverwell's argument, but bids us remember that the world cannot be cut up into a number of parallel zones shut off from each other by solid partitions, each one of which can be treated as a separate climatic region, but that the climate of every zone is very largely indeed the result of heat brought in or carried away by air and water from or to other zones. No one disputes this. It is in fact an elementary postulate of meteorology, and applies as much to Sir R. Ball's arbitrary zone termed a hemisphere as to any other.

What we want Sir R. Ball to do is not to rest content with this barren postulate, but to apply it as Croll applied his postulates, and to prove that, granting the greatest possible alteration of the relative length of the seasons due to eccentricity, &c., which, as Mr. Culverwell has shown, will by itself tend to shift the climate of each zone about five degrees, how is this going to affect the circulation of the air and of ocean currents sufficiently to constitute an Ice Age? This was the problem Croll virtually set himself to analyse by a minute and ingenious investigation.

Croll's arguments have been riddled through and through by several writers, and in this behalf I may perhaps venture to again refer to a minute dissection of them in a chapter, headed "Transcendental Meteorology," in the work already cited, namely, the "Glacial Nightmare," and which I have been told by some eminent physicists is unanswerable. I can, at all events, say it has not been answered.

If Dr. Ball can discover some method of curing the radical defects of Croll's arguments, he will have made us a valuable present. Meanwhile, if I do not entirely misunderstand his present position, it is more clear than ever that he owes it to us all to withdraw his "Cause of an Ice Age" from circulation, for it has not only been condemned by its distinguished and formerly friendly critic, but has been actually condemned by its own author. HENRY H. HOWORTH.

Athenæum Club, January 30.

The Positions of Retinal Images.

PROF. KULPE, in his "Outlines of Psychology" (translation by Prof. Titchener), sets out with much effectiveness the argument in favour of believing that the visual perception of extended surface is an original datum of consciousness attached to the extended retinal surface (and no more to be explained than why the sensation red feels the way it does, and not otherwise); and he also shows conclusively that the peculiarity of nerve-excitation by which right- and left-ness and up- and down-ness are distinguished, is of peripheral (and not of central) origin; by adducing the facts of metamorphopsia, that is, the cases in which a portion of the retina has become detached by a wound, and has afterwards grown on again, and in which vision is correspondingly inverted—exactly as when a piece of the skin of the forehead has been grafted upon the nose, say, and upon touching it we seem, for a long time afterwards, to be touching the forehead. He thus attaches himself to the innate-space-sensation theory of James and Sumpf. But his effort to show that the out- and in-sensation is fundamentally dependent upon the different shape of the image cast upon the two retinas by an object, carries less conviction with it. This is, of course, an essential element of the sensation when the object looked at is so complex as to consist of two points at a given distance from each other. But when it consists of a single bright point only, we are still perfectly able to determine its position in depth (if it is looked at with two eyes), and the sensation-element which enables us to do this is plainly more *fundamental* than the other. To say the least, it is something which ought not to be overlooked.

It is plain that in this case the only criterion which is left us (granting, what is the case, that the localisation can be effected with certainty with two eyes, but only vaguely and indefinitely with one) is *the distance apart of the double images*; it is that which we estimate, unconsciously of course, in spite of the fact that one image is in one eye and the other in the other, and it is that which we translate, without difficulty, into a feeling of depth. But there is always an ambiguity; for every point, O (Fig. 1), without the horopter-circle, which casts images upon the retina at the points r and l, there is a congruent point, O′, within the horopter-circle, which casts images upon the corresponding retinal points, l' and r', and which, therefore, gives images which are at the same distance apart. We have no difficulty in sensation in distinguishing between a bright point at O and one at O′, but how can this be effected? There is still a difference in sensation between the two cases. The nasal half of each retina gives distinctly brighter images than the temporal half; in the case of the object O, which gives the two images, r and l, the remoter one is the brighter, while in the case of the object O′, which gives the images l' and r', it is the nearer one which is the brighter. A bright image of the object, which seems to us to be the thing itself, is attended by a somewhat fainter secondary self, whose presence we are absolutely unconscious of, in our non-scientific lives, as an image,[1] but which we evaluate with the utmost nicety as a sign of the distance away of the real object,

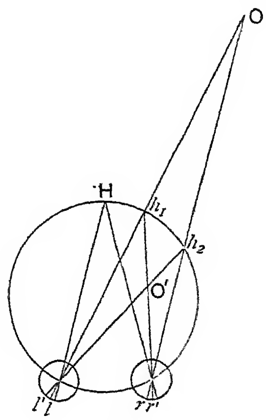

FIG. 1.

and which has, moreover, a different significance according as it stands nearer to, or further from, the fixation point than the image which we regard as the object itself. This explanation may seem at first to vary much in the air, but its correctness has been demonstrated by Schön in a very ingenious manner (*Arch. f. Ophthalm.*, xxii. and xxiv.). His experiment has been unaccountably overlooked by all the makers of text-books, as far as I have seen, but it is of critical importance. He arranges a series of screens with openings in them in such a way that *two different* bright objects are seen, one by the right eye only, in the line h_2 O produced, and the other by the left eye only, the line h_1 O produced. The *positions* of the double images now correspond equally well for an object at O or at O′; and the person experimented upon thinks he sees an object now at O and now at O′, exactly in accordance with the way in which the relative brightness of the objects beyond the screens is made to vary. When the image which falls at r is brighter than that which falls at l, the object is seen at O; when the image which falls at l is brighter than that which falls at r (sufficiently brighter, of course, to counteract the relative efficiency of the different halves of the retina) the object is seen at O′. It is therefore demonstrated that it is the relative brightness of the images which is the determining factor in enabling us to localise objects in one or other of the two congruent worlds without and within the horopter-circle. I have myself repeated the experiment with perfect success. C. LADD FRANKLIN.

Baltimore, January 13.

[1] There are many people who cannot bring the secondary image into consciousness, no matter how hard they try, when it falls at any distance from the fovea.

Brazilian station, and it affords me very great pleasure to bring this before you, because it enables me in this public way, as President of the Vesey Club, to tender thanks to Sir Benjamin Stone for the help he gave the Brazilian party.

We next pass to the results which were obtained by Messrs. Fowler and Shackleton, who were in charge of the instruments at the two stations. The diagrams will indicate the kind of celestial hieroglyph—to come back to the old image—we have to deal with when this method is employed.

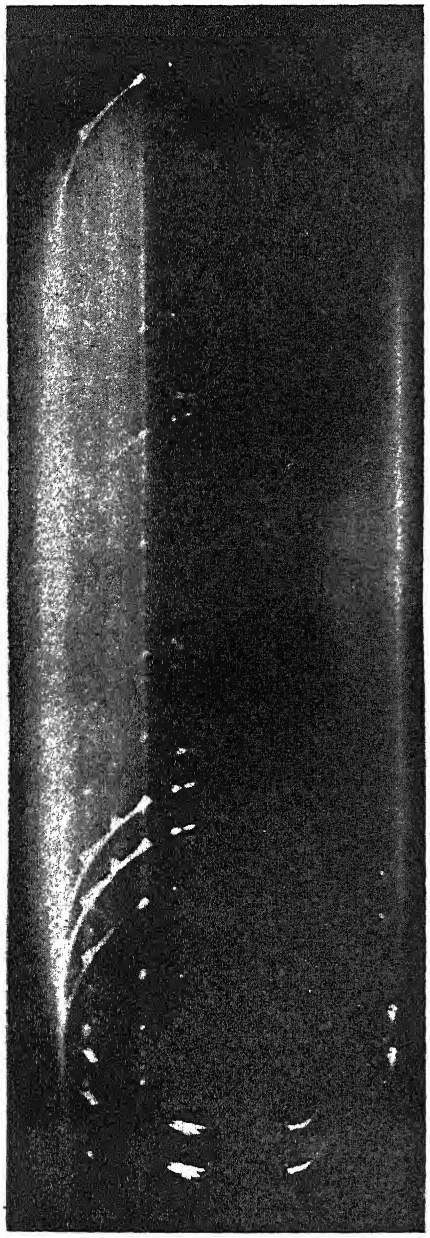

FIG. 11.—Untouched reproduction of photograph (African station) taken very shortly after the commencement of totality, the exposure being "instantaneous." At this phase of the eclipse a considerable arc of the chromosphere was visible, and its spectrum is therefore shown in addition to the spectrum of the higher reaches of some of the large prominences extending beyond the moon's limb. It will be seen that at H and K there are long arcs of chromosphere and prominences, the absent portions being of course obscured by the moon. One very small prominence is especially rich in lines.

We get more or less complete rings when we are dealing with an extended arc of the chromosphere, or lines of dots when any small part of it is being subjected to a disturbance which increases the temperature and, possibly, the numbers of the different vapours present.

The efficiency of this method of work with the dispersion employed, turns out to be very marvellous, and in securing such valuable and permanent records as these, you will acknowledge that we have done very much better than if we had contented ourselves with the style of observations that I have referred to as having been made in 1871.

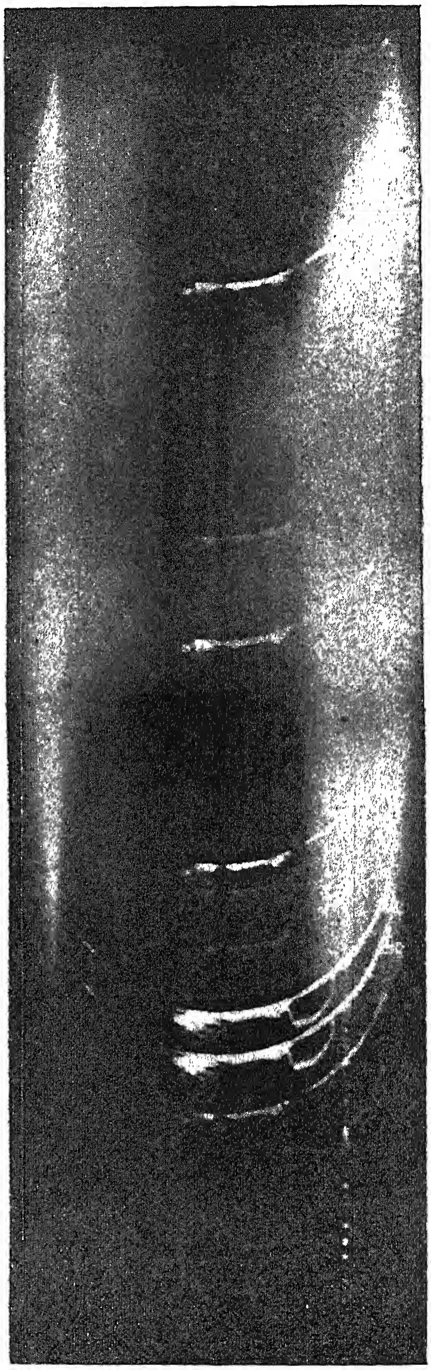

FIG. 12.—Photograph 21 (African station), taken shortly before the end of totality. A portion of the chromosphere on the other edge of the dark moon is now visible in addition to numerous prominences. It will be seen that one of the smallest prominences is rich in lines, and closely resembles that which appears in Fig. 11.

And now the plot of my story begins to thicken. On examining these eclipse records, we find that we have to do exactly with those unknown lines which had already been photographed in the stars and in the nebulæ.

As was to be expected we, of course, deal with the lines recorded in the first observations of the solar dis-

turbances, and chronicled in that table of Prof. Young's, to which I have already called attention; but the important thing, the unexpected thing, is the marvellously close connection between eclipse- and star-spectrum photographs.

CHAPTER V.

Again I recall you from the heavens to the earth; the time is the beginning of the present year.

You remember that last year was made memorable by the announcement of the discovery by Lord Rayleigh and Prof. Ramsay of a new gas called argon, and you know that the discovery was brought about chiefly in the first instance by the very accurate observations of Lord Rayleigh, who found that when he was determining the weight of air in a globe of a certain capacity, the weight depended upon the source from which he got the nitrogen.

From the nitrogen from atmospheric air he obtained one weight, and from that obtained by certain chemical processes he obtained another, and ultimately it was found that there was an unknown element which produced these results, these various changes in the weight; and as a consequence we had the discovery of argon.

It struck Mr. Miers, of the British Museum, that it might be desirable to draw attention to the nitrogen which we have seen Dr. Hillebrand in 1888 obtaining from his crystal of uraninite; his observations, of course, were more in the mind of Mr. Miers than in the minds of the pure chemists. He therefore communicated with Prof. Ramsay, who lost no time, because it was very interesting to study every possible source of nitrogen and see what its behaviour was in regard to the quantity of argon that it produced, and in the relation generally of the gas to the argon which was produced from it.

Prof. Ramsay treated uraninite in exactly the same way that Dr. Hillebrand had done in 1888. The gas obtained as Dr. Hillebrand had obtained it was eventually submitted to a spectroscopic test, following Dr. Hillebrand's example. But here a noteworthy thing comes in. *It so happened* that the pressure and electrical conditions employed by Prof. Ramsay were so different from those used by Dr. Hillebrand that, although nitrogen was undoubtedly present, the fluted spectrum which, as I have previously stated, floods the yellow part of the spectrum with luminous details, was absent. But still there was *something* there.

Judge of Prof. Ramsay's surprise when he found that he got a bright yellow line; that was the chief thing, and *not* the strong suggestion of the spectrum of nitrogen. Careful measurements indicated that the twenty-six-year-old helium had at last been run to earth, D^3 was at last visible in a laboratory. Prof. Ramsay was good enough to send specimens of the tubes containing this gas round to other people, and he sent one of them to me.

I received Prof. Ramsay's tube on March 28, but as it was not suitable for the experiments I wished to make, in his absence I obtained some gas for myself by a different method with which I need not trouble you. From March 30 onwards my assistants and myself had a very exciting time. One by one the unknown lines I had observed in the sun in 1868 were found to belong to the gas I was distilling from bröggerite, not only D^3 but 4923, 5017, 4471 (Lorenzoni's *f*) 6677 (the BC of Fig. 7), referred to previously, and many other solar lines, were all caught in a few weeks.

But this was by no means all. The solar observations had been made by eye, and referred therefore to the less refrangible part of the spectrum, but I had obtained and studied hundreds of stellar photographs, so I at once proceeded to photograph the gas and compare its more refrangible lines with stellar lines.

Here, if possible, the result was still more marvellous. In the few-lined stars, by May 6, I had caught nearly all the most important lines at the first casts of the spectroscopic net. Fig. 13, which includes some later results, will give an idea of the tremendous revelation which had been made as to the chemistry of some of the stages of star-life.

These results enabled us at once to understand how it

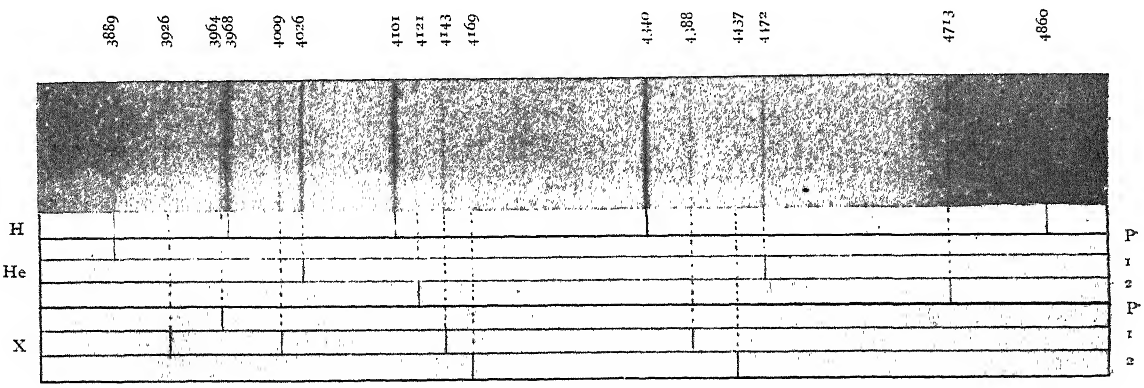

FIG. 13.—The spectrum of Bellatrix showing the lines of hydrogen and those which have been traced to the gas obtained from minerals.

was that the "unknown lines" had been seen both in the sun's chromosphere and some nebulæ and stars. The gas obtained from the minerals made its appearance in the various heavenly bodies in which the conditions of the highest temperatures were present, and the more the work goes on we find that this gas is really the origin of most, but certainly not of *all*, of the unknown lines which have been teasing astronomical workers for the last quarter of a century.

A great deal of work has been done upon these gases from other points of view than those which affect my story, and perhaps I may be allowed just to refer for a minute or two to one of the results which have been obtained by myself.

It is perfectly obvious that the gas as obtained from uraninite is a mixture of several gases; that the gas which gives the yellow line has not yet been isolated, but is always mixed up with other gases which give other lines.

In May I communicated to the Royal Society some experiments which indicated in a most conclusive manner the fact that the lines D^3 and 667, to deal with two only for the sake of simplicity, were not produced by the same gas, and that 667 seemed to be a compound gas of which D^3 represents one of the constituents.

Some little time after, Profs. Runge and Paschen, from

an entirely different standpoint, arrived at exactly the same conclusion. They recognised two gases, one represented by D^3, the other by 667, and further they showed that the lines might be arranged into six similar and beautifully rhythmic series, a principal and first and second series for each gas. These are indicated in the diagram of Bellatrix on p. 345, and in Fig. 14; He = helium is the gas which contains D^3, the other gas I so far call "gas X."[1]

This result is, however, more important from the chemical than from the astronomical point of view *at present*.

A word in conclusion referring to the occurrence of this gas in terrestrial minerals.

We are brought face to face with one question, which ought to influence many lines of work for many years to come. I have already suggested to you that we really now can talk with something like certainty and definiteness about hot stars and cooler stars, and that in the hottest stars we know of, the atmospheres of those stars consist almost entirely of hydrogen and helium.

But see what a little trace of helium we have in this small planet of ours, which undoubtedly was once a sun, which undoubtedly once had an atmosphere just as glorious in its hydrogen and its helium as any of the other stars are now glorious.

What has become of that helium? This question will have to be very carefully considered in the next few years.

We appear to be in presence of the *vera causa*, not of two or three, but of many of the lines which so far have been classed as "unknown" by students both of solar and stellar chemistry, and we are also apparently in the presence of a new order of gases of the highest importance to celestial chemistry, though perhaps they may be of small practical value to chemists, because their compounds and associated elements are for the most part hidden deep in the earth's interior. Why do I suggest a *new* order of gases? Look at the facts.

All the old terrestrial gases, with the exception of hydrogen, are spectroscopically invisible in the sun and stars—though they doubtless exist there—and these new gases, scarcely yet glimpsed, have already supplied us with many points of contact between our own planet and the hottest part of our central luminary that we can get at, and stars like Bellatrix.

The work certainly is full of hope for the future, not only in relation to the possibility of more closely correlating celestial and terrestrial phenomena, but since it indicates that terrestrial chemistry, founded on low density surface products in which non-solar gases largely enter, is capable of almost infinite expansion when the actions and reactions of the new order of gases, almost, it may be said, of paramount importance in certain stages of stellar evolution, shall have been completely studied.

I have some other results to refer to, but it is quite sufficient, I think, to leave my story as I have told it to you without going back on any of the characters, or without dealing in any greater detail with the *dénouement* of the plot.

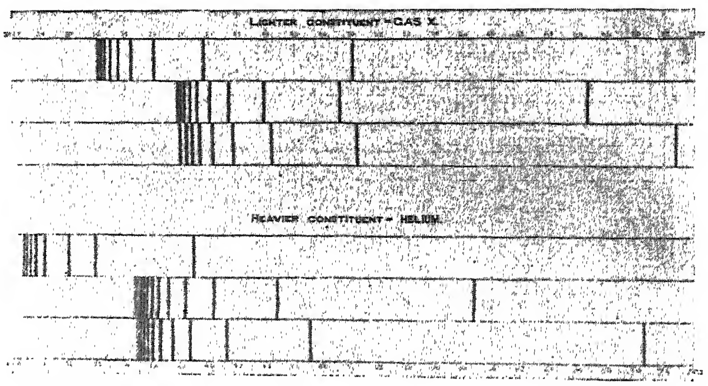

FIG. 14.—Runge and Paschen's results suggesting that cleveite gives off two gases, each with three series of lines.

[1] In the many comparisons I had to make, I soon found the inconvenience of not having a name for the gas which gave 667, 501, and other lines. When, therefore, Profs. Runge and Paschen, who had endorsed my results, and had extended them, called upon me, I thought it right to suggest to them that, sinking the priority of my own results, we should all three combine in suggesting a name. Prof. Runge (under date October 20) wrote me, "the inference that there are two gases is a spectroscopical one, being based on the investigation of the 'series.' Now, though we think this basis quite sound, we must own that the conclusion rests on induction. . . . For this reason we do not want to give a name to 'gas X.'" I have so far suggested no name, though Orionium and Asterium have been in my mind.

But the story has a moral. The more we can study the different branches of science in their relation to each other, the better for the progress of all the sciences. Another point is, that in the study of nature we behave in a very foolish way if we think there is anything unimportant which comes under our eyes. *If it had so happened* that Dr. Hillebrand had seen the line spectrum of nitrogen in 1888, we should have saved all these seven years of waiting for this terrestrial source of helium; and I may add, further, that argon would have been discovered as well in the first hour's work. In science, results of the first importance depend upon the minute examination of so-called residual phenomena; it is too much the general tendency, of scientific work on a large scale, to think too much of those results which may have a practical importance.

Geologists, natural philosophers generally, have been familiar with the mineral world for a considerable number of years. What have they been doing all the time? They have confined their attention too exclusively to the contained metals, and have neglected the gases; whereas it now seems that if they had been less careful of the metals, and had studied the gases, it would have been very much better for our nineteenth century knowledge. And that is the moral of my simple story.

J. NORMAN LOCKYER.

SCIENCE TEACHING IN SECONDARY SCHOOLS.

THE School Syllabus of Chemistry and Physics, which has just been put forward by a Committee of the Incorporated Association of Headmasters, is an attempt to indicate to those who are dissatisfied with the ordinary course of qualitative analysis, the lines on which the practical study of science may be made more profitable.

It is a great misfortune that in constructing a syllabus for use in schools, one has constantly to keep in mind its relation to the examination fiend. A short notice upon this syllabus, in this journal on Jan. 16 (p. 262), contained the observation that the teaching in schools is governed entirely by the examinations; and nothing could be more sadly true, nor a greater hindrance to a more rational system of teaching.

A syllabus may be perfect of its kind, but school authorities do not ask "How will it develop certain powers?" but "How will it examine?" and they base their estimation of it upon the answer to this question; while the relative value of the two in the eyes of parents

may be judged from the fact that many a parent who grumbles at having to pay £6, £7, or £8 a year for his son's education, willingly pays a 30*s.* or 40*s.* fee for the examination which tests it. As a matter of fact, if £7 be a fair sum to pay annually for a boy's education, an examination at the same rate would be rather overpaid with half-a-crown.

Our whole system of examinations rests upon a wrong basis; it assumes that the value of a boy's education depends upon how much he has learnt, whereas the true criterion is how he has learnt it. The climax of absurdity is reached in those examinations which test the knowledge of a language, as French or German, by the knowledge a pupil has of one specified book; it is true that some of our examining bodies have attempted to meet this difficulty by setting books of an extremely uninteresting character, in order that the pupil's attention, not being able to find interest in the subject-matter, may be solely occupied with the language, but that is a digression.

Those who have taught science in schools have long been dissatisfied with the ordinary course, and have felt the necessity of a change; but the question, "What change?" has hitherto been asked in vain. In answering this question, it is important to bear in mind that we do not want to train boys to be chemists or physicists; that is the part of the technical institute, and a system of instruction which may be excellent for producing trained chemists may be extremely unsuitable for developing the latent powers of children.

The chief principles which it is hoped to introduce by means of this syllabus are as follows.

The insistance at the outset of *measurement* as the chief factor in scientific work, and as the basis of reasoning. It is not too much to say that all scientific reasoning is the outcome of measurement, but measurement has been conspicuously absent hitherto from our school courses, and the balance, which is often stated to be the instrument of precision of chemistry, has never yet had its due place in the chemical teaching. The mental realisation of the value of numbers, and what a theologian would call an "experimental faith" in arithmetic, are important results from this kind of work. The figures in an arithmetic book, however they may profess to deal with concrete substances, represent to a boy's mind only abstract ideas, which, by means of skilful juggling, may be made to produce certain "answers," but the answers convey to him no meaning. A good instance of this is found in his view of decimals; any average boy will tell you that a mistake in the first or second decimal place causes his sum to be wrong, but the misplacement of a decimal point is not worth considering; in practice the former error is a trifle, the latter causes a grotesque absurdity.

Another point of value in the syllabus is that it teaches a boy to perform experiments with a definite purpose, and to suggest experiments himself—to put, in fact, questions to nature. Herein lies its great superiority to qualitative analysis, which, as practised in most schools, is scarcely superior to the setting of puzzles. Any boy who has worked intelligently through this course can scarcely fail to have a much better idea of the problems which natural science has to attack, and of the reasoning which is brought to bear upon them, than one who has obtained a greater amount of knowledge from text-books and lectures.

A valuable lesson which may be learnt from this syllabus is that of writing down in good English prose a systematic account of any experiment done, and of the conclusions to be drawn from it. The lesson, in fact, becomes largely a literary one. The faculty of doing this is extremely rare amongst boys leaving school, because it has hitherto never been cultivated, and the ordinary courses of analysis, whether quantitative or qualitative, rather discourage it than otherwise. Professors who continue our boys' education in higher colleges complain, with reason, of its absence, and, once acquired, it cannot fail to be of great advantage in every walk of life.

A great advantage to which I, as a schoolmaster, can bear witness, is the influence of this teaching upon the other work of the school; it has caused masters who teach other subjects to appreciate the value of teaching practically, and of reducing text-books to a secondary place. No consummation could be more devoutly to be wished especially in view of the present colossal output of worthless text-books, which boil down every difficulty and compress all knowledge into a few pages; and the general value of which is well instanced by the advertisement of a French grammar now before me, which states that several school masters and mistresses have given very successful lessons out of this book, *without any previous knowledge of the language.*

I have omitted some of the more obvious advantages of this syllabus, the importance of a definite connection between lectures and laboratory work, the training in manipulation, and the development of step-by-step reasoning, and I pass on to consider some of the objections which have been urged against this syllabus.

Although there have not been wanting objectors to the syllabus, especially the chemistry part of it, I have found it difficult to induce them to formulate objections definitely; and when they have done so, many of the objections raised appear to me to be positive advantages. Amongst these I class the following statements.

That it requires closer attention and more work on the part of the teacher, that it necessitates small classes, that it is unsuitable for examination.

The only objections I have ever heard which appear to me to require answering are the three following:

(1) That many of the experiments are unsuitable for boys; one experiment which has been specially mentioned in this connection, and which, I own, startled me before I tried it, is the production on burning hydrogen of sufficient water to estimate its physical constants. The best answer to this is, "Try it." If a boy can be taught to burn a jet of hydrogen at all, nothing is easier than that he should burn it under a retort kept cool by a stream of water running in at the tubulure and out at the neck; and if eight or ten couples are doing this, it is surprising what a large amount of water can be collected in half an hour. A little experience will enable any teacher to simplify the experiments to the capacity of his class.

(2) That the results of experiments are often so far from accurate as to be worthless. This objection proceeds from an insufficient appreciation of the aims of the work. It is true that a schoolboy will not obtain Stas's numbers, but he will obtain numbers which show a remarkable concordance when the average of all the experiments done by various members of the class are taken, and which will enforce upon his mind the law of definite proportions.

A boy may find that H and O combine in the proportion of 1 : 7·3, that chalk contains 42·8 per cent. of CO_2, or that phosphorus and oxygen combine in the proportion of 100 : 113; but when eight or ten couples have obtained similar figures, the lessons of the definiteness of the reaction, and the importance of careful quantitative work, may be learnt as thoroughly as from more accurate results.

(3) Is it not a waste of time for a boy to laboriously work out a fictitious discovery when he could learn it in five minutes by being told it, or by reading a book? *Yes*, if committing facts to memory be the desired end; but *No*, if the end be to form habits of inquiry and of thought, to understand scientific reasoning, and to prepare the mind for dealing with problems where the text-book is not available.

If I may be allowed to speak of my own experience as a teacher, I have now taught on these principles for some time, and I can positively say that I believe this system

to be infinitely superior to the ordinary method of lecturing on the non-metallic elements and on physics, and setting qualitative analyses as practical work. The only examination of which I had experience lately is the London University Matriculation, which has recently introduced practical questions; my boys have always gone up with confidence, and found these distinctly easy, a matter in which others with whom they compared notes have not agreed with them. I have never had a failure in chemistry.

At the same time, I must insist upon the point that I do not believe that this kind of knowledge can be properly tested by examination; the true criterion of the success of this syllabus must be the opinion of those professors who carry on the scientific education of our boys after they have left us. I have received a large number of letters from various professors, in which they complain bitterly of the present preparation of most of their students, and state that they believe such changes as those contemplated by this syllabus would be of the greatest value. One of these I feel justified in quoting.

"I am a very strong advocate for change in the method of teaching science in schools. The method that usually prevails is, in my opinion, worse than barren. Not only is no satisfactory foundation laid for future teaching, but bad and slovenly habits of mind and manipulation are formed, with the result that a large portion of my work and that of my colleagues consists in the attempt (too often futile) to eradicate these habits."

The syllabus, if it has a fault, is that it is too long for an elementary course. Several of the Committee were of opinion that a course on mechanics, to lead up to the construction and use of a balance, would be sufficient; but it was pointed out that the Science and Art Department would not accept any syllabus which did not include a complete course of statics. This will explain why the syllabus includes an amount of statics out of all proportion to the other subjects; it is a sacrifice to the examination fiend; personally I should leave this work for a more advanced course.

I can, in conclusion, heartily recommend to all science teachers to try this syllabus with their classes of beginners, not following it slavishly, but adopting those points which appeal to their experience.

CHARLES M. STUART.

NOTES.

LORD KELVIN reaches this year his jubilee as Professor of Natural Philosophy in the University of Glasgow. The event will be recognised by a joint celebration, in which the City, University, and students will take part, on June 15 and 16. It is anticipated that delegates and addresses will be sent from numerous home and foreign Universities to express the esteem in which the distinguished investigator is held.

THE date fixed for the next "meeting for discussion" at the Royal Society is April 23, when the subject will be "Colour Photography," and the discussion will be opened by Prof. Lippmann.

THE Bakerian Lecture will be delivered before the Royal Society on the 20th inst., the lecturer for the year being Prof. Roberts-Austen, and the subject, "The Diffusion of Metals." The Croonian Lecture will be given, probably on March 12, by Dr. A. D. Waller, who has chosen for his subject, "Electrical Changes in Isolated Nerve."

THE Odessa correspondent of the *Times* says that the Russian Government will send a special scientific expedition to observe the total eclipse of the sun on August 9. The expedition will be in charge of three astronomers from the Nikolas Observatory at Pulkova, and leaves Odessa in May, by one of the cruisers belonging to the Russian Volunteer Fleet Committee, for Vladivostok, whence it will go near the mouth of the river Amour for observations. The Committee has agreed with the Government to convey the party from Odessa to Vladivostok and back again to Odessa free of charge.

A COMMITTEE was formed in Paris, in December last, to obtain the means for erecting a monument to Pasteur, by international subscriptions. In the furtherance of this resolution a circular has been widely distributed, appealing for funds, and asking for the organisation of local committees, so that the monument in Paris shall be worthy of the man whose labours against disease and death it will commemorate. The French Comité de Patronage includes the President of the Republic, many of the Ministry, and a large number of distinguished scientific men; while the Commission which is organising the memorial is composed of members of the Council of the Pasteur Institute. It is to be hoped that a generous response will be made to the committee's appeal for subscriptions and assistance.

A CIRCULAR has recently been issued to draw the attention of biological professors and lecturers to a course of instruction in Marine Biology which has been organised in connection with the Plymouth Laboratory of the Marine Biological Association. This course, which is intended to be supplementary to the ordinary academical courses in Comparative Anatomy, will be conducted during the forthcoming Easter vacation between March 23 and April 24, and will be superintended by Mr. W. Garstang, Fellow and Lecturer of Lincoln College, Oxford, and formerly naturalist on the staff of the Plymouth Laboratory. England has undoubtedly been behind the times in the lack of any organised arrangements by which biological students could be enabled to enjoy the various advantages which a well-equipped marine laboratory affords for the study of some of the more fascinating aspects of animal life; and it is to be hoped that this new departure in biological education in England will meet with the success and encouragement which it deserves.

JUDGING from a Reuter's telegram, a meteorite which fell at Madrid on Monday produced exceptionally striking effects. Reports of remarkable meteoritic falls are comparatively rare, so we give a fairly full transcription of the telegram:—"At half-past nine this morning an aerolite of considerable size exploded in the atmosphere above Madrid. The phenomenon was accompanied by a vivid glare of blinding light, followed by a loud report, which caused a general panic among the people. All the buildings in the city were shaken, and many windows were smashed by the concussion. The sky was clear and the sun was shining brightly at the time of the explosion, all that was visible in the heavens being a white cloud bordered with red, which was travelling eastward at a great rate, leaving behind it a train of fine, light dust. The panic was general throughout the city. Many shopkeepers closed their establishments. Not only were buildings shaken, but at least one house is known to have collapsed. At the United States Legation a partition wall fell in, and many of the windows were shattered, but no other damage was done to the building. A great many houses throughout the city sustained similar damage, partition walls being shaken down by the force of the explosion. The excitement in the city, and especially in the suburbs, has not yet calmed down. The explosion was heard over a distance of several kilometres from Madrid. At Guadalajara, a town about forty-six miles from the capital, the explosion was very strongly felt." The following official communication has been issued from the Madrid Observatory:—"At 9.29 this morning a strong light was observed proceeding from a small cloud moving from the south-west to the north-east. A minute and a half later a terrific report, followed by several others of less intensity,

occurred, accompanied by a shaking of the ground and of buildings. A red-tinted cloud was for a long time visible in the east. The directors of the Observatory suppose that the phenomenon was caused by an aerolite. Owing to the time that elapsed between the observation of the explosion and the report, the aerolite must have burst at a great distance from the earth." The note adds that no traces of the meteorite have yet been found. Nevertheless, it is reported that several small pieces of greyish stone, still warm, have been picked up in Madrid.

GREAT interest has been aroused in France by the discoveries of Prof. Röntgen, and experiments have been at once made confirming and extending the original results. Last week's number of the *Comptes rendus* contained further work by M. Jean Perrin on the properties of the kathode rays (see *ante*, p. 298), showing that they are not identical with the Röntgen rays. The current issue (February 3) contains papers on this subject by MM. L. Benoist and D. Hurmuzescu, A. Nodon, V. Chabaud, and G. Moreau. The first of these gives an account of a most remarkable property of the rays, that of completely and rapidly discharging an insulated charged electroscope, the effect being produced more rapidly if the charge borne by the gold leaves is a negative one. This phenomenon is not in any way interfered with by an aluminium screen, although the latter protects the electroscope perfectly from both light and electricity. The note by M. Nodon further emphasises the difference between these rays and the ultra-violet rays. An ordinary dry plate wrapped in several thicknesses of blackened paper was exposed at a distance of 40 c.m. from a powerful arc lamp (20 amperes) for fifteen minutes; on developing, the plate was unaffected, although under the same conditions the Röntgen rays produced a very marked result. The latter also were found to pass with equal facility through differently coloured screens of the same material. The transparency of metals to the X-rays is the subject of the communication by M. Chabaud. Fourteen metals and alloys were examined by the photographic method, the results being substantially identical with those published by Prof. Röntgen in his original paper; results which were obtained very simply by the use of a phosphorescent screen. M. Chabaud makes no reference to these earlier experiments on the same subject. The two metals most opaque to these rays are those of the highest atomic weights, platinum and mercury, the most transparent being that with the lowest atomic weight, aluminium. M. Moreau dispenses with the Crookes' tube altogether, and uses the brush discharge of an induction coil; the curious result being obtained, that if the box containing the plate be placed normally to the brush, there is no effect, whilst placed parallel to the brush, strong, clear negatives are produced. No explanation of these experiments is attempted.

THE same number of the *Comptes rendus* also contains a second note by M. G. Le Bon, on photography with "dark light." By placing a sensitive plate under a negative, covered with a metallic plate 0·5 mm. in thickness, and exposing to the light of a lamp, good images are obtained on development, especially if a piece of lead is bent back over the frame, so that the whole printing frame is in a sort of metallic box. M. G. H. Niewenglowski mentions that these results can be obtained without any lamp at all, and hence suggests that they must be due to luminous energy stored up in the negative. But further experiments by M. Le Bon have completely eliminated this source of error, as the same results are obtained with negatives which have been previously submitted to blank experiments in the dark. From the point of view of Maxwell's theory of light, rays which can pass through 0·5 mm. of copper must differ essentially from ordinary light, and M. Le Bon proposes to next examine within what limits these dark rays submit to the laws of refraction, and how far they are affected by a magnetic field.

IT is announced that Dr. Kitasato, of Japan, has succeeded in inoculating for leprosy, and that the disease is curable.

THE formal presentation of the portrait of Mr. W. Carruthers, F.R.S., to the Linnean Society, was made at its meeting on February 6, by Sir W. H. Flower, on behalf of the subscribers.

THE Annual Congress of the French Association for the Advancement of Science will be held this year at Tunis, between the 1st and 11th of April. The Botanical Society of France will also hold its Extraordinary Session at the same place, and about the same time.

A COURSE of six lectures to working men, on "Fermentation," by Dr. W. P. Wynne, will be given in the Lecture Theatre of the Museum of Practical Geology, Jermyn Street, commencing on Monday, February 24.

A CONGRESS of Natural History and Scientific Societies of the South-East of England will be held at Tunbridge Wells on Saturday, April 25, under the presidency of the Rev. T. R. R. Stebbing.

THE practical extinction of the buffalo, or American bison, is very forcibly shown by an article recently published, which states that 300 dols. is now refused for a good buffalo robe, such as could at one time early in the seventies have been bought for a dollar, or even less.

WE are requested to state that the arrangements are now complete for lighting in the evening the Southern Galleries of the South Kensington Museum on the west side of Exhibition Road, which contain the collections of machinery and naval models. These Galleries will be open free to the public from February 17 on three evenings a week—Mondays, Tuesdays, and Saturdays, till 10 p.m.—in the same manner as the main building.

ANOTHER of the wonderful potentialities of the Niagara water-power is its application to the new process of Blumenberg for the manufacture of chlorate of potash by the action of the direct electric current upon tanks of potassium chloride. The electric current is at a remarkably low voltage. Important by-products are also obtained. Operations will begin next July. The Alkali Union, which controls the world's output of chlorate of potash, has reduced the price from 17 to 10 cents a pound, in anticipation of this undertaking; but the new manufacturers will probably undersell them in all the markets of the world.

THE new illuminant, acetylene, seems to be notable for its efficiency and the cheapness of its production by the electrical manufacture of calcic carbide, from which it is evolved by the mere application of water. Calcic carbide is already made at Spray, North Carolina, at a cost of 20 dols. per ton, by the alternating electric current passed through a mixture of powdered coke and lime. Works have been erected at Niagara which will produce the calcic carbide at 10 dols. a ton, beginning about the middle of this month. One ton of the carbide yields 11,000 cubic feet of acetylene gas, which has many times the illuminating power of common illuminating gas. The light, moreover, is clear and "solid"—that is, it has not the unilluminated centre of an ordinary gas-light. Acetylene gas is readily solidified, and may be conveniently distributed in cylinders, like carbon dioxide and other gases.

THE Geographical Survey of the United States has issued the report of a party of department geologists who recently made an extended investigation and survey of the Cripple Creek region. The mining district is thirty miles west of Colorado Springs, and seventy-five miles south of Denver. It covers an area of six

miles in length by five and a half miles in width, between the two main ranges of the Rocky Mountains in Colorado. As long ago as 1874 it was thought that a big gold vein had been discovered near Mount Pisgah; and the second mining excitement was in 1884; but during these two periods not one of the really valuable ore bodies which are worked to-day was discovered. Rich ore was discovered in 1890, and the rush of miners began in 1892. The first gold in the district was produced in the latter part of 1891, and since that year the output has steadily increased, being variously estimated at 5,000,000 dols. to 7,000,000 dols. The ores of the Cripple Creek district are almost exclusively gold ores, with seldom silver enough to be important. The gold occurs both in a coarse and a fine condition, sometimes in particles so small as to be invisible to the naked eye, and at other times in plates or spongy masses from an eighth to a quarter of an inch in diameter. It is rarely clear and bright, and is generally coated with a thin rusty film of a yellowish-brown compound.

A GENERAL meeting of the Members of the Federated Institution of Mining Engineers will be held in Sheffield on Wednesday, February 19. Arrangements have been made for visits to cutlery and silverplate works and the technical schools in Sheffield on February 19, and to collieries and ironworks on the following day. The following papers are down for reading: "The Eastern Limits of the Midland Coal-field," by Prof. Ed. Hull, F.R.S.; "Electric Welding," by Mr. T. Scott-Anderson; "The Vibromotor as applied to the Screening of Small-coal," by Mr. Emerson Bainbridge, M.P.; "The Matabele Gold-fields," by Mr. F. G. Shaw; "Photography in the Technology of Explosives," by Mr. Alfred Siersch; "Lead and Lap of Winding and other Engines," by Mr. Hargrave Walters; "The Elliott Coal-washer," by Mr. J. Platt.

THE *Comptes rendus* for February 3 contain a paper by M. Maurain on the measurement of the energy dissipated in iron due to hysteresis. The amount of heat generated in a sample of iron when subjected to an alternating magnetic field is measured by enclosing the iron inside a cylindrical glass reservoir furnished with a capillary tube. This cylinder is filled with alcohol, and placed within a long magnetising coil. The reservoir being carefully protected from the heat generated by the passage of the current through the magnetising coil, the quantity of heat developed in the iron is deduced from the amount of the expansion of the alcohol. The development of heat due to Foucault currents is almost entirely prevented by using a bundle of very fine iron wires. The curve which gives, as a function of the time, the position of the surface of the liquid in the capillary tube during an experiment, consists of a straight line until the losses of heat due to radiation and conduction through the walls of the reservoir become appreciable when the line becomes curved. A preliminary experiment having indicated the form of this curve; in the final measurement care is taken that the observation does not extend beyond the straight part of the curve. The author finds that the quantity of heat developed during one cycle diminishes as the rapidity of the alternations increases. This diminution, however, becomes smaller and smaller as the frequency increases, and seems to be practically independent of the magnitude of the magnetising force. The author considers that the diminution observed is probably due to the screening action of the outside layers of the iron, and some experiments on which he is now engaged seem to favour this view.

THE number of the *Bulletin of Miscellaneous Information* of the Royal Gardens, Kew, for January, contains some interesting particulars of the effects on the Gardens of the long and severe frosts of the early months of 1895. These were in some respects different from what might have been anticipated from previous experience. Thus, while some herbaceous plants and shrubs reputed to be nearly hardy have perished, the laurustinus, the bay, and the arbutus escaped almost unharmed, as also did the evergreen oaks. "Alpines" suffered severely, though of course the cold was not so intense as the ordinary winter temperature to which many of them are exposed in their native habitat; but there they are protected through the winter by a covering of snow. The bamboos in the open ground were but little injured, while the pampas grass was largely killed. Of our native plants, the ling and the gorse were greatly damaged. Perhaps the greatest destruction was among the bulbs, of which very large numbers were entirely killed, especially the narcissi and hyacinths. In the same journal the number of visitors to the Gardens during 1895 is estimated at 1,407,369. This is about 30,000 more than the number for 1894, but somewhat less than the average numbers for the last ten years.

WE have received from Mr. J. Eliot, F.R.S., Meteorological Reporter to the Government of India, a preliminary discussion of certain oscillatory changes of pressure of long period and short period in India, being part ii. vol. vi. of *Indian Meteorological Memoirs*. The author points out that the discussion of pressure conditions in India requires that the observations should be of a high standard of accuracy, and for many years the greatest attention has been paid by the India Meteorological Department to the methods of observation, and to the critical comparison of the data. The first part of the paper deals with the normal conditions of pressure, and shows that the ordinary seasonal changes are very regular and uniform, while the abnormal conditions, such as are associated with the occurrence of storms, are, as a rule, very slightly marked. The largest regular oscillation is the annual change; the readings are highest in January, and fall until June, after which they rise until the end of the year. The amplitude of this change is smallest in Southern India, and increases with latitude. The smallness of the daily pressure changes is remarkable; only about five per cent. of the changes exceed a tenth of an inch. The second part of the paper deals in great detail with oscillations of pressure differing from the annual and diurnal changes, and which appear to be associated with atmospheric movements common to the whole of Southern Asia and the adjacent seas. In the long-period oscillations, the transfer of air across the equatorial belt tends during one half of the year to give an accumulation of air and high pressure over Central and Southern Asia, whilst in the other half of the year the air is drained away. The short-period oscillations are less regular than either the diurnal or annual, and approximately average four days in length. They appear to be common to the whole Indian area, and occur almost simultaneously; they are apparently not due to the transmission of waves in a horizontal direction, but possibly to waves of rarefaction and condensation, transmitted slowly upwards and downwards in the atmosphere, caused by variations of temperature. Although the discussion is only preliminary to a future paper, it teems with instructive matter which will well repay careful study.

A GOOD portrait of Lord Kelvin, reproduced by collotype, is presented as a supplement to *Industries and Iron* of February 7.

THE newly-established Société de Spéléologie of Paris has sent us the first three numbers of its quarterly journal, *Spelunca*. Accounts of caverns in various parts of the world are gathered together in the journal, several of them being illustrated by maps and other figures.

THE annual report of the New South Wales Railway Commissioners for 1894–95—being the final one for the original term of their appointment—contains, in addition to the ordinary very detailed statements, a full account of the extensive alterations and improvements made in the railway system since 1888. The

report is illustrated by maps, photographs, and diagrams; and the statistical tables are admirably compiled.

THE January number of the *American Geologist* contains an account of the late Prof. J. D. Dana, with a portrait and bibliography. Mr. Warren Upham discusses the flow of glacial ice, with especial reference to the views of Messrs. Fletcher and Deeley, mentioned in these columns about a year ago. A description of cases of the flotation of sand, by Mr. F. W. Simonds, and an essay on the use of Palæontology as "The Timepiece of Geology," by Prof. Claypole, are among the other contents.

THE *Annuaire* of the Municipal Observatory of Montsouris for this year has just come to hand; the observations—meteorological, chemical, and bacteriological—tabulated and discussed in it, refer to the year 1894. Another *Annuaire* which we have received is that of the Belgium Académie des Sciences, des Lettres, et des Beaux-Arts. A full notice of the life and mathematical works of Eugéne Charles Catalan, with a portrait, appears in this annual of the Brussels Academy.

WITH the motto *Magnus magnes ipse est globus terrestris*, the new international quarterly journal, *Terrestrial Magnetism*, the forthcoming publication of which was announced in these columns a few weeks ago, has made its appearance. The articles in the journal are: "On electric currents induced by rotating magnets, and their application to some phenomena of terrestrial magnetism," by Prof. A. Schuster; "Die vertheilung des Erdmagnetischen Potentials in Bezug auf Beliebige Durchmesser der Erde," by Dr. A. Schmidt; and "Halley's Earliest Equal Variation Chart," by Dr. L. A. Bauer, the map being reproduced in facsimile. There are also letters, notes, and reviews dealing with terrestrial magnetism and cognate subjects. The journal is published under the auspices of the Ryerson Physical Laboratory, University of Chicago.

WE have had upon our table for some time a copy of Napier's celebrated and rare work on the construction of logarithms—"Mirifica Logarithmorum Canonis Constructio"—reprinted in facsimile by M. A. Hermann, 8 Rue de la Sorbonne, Paris. Napier's discovery of logarithms was announced in his "Mirifici Logarithmorum Canonis Descriptio," published in 1614; but the explanation of the method by which the logarithms were calculated appeared in the "Constructio," a posthumous work not issued until 1620. To this work, which M. Hermann has now reprinted, Henry Briggs, who was one of the first to recognise the value of logarithms, appended some notes. The reprint will be valued by all students of the history of mathematics.

THE Geological Society of London has just published a list of the geological literature added to its library during the year 1895. As compared with the only previous issue in this form, we note that while the price remains unaltered, the volume has swollen to nearly threefold—an increase only partly accounted for by the fact that the present list represents a whole year's additions as against a half-year's in the previous one. The omission of maps from the list, to which we drew attention when the previous list was published, has been repaired; maps are entered under the names of the authors responsible for them in the general list, but there are cross-references under "Maps" in the subject-index. The publication will be found a most useful one by all geologists.

THREE papers were read at the recent meeting of the Institution of Mechanical Engineers, viz.: "Telemeters and Range-Finders for Naval and other Purposes," by Profs. Barr and Stroud; "Calculation of Horse-power for Marine Propulsion," by Lieut.-Colonel Thomas English; "Notes on Steam Superheating," by Mr. William H. Patchell. The paper by Profs. Barr and Stroud was confined to a description of two instruments, viz. (1) the range-finder which is now in use in the navies of this and many other countries; and (2) a small hand instrument, identical in principle with that for naval use, but much more portable and much simpler in its details. Lieut.-Colonel English's paper called attention to a method of calculating, from the results of a single sea-trial of one ship, the horse-power necessary to propel another ship, of the same type, at any required speed. By this method it becomes practicable, with the ordinary appliances of a shipyard, to approximate closely to results which could otherwise be obtained only by the use of the refined apparatus of a model tank. Mr. Patchell described a number of superheaters, and gave the results of tests with them.

THE additions to the Zoological Society's Gardens during the past week include a Klippspringer (*Oreotragus saltatrix*, ♂) from Nubia, presented by Commander Alfred Paget, R.N.; an Indian Wolf (*Canis pallipes*, ♂) from India, presented by Mr. Duncan Darroch; a Barn Owl (*Strix flammea*), British, presented by Mr. Bernard R. White; a Gould's Monitor (*Varanus gouldi*) from Australia, presented by Mr. Arthur R. H. W. Leach; a Sharp-nosed Crocodile (*Crocodilus acutus*) from Jamaica, presented by Mr. Arthur P. Cohen; a West African Love Bird (*Agapornis pullaria*) from West Africa, presented by Mrs. Roberts; an Alpine Marmot (*Arctomys marmotta*), European, a Yellow-headed Conure (*Conurus jendaya*) from South-east Brazil, deposited; a Crested Grebe (*Podiceps cristatus*), a Curlew (*Numenius arquata*), British, purchased; a Malaccan Parrakeet (*Palæornis longicauda*) from Malacca, received in exchange; two Rufous Rat Kangaroos (*Hypsiprymnus rufescens*, ♂ ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE ASTROPHOTOGRAPHIC CATALOGUE.—At the last meeting of the Royal Astronomical Society, the Astronomer Royal gave some particulars relating to the progress at Greenwich of the international photographic star catalogue. A special staff for dealing with this work has been organised under Mr. Hollis, and already 130 of the plates taken for the catalogue have been measured. It is estimated that about 180 plates can be measured, and 160 of them reduced in the course of a year, so that at this rate the section allotted to Greenwich, comprising about 150,000 stars, will be completed in five or six years. Assuming that the other sixteen co-operating observatories are proceeding equally well, the world will soon be in possession of a colossal catalogue, comprising between two and three million stars.

ORBIT OF α CENTAURI.—Dr. Doberck, of the Hong Kong Observatory, has revised the elements of the orbit of α Centauri, which he determined in 1877, with the following results (*Ast. Nach.*, No. 3330).

Ω ...	$25° 25'$	T ...	1876·02
λ ...	$52° 53'$	e ...	0·51184
γ ...	$79° 14'$	P ...	79·123 years
μ ...	$4°·54987$	a ...	$18''·450$

The sum of the masses, as determined from these elements, is 2·3780 times the mass of the sun. Taking the parallax as $0''·75$ the major semi-axis is 24·60 times the earth's distance from the sun, so that the distances between the components are about the same as those of the outer planets from the sun in our own system. If the diameters of the stars are not very different from that of our sun, each would appear from the other as a mere star to unaided vision, the distance being too great to show a disc. An ephemeris up to 1920 is given in the paper, as well as a comparison of observations with the places calculated from the adopted orbit.

COMETS OF SHORT PERIOD.—From an interesting article on comets of short period, by Mr. W. E. Plummer (*Knowledge*, February), we extract the following table, indicating the comets which may with reasonable certainty be expected to reappear.

They are arranged in the order of the mean distances from the sun.

Name.	Period in years.	Date of last Perihelion passage.	Approximate date of next return.
Encke	3·303	1895, Feb. 4	1898, May 26
Tempel	5·211	1894, April 23	1899, July 10
Tempel-Swift ...	5·534	1891, Nov. 14	1897, May 28
Winnecke	5·818	1892, June 30	1898, April 25
Finlay	6·627	1893, July 12	1900, Feb. 26
D'Arrest	6·691	1890, Sept. 17	1897, May 27
Wolf	6·821	1891, Sept. 3	1898, June 30
Faye	7·566	1896, March 19	Now visible.

The mean distances of the comets from the sun range from 2·218 to 3·854, but the aphelion distances do not vary so greatly in proportion—a fact which suggests the controlling influence of Jupiter. It is remarkable that such a small number of regularly returning comets seem to be permanently attached to our system.

EFFECT OF SPOTS ON SUN'S DIAMETER.—Observations of the sun's diameter, made in the latter half of last year by J. Sykora, of the Charkow Observatory, have led to a result which may be of considerable importance if established by further investigations (*Ast. Nach.*, No. 3330). The observations were made with a 6-inch refractor by projecting the image of the sun together with that of the micrometer wires. The diameter measured in the direction of the points of appearance or disappearance of spot groups was found in the great majority of cases to be greater than the diameters in neighbouring parts of the sun as measured on the same days. Some of the results are as follows, the first column giving the diameter in the direction of spot groups, and the other two showing adjacent diameters:

	m. s.	m. s.	m. s.
June 22 ...	2 8·62 ...	2 8·38 ...	2 7·97
July 5 ...	8·37 ...	8·04 ...	8·21
,, 12 ...	8·30 ...	8·27 ...	8·27
Sept. 5 ...	8·52 ...	8·25 ...	8·44
,, 9 ...	8·41 ...	8·29 ...	8·36

It is concluded that although the spots themselves may be depressions, they produce an elevation of the surface of the sun in the regions where they are formed.

THE SPECULATIVE METHOD IN ENTOMOLOGY.

THE annual general meeting of the Entomological Society of London was held on January 15, the President, Prof. R. Meldola, F.R.S., being in the chair. After referring to the affairs of the Society and to the great literary activity of English entomologists during the past year, the President called attention to Mr. Oswald Latter's discovery of the secretion of potassium hydroxide by *Dicranura vinula*, &c., and to Mr. F. Gowland Hopkins's researches on the pigments of Pierine butterflies. The address then proceeded as follows:—

The association of chemistry and biology in researches such as those to which I have drawn attention, has suggested a comparison between the methods of research in vogue in the two great departments of science of which these two subjects are respectively typical. All science necessarily begins with observation or experiment, *i.e.* with ascertained facts, and it is perhaps unnecessary to assert that no mere collection of facts can constitute a science. We begin to be scientific when we compare and coördinate our facts with a view to arriving at generalisations on which to base hypotheses or to make guesses at the principles underlying the facts. Having formed the hypothesis we then proceed to test its accuracy by seeing how far it enables us to explain or to discover new facts, and if it fails to do this to our satisfaction we conclude that our guess has been a bad one and requires modification or replacing by a better one, *i.e.* by one more in harmony with the facts. I take it that the course of progress is the same in so far as these fundamental methods are concerned in both departments of science, the physical and the biological. It is possibly a matter of individual opinion as to how large a body of facts should be accumulated before we attempt to draw any general conclusions. There can be no doubt that the requirements of one branch of science cannot be measured by those of another branch to which it has no near relationship. But however large the number of facts, and however cautious or conservative the worker may be, it is an established doctrine taught by the whole history of science, that real progress only begins when we go to seek for facts armed with at least the suggestion of a principle if not with a complete theory based on facts already accumulated by observation or experiment. This is the whole difference between scientific observation or experiment and mere random or haphazard observation. A naturalist of the old school, William Swainson, writing in 1834,[1] speaks of the "observance of nature, without making any attempt to generalise the facts so acquired," as "a mere amusement, fascinating indeed, and even useful, but totally disconnected with the objects of philosophic science." Now I venture to think that entomology in this country has been retarded in its development for want of a little more of this "philosophic science"; by an unwillingness on the part of our most active workers to give rein to the imagination—by an overcautiousness which is damping to the speculative faculty. There are no doubt many present who will not agree with this view, but I claim indulgence while I state my case in its support. It will, I think, be conceded that we have passed beyond the mere fact-collecting stage. It appears to me that in entomology we have arrived at a state where we are suffering from a plethora of facts; if we are not in a position to explain everything connected with the development, life-histories, instincts, classification and distribution of insects as a class of animals, we are at any rate in a position, speaking paradoxically, to know what we want to know, and I do not see how we are going to advance unless a more generous use is made of hypothesis as a scientific guide. It is this point which I desire to urge and to show that there is no real danger in boldly facing what the late Dr. Romanes aptly calls the bugbear speculation.

In the first place, with respect to the physical sciences, there is abundant justification for the view which I am advocating. We have there long ceased to collect random facts; observations and experiments are suggested by hypothesis. That prince among experimental philosophers, Michael Faraday, was wont to say: "Let us encourage ourselves by a little more imagination prior to experiment." The state of affairs is well summed up in one of the latest works on chemistry in which the author, in introducing the fundamental principles of modern investigation says:

"The history of the exact sciences teaches us that we may discover new laws of nature in two essentially different ways, one of which may be designated as the empirical, the other as the theoretical. Thus in one way by suitable observations, one collects abundant material . . . and then by a repeated and purely empirical grouping of the data so obtained, he seeks to approach the desired goal. . . . The second way, on the other hand, leads from suggested conceptions regarding the nature of certain phenomena, through pure speculation to new information, the correctness of which must be determined by a subsequent research."[2] One other recent utterance by my colleague, Dr. W. M. Hicks, the President of Section A at the last Ipswich meeting of the British Association, will serve to give us a glimpse into the spirit of progress in pure physics: "By our imagination, experience, intuition, we form theories; we deduce the consequences of these theories on phenomena which come within the range of our senses, and reject or modify and try again. It is a slow and laborious process. The wreckage of rejected theories is appalling; but a knowledge of what actually goes on behind what we can see or feel is surely, if slowly, being attained. It is the rejected theories which have been the necessary steps towards formulating others nearer the truth."[3]

And now let us consider how far these methods, recognised as valid in the physical sciences, are applicable to the biological sciences, of which entomology constitutes a branch. Of course, I am not claiming for our subject the position of an exact science, and to suppose that it could be advanced by purely deductive methods would be absurd. But I am endeavouring to hold the balance between a more liberal use of the speculative method, on the one hand, and the deadening influence of refusing to speculate at all, on the other hand. I am putting forward a plea for an increased use of the imagination, because I hold that

1 "Preliminary Discourse on the Study of Natural Science," p. 51.

2 "Theoretical Chemistry," by Walter Nernst, translation by Prof. Palmer, 1895, p. 2.

3 Address to the Mathematical and Physical Section of the British Association, Ipswich 1895.

the time has arrived when this may—nay, must be allowed, if our science, with its immense wealth of raw material, is to take that rank to which it is entitled among the departments of modern biology. If, as is undoubtedly the case, the speculative method has been found fruitful in other fields of natural history, it behoves us as co-workers in the great battle for truth to re-examine our weapons—to ask ourselves seriously whether the time and energy of our most active workers is being utilised in the best way for the advancement of knowledge.

To many it may appear that the use of hypothesis as a guide to investigation is so obvious, that no special advocacy is required. All I have to say, in this case, is to express the earnest wish that the Fellows of this Society who hold such a view may be numerous—the more numerous the better. I will venture to remind you, however, that my predecessor in this chair has stated, with respect to this method of handling entomological problems:

"I feel, however, for myself, and I think that others must also feel, that however great and important is the knowledge which we may ultimately attain, by endeavouring to discover the laws which govern the development, variation, and distribution of insects, the knowledge we have of the actual facts is in many cases quite insufficient to bring such speculations to a definite end. I also feel that the number of persons whose talents are sufficiently great to enable them to steer a straight course through the numerous difficulties, contradictions, and doubts which constantly surround such inquiries is very limited" (*Proc. Ent. Soc.* 1893, p. xlvi.).

I am sure Mr. Elwes will not ascribe any personal motive to me in making use of this passage, as representing the views of what may be called the conservative school of entomologists. I feel only too acutely the truth of his remark that many agree with him in this opinion; at the same time I am sanguine enough to believe that there are many who do not, and on behalf of this constituency I have felt it a duty to urge a claim for the speculative method, not as displacing the older method of collecting and recording facts altogether, but as a stimulus to more systematic investigation, rendered imperative by the general advance of biological science. For my own part, I believe that the time has gone by when every attempt at discovering natural law in the organic world by the aid of entomological observations, is to be met by this prevalent cry of *non possumus*.

If we turn to results as a measure of the value of methods, it will, I imagine, be conceded that we can show good cause in favour of theorising. I may be permitted to draw some illustrations from the Lepidoptera, the only order to which I can lay claim to some slight special knowlege, and in which our former President is a recognised authority. In the following remarks I desire most emphatically to dissociate myself from controversial matters, because my sole aim in this address is to clear the atmosphere for the more healthy use of the speculative faculty by our younger and rising workers. I wish it to be understood that in speaking of any particular hypothesis, I am not now raising the question of its soundness or unsoundness—that is, logically, a distinct issue—but I am simply adducing the hypothesis in order to illustrate the results of its introduction into modern scientific thought. I begin with the phenomena of mimicry and protective resemblance among butterflies and moths as first explained by our late distinguished Fellow and past President, Henry Walter Bates, in his memorable paper of 1861, which was followed by the well-known memoirs of Wallace and Trimen on the same subject. It will be remembered by all who are familiar with the history of the subject, that this was the first application of the theory of natural selection of Darwin and Wallace to explain a new set of phenomena. It was a speculation evolved by Bates, not when collecting in the Amazon Valley, as is generally supposed, but while looking over his specimens when he had reached London, and was pondering, at his own fireside, over the meaning of the remarkable superficial resemblances among the butterflies of different groups which he had brought home.[1]

The Batesian theory was fruitful; it carried with it the explanation of the resemblance between insects of distinct orders and of the assimilation of insects and other animals in colour and form to the objects among which they lived; it prompted further observation and experiment because more evidence was required as to the protected character of the insects which were copied; it raised the whole question of the existence of such protected species in nature, and the question has been answered so far in the affirmative, although there is still a large field for further experimental observation waiting to be explored. The facts have increased enormously since 1861, the search for new instances having been stimulated by the explanation suggested by Bates, and the systematist is now no longer in danger of being deceived by superficial resemblances.

The theory of Bates left unexplained the resemblance between species belonging to protected groups to which he had himself called attention in his original paper: an extension was required and was made by our Hon. Fellow, Fritz Müller in 1879, and as a result, whether this extension be considered valid or not—a point which I am not now raising—the systematist is now more fully alive to the superposition of external similarity upon structural resemblance due to true blood-relationship, as can be seen from the writings of Moore on the genus *Euplœa*, and of Wood-Mason and others on certain Papilionidæ. As another result of Fritz Müller's hypothesis, the question of inherited knowledge of edible and inedible species on the part of insect-eating creatures has likewise been raised, and has already led in the hands of Prof. Lloyd Morgan to some interesting experimental conclusions.

As the product of a theory we thus have a large body of real and tangible knowledge gleaned from nature! Mere casual observation would never have revealed the widespread existence of the phenomenon if the stimulus to look out for it had not come from the theoretical side.

It is not the bare record of the comparatively few cases of mimicry that constitutes the highest value of these classical memoirs—it is the speculation, the hypothesis, the suggested *cause* of the phenomenon that has given vitality to what would otherwise have been a disconnected and meaningless set of facts. But the consequences of the introduction of the theory of natural selection into the subject of insect colouration have not yet been exhausted. From the observation that the species which are mimicked are generally gaudily coloured and take no special means to hide themselves, it is but a step to the well-known theory of warning colours propounded by Wallace in 1867. That theory, in itself the outcome of a question raised by Darwin in connection with his theory of sexual selection, stimulated the experiments of the late Jenner Weir and of A. G. Butler, the striking observations of Thomas Belt in Nicaragua, the detailed researches of Weismann into the origin and meaning of the colours of caterpillars, and the later systematic series of experiments conducted by Poulton. Yet another example I will permit myself to make use of because it is one in which I have some personal interest. In considering the subject of adaptive colouration as explained by Bates and Wallace, a difficulty occurred in the case of species which are of variable colouring: I ventured to suggest, as far back as 1873, that this kind of colouring would be explicable by natural selection, if we supposed that this agency could confer a power of adaptability on the individual. At that time no mechanism could be conceived of by which such individual adaptability could be acquired, excepting the direct assimilation of the colouring-matter of food-plants in the case of caterpillars or other vegetable feeders. This, of course, carried with it the implication that natural selection could work on physiological processes if they were of use, just as well as upon any external morphological character. Stimulated by this hypothesis, other cases of variable colouring were sought for and found. The subject was later taken up by Prof. Poulton, who, for many years, conducted experiments and obtained results which are now familiar to all naturalists. The original speculation, that variable colouring was the result of an individual adaptability due to natural selection, implies that this faculty is of bionomic value. I am not now concerned with the validity or otherwise of this assumption; that is an issue on which opinion appears to be divided; although, I have no doubt in my own mind on the point, it is not necessary to state the case with any bias on the present occasion. Now the experiments of Poulton have shown that this colour variability is of very much more frequent occurrence than was ever dreamt of in 1873, and his facts have, in the main, been substantiated by the independent observations of many other experimenters. And it turns out also that the mechanism of the process is not even the simple assimilation of colouring-matter from the food-plant, excepting in the case of green caterpillars, in which it has been shown that chlorophyll in a modified form passes into the blood. The colour variability of caterpillars and pupæ in response to the external stimulus exerted by coloured surfaces, as established by these experiments, has brought us face to face with a fundamental

[1] I owe this statement to Mr. Bates himself, who has often made it to me.

problem in insect physiology, the solution of which we are anxiously awaiting. The mere possibility of being able to state the problem in its present form—apart from any question of the adaptive value of the colouration—is a step forwards; is an incentive to further experiment, and this is the legitimate end and aim of all scientific speculation.

Were I to attempt, however, to pass from what has already been accomplished to that which is yet awaiting investigation—to the questions which rise on all sides as pressing for solution, there would be no limit to this address. In view of the splendid opportunities afforded by insects for treatment as living organisms capable of revealing natural laws by skilled experimental research, is it not pardonable if we sometimes give way to the unphilosophic thought that the possession of chitinous exoskeletons by these creatures, whereby they lend themselves so admirably for preservation as cabinet specimens, is an arrangement expressly designed for the retardation of entomological science? The scientific workers at living insects in this country are deplorably few as compared with those who devote themselves to cabinet entomology. The one great desideratum of modern biology is an experiment station where protracted observations can be carried on year after year on living animals, each set of experiments prompted by hypothesis and with the definite object of answering some particular question in relation to variability and inheritance, the nature of the action of the environment, the effect of selection, &c. This was a dream of the late Dr. Romanes; he has not lived to see it fulfilled, but if it should be realised in our time our entomologists will, I venture to hope, not be behind with suggested lines of work.

If by way of comparison we now turn to that branch of the subject in which the empirical method has hitherto almost exclusively been employed, viz. the taxonomy of this same order Lepidoptera, the results are most instructive. In view of the immense body of facts, the number of named species and the mass of published descriptive matter, I do not think I shall be wrong if I say that the best energies of the acutest workers have been concentrated on this subject from the middle of the last century down to the present time. A record of nearly a century and a half against the thirty odd years that have elapsed since the introduction of the theoretical method into the biological sciences. Is there any indication that all this work has brought us nearer the "definite end" to which it was and is directed—the natural classification of the Lepidoptera—to an extent commensurate with the number of workers and the time bestowed upon it? It is only quite recently that any decided advance has been made, and that through the work of Hampson, Comstock, Chapman, Meyrick, and others. It cannot be said that we have been waiting all these years for materials—for a few thousand new species is one of the best "collected" groups in the whole world of insects—in order that this sudden rush might be made. I take the view that we have been waiting rather for method than for additions to the lists of species; that we have hitherto too much disregarded the spirit of the speculative method in our taxonomic work, and that we have now happily found a band of workers who refuse to submit to the plea of inability because all the existing species of Lepidoptera have not been collected and named.

After advancing these arguments in favour of a more liberal use of the "scientific imagination" in connection with entomological subjects, I feel it incumbent upon me to define the position a little more fully in order to prevent misunderstanding. The conditions of speculation in the two great departments of natural science which have been under consideration are not exactly the same, and the differences in the method of treatment must not be lost sight of. If in the physical sciences there is, to use the expression of the late Prof. Stanley Jevons, "unbounded license of theorising," it is because we can appeal to nature so readily by the experimental method, and get our answer one way or the other, by imposing rigid conditions which are under our control. In the biological sciences this is not the case; all who are acquainted with experimental work in biology know how difficult it is, generally, to get definite answers to our questions—the conditions are vastly more complex when we come to deal with living organisms. I remember once remarking to the late Mr. Darwin how difficult it was to get nature to give a definite answer to a simple question, and he replied, with a flash of humour: "She will tell you a direct lie if she can." The practical result of this difference is that the speculation of an hour may take a lifetime for its verification. But I see no reason why, on these grounds, we should repress the spirit of speculation. If, as our former President says, it is given to few to be able to speculate with advantage—and in this I thoroughly agree with him—it is our paramount duty for the present and future welfare of our science, to give every man's honest thought our most serious attention, and to encourage the faculty whenever and wherever we find it, as the most precious means of advancing scientific knowledge. The "bugbear" is a very harmless animal if you look him boldly in the face, and if you treat him gently and put him into harness he will drive the chariot of science for you at a speed that will leave the empirical method far behind in the race for the knowledge of nature's ways.

The great service which the founders of the modern doctrine of evolution have rendered to science has, in my belief, been not only the particular theory of species transformation with which their names will ever be associated, but the importation into biology of the methods of the physical sciences. Writing to Wallace, in 1857, Darwin said: "I am a firm believer that without speculation there is no good and original observation" ("Life and Letters," vol. ii. p. 108). In the same letter he remarks: "You say that you have been somewhat surprised at no notice having been taken of your paper in the *Annals*. ["On the Law that has regulated the Introduction of New Species," *Ann. and Mag. Nat. Hist.*, 1855.] I cannot say that I am, for so very few naturalists care for anything beyond the mere descriptions of species." This statement of 1857 does not hold good in 1896; other methods of biological research have been introduced—the road to biological fame is no longer through the sole channel of technical systematic work, and we owe it to the writer of that letter more than to any other worker and thinker of our time, that the horizon has been extended on all sides.

The misapprehension to which my remarks may possibly give rise, and which I am most anxious to prevent, is that in urging the claim of the theoretical method I am introducing the danger of rash and promiscuous speculating by all kinds of dabblers in the subject. There is much justification for this attitude, but an analysis of the supposed danger will, I think, serve to show that it is not a very formidable one after all. It appears to me, moreover, that the advantage of giving an impetus to observation along preconceived lines far outweighs any passing danger arising from hasty speculation. It is notorious in the history of modern science that no single branch has escaped the efforts of well-intentioned, but quite irresponsible outsiders, to set our various houses in order for us. On critical examination it will be found, however, that none of these attempts, even when they have been lucky enough to forestall the conclusions arrived at by legitimate methods, have led to any practical issue in the way of observation or research. I am addressing my remarks on the present occasion to a Society composed more or less of experts; I am not inviting "the man in the street" to favour us with his views on this, that, or the other question, but I am asking the working entomologists among us to bear in mind that their studies may be directed so as to throw light on some of the broad biological problems of the day, if they will, as Faraday said, encourage themselves by a little more speculation. Judging from the part played by this method in the development of modern science, it is perhaps not going too far to say that it is better to have speculated erroneously than never to have speculated at all. Illustrations might be adduced showing that erroneous theories have often done good service to science, and that for this reason they have been temporarily retained, even when recognised as inadequate to meet the growing body of new evidence. This was the case, for example, with the old "fluid" theory of electricity. So also the "corpuscular" theory of light enabled Newton to develop optical science to a remarkable extent, although this theory is now among what Dr. Hicks calls the "wreckage."

Another source of danger in biological speculation to which I am also alive, is that we have the public eye upon us to an extent that is not experienced in other departments of science. I am bound to confess that I never could quite make out why this should be the case. It is possible to speculate about the constitution of matter, the degradation of energy, the age of the solar system, and other great problems of the universe, with any degree of dogmatism without exciting public discussion. But as soon as ever an effort is made to explain something in the living world, no matter how modestly, the speculator is forthwith treated as though he had thrown down a public challenge. Perhaps it is for this reason that biology is more subject to

unauthorised and unscientific intrusion; because it gives opportunity for the pure *littérateur* to pose as a theorist. The speculations of the physicist or chemist are, moreover, generally expressed in a symbolical language which is not understood by the public at large, and their ideas, however revolutionary, thus escape newspaper and magazine notoriety. As far as my reading extends, I am inclined to believe that even in the case of the purely literary treatment of biological problems by writers who are not experts, the danger of overweighting the science with hypothesis is much exaggerated. Writers of this class are often capable of taking a wider and more philosophic grasp of a problem than a pure specialist, and ideas of lasting value have sometimes emanated from such sources. I imagine that nobody will dispute that Mr. Herbert Spencer's writings have largely influenced the public mind—whether we agree with the details of his doctrines or not—in accepting the broad principle of evolution, although this profound thinker lays no claim to an expert knowledge of any branch of natural history. But every working naturalist can ascertain for himself the credentials of any particular writer: my remarks are simply offered with the object of claiming more consideration for such writers, as a class, on the part of practical workers. The philosophic faculty is quite as powerful an agent in the advancement of science as the gift of acquiring new knowledge by observation and experiment. It is not often that the faculties are combined in one individual.

The general conclusion to which these considerations point is that the biological theorist, by virtue of the complexity of the factors, the difficulty of experimental verification, and the tendency on the part of the public to mistake tentative hypotheses for established theories, should put forward his views with more explicit caution than is necessary in the case of the physical sciences, where experimental evidence is more easily obtainable, and where the self-constituted philosopher but rarely gets a hearing. All this amounts, however, to nothing more than a plea for caution, and not for total abstinence. To disallow speculation because a complete theory cannot be formed out of the existing materials, is simply to put a check upon legitimate advancement. I freely admit that it is possible to carry speculation to an unscientific extreme—to fritter away a plausible hypothesis by mere metaphysical discussion, or to bury a real and important issue under an incubus of verbiage. But this is not the legitimate use of the speculative method; it is an accident, which the scientific worker will know how to avoid, and which is contingent upon the present condition of biological investigation. We cannot test our speculations off-hand by a few crucial experiments, as in physical science, and in the meantime the logic-chopper may get hold of our idea and whittle it away. On these grounds, however, I again fail to see any reason for repressing speculation. It might as well be argued that because the action of fire, carried to an extreme, carbonises organic matter, we should therefore eat our food raw. The irresponsible manipulation of biological hypotheses by pure speculators does no real or permanent injury to the cause of science, and may indirectly do good by directing public attention to the work which is being carried on. I rather think the absence of public sympathy, in connection with theoretical research in chemistry and physics, exerts a depressing influence; the inventor of a new hypothesis in these subjects moves entirely in an atmosphere of his own creation, which even his colleagues seldom venture to penetrate. That biological speculations are more prone to such unauthorised treatment is no more a reason for refusing to speculate than the circumstance that generations of fact-collectors have wasted their time in amassing large stores of disconnected observations, which for want of system are practically of no avail to the scientific worker, is an argument in favour of repressing observation. It is possible to be quite as unscientific in the accumulation of facts as it is to become metaphysical by over-speculation; there is as much danger in one direction as there is in the other. Yet the most ardent advocate of the theoretical method has not taken it upon himself to declare that observation must cease until he has explained all the facts at present available. This, however, is practically the position taken up by those who refuse to recognise that existing knowledge is sufficient to enable considerable advance to be made by the legitimate use of the theoretical method.

One other point demands consideration, in conclusion. If latitude for the exercise of speculation is to be allowed, where, it may be asked, is the line to be drawn? How are we to distinguish between the cautious theoriser and the writer who permits himself "unbounded license?" These are questions to answer which requires nothing but an exercise of individual judgment. A sound speculation may emanate from the happy possessor of a philosophic mind although he may never have done any technical biological work. But this kind of speculator naturally fails to secure that hearing to which the practical worker is entitled. Although valuable generalisations may occasionally be given out by great thinkers, the expert biologist shows wisdom in giving his most serious attention only to those who are familiar with their data at first hand—who have themselves gleaned their information directly from nature. By such workers only can the true value of the evidence be fairly weighed and estimated. I should be very sorry if the remarks which I have ventured to offer in the course of this address were to be interpreted into a general public invitation to speculate on biological problems. But I do raise the question here as to the kind of biological work which is to be recognised as a fitting preparation for the exercise of the speculative faculty. It used formerly to be asserted that he only is worthy of attention who has done systematic, *i.e.* taxonomic, work. I do not know whether this view is still entertained by entomologists; if so, I feel bound to express my dissent. It has been pointed out that the great theorisers have all done such work—that Darwin monographed the Cirripedia, and Huxley the oceanic Hydrozoa, and it has been said that Wallace's and Bates's contributions in this field have been their biological salvation. I yield to nobody in my recognition of the value and importance of taxonomic work, but the possibilities of biological investigation have developed to such an extent since Darwin's time that I do not think this position can any longer be seriously maintained. It must be borne in mind that the illustrious author of the "Origin of Species" had none of the opportunities for systematic training in biology which any student can now avail himself of. To him the monographing of the Cirripedia was, as Huxley states in a communication to Francis Darwin, "a piece of critical self-discipline,"[1] and there can be no reasonable doubt that this value of systematic work will be generally conceded. That this kind of work gives the sole right to speculate at the present time is, however, quite another point. It might be argued with some show of reason that exclusive devotion to systematic work cripples the imaginative faculty.[2] The methods of attacking the problems connected with living organisms have been increased and improved from every side, and the anatomist and physiologist, the morphologist, the embryologist, the student of bionomics, have all an equal claim to contribute to biological theory. The particular problems relating to the transformation of species are no doubt best dealt with by those who, by systematic work, have acquired a true notion of what is meant by the term "species." But so far as entomology is concerned, it must be confessed that the greater part of our systematic work has emanated from cabinet entomologists, who know nothing of the species they describe as living organisms by direct observation, and to me it appears doubtful whether this kind of work does confer any special faculty of speculating with advantage on the species question. It seems rather that the "field-naturalist" in the old sense of the term has the advantage, and I may remind you in this connection that during the voyage of the *Beagle*, when Darwin began to make those observations on island life which afterwards led him to take up the question of species transformation, he was essentially a "field-naturalist," his systematic work on the Cirripedia not having been commenced till after his return. So also Wallace, at the time when he independently elaborated the theory of natural selection, was certainly not a systematist in this narrow sense. He has been good enough to favour me with his views on this point, in a letter dated December 31, 1895, in which he says: "I do not think species-describing is of any special use to the philosophical generaliser, but I do think the collecting, naming, and classifying some extensive group of organisms is of great use, is, in fact, almost essential to any thorough grasp of the whole subject of the evolution of species through variation and natural selection. I had described nothing when I wrote my papers on variation, &c. (except a few fishes and palms from the Amazon), but I had collected and made out species very largely, and had seen to

1 "Life and Letters," vol. i. p. 348. Even in the days of my studentship, Huxley lectured on Natural History at the Royal School of Mines with the aid of diagrams and specimens only: practical work in the laboratory was unknown.

2 See a letter from Darwin to Bates in 1861, "Life and Letters," vol. ii. p. 379.

some extent how curiously useful and protective their forms and colours often were, and all this was of great use to me."

I had hoped to be able to discuss some of the current problems which are before biologists, and towards the solution of which entomology might contribute largely. Such, for example, are Galton's and Weismann's views on the non-transmissibility of acquired characters, the *rôle* of what Mr. Bateson calls "discontinuous variation" in the origin of species, the recent efforts to throw light on the all-important subject of variability by the statistical methods introduced by Galton and now being worked at from the experimental side by Weldon, and from the mathematical side by Karl Pearson. I feel, however, that I have trespassed already too long upon your forbearance, and while again thanking you for the honourable position in which you have placed me, I can only express the hope that my special plea for a more liberal use of the speculative method among our working entomologists will not be regarded by those who hold different views as a breach of the privilege of that office to which by your courtesy I have been elected. Should there be any who entertain this opinion, I beg them to make a liberal discount for personality, and they will find that the ultimate motive has been to promote the best interests of our science.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Waynflete Professor of Mineralogy (Mr. H. A. Miers), who has been absent during the early part of the term through illness, announces a course of lectures on Elementary Crystallography.

In a Congregation held last week, the proposal that a sum not exceeding £150 per annum for three years from October 1, 1894, should be applied out of the Common University Fund in maintaining a scholarship to be held by a student at the Marine Biological Station at Naples, was agreed to, *nemine contradicente*.

In a Congregation to be held on February 18, a form of statute amending the provisions of a statute made for the administration of the Lichfield Trust for Clinical instruction, will be proposed. The object of the statute is to provide for the conduct of the Pathological Department at the Radcliffe Infirmary by the Regius Professor of Medicine, or a person appointed by him, and for giving instruction in Pathology in accordance with the Regulations of the Board of the Faculty of Medicine.

The interest of the University is at present absorbed in the resolutions respecting the admission of women to the degree of B.A., which are to be submitted to Congregation on March 3. The first resolution, which proposes that women shall, under certain conditions, be admitted to the degree of B.A., will if carried tend to promote the study of every subject by women in Oxford, and therefore has an ultimate bearing on scientific studies. At the same time it will compel women to go through Responsions and the other examinations from which they are now exempt. There are some who think that this will be injurious to their interests. The most that can be said in the case of those who wish to read Natural Science is, that it will compel them to learn Latin and Greek either before they come to Oxford, or after they have come up. If the latter, they will find themselves obliged to keep four years residence, which most do not as things now are. If they know enough Latin and Greek to pass Responsions before coming into residence, their case will not be altered, for a woman competing for honours in one of the final subjects in the Honour School of Natural Science always passes the preliminary examinations required by the statutes in the case of men. It is not proposed that the strict B.A. course should be obligatory on all women students. Those who do not wish totake up Latin and Greek, but wish to read Natural Science or another subject such as History, will be allowed to do so under existing regulations, and so may escape Responsions; but they will also have to forego the distinction of the degree.

CAMBRIDGE.—St. John's College has made arrangements for the admission of post-graduate students desiring to pursue a course of advanced study or research under the new regulations of the University. Until the statutes now before the Privy Council are approved, candidates for admission are required to present a letter of recommendation from the Professor or other teacher under whom they propose to work in Cambridge. Further particulars may be learned on application to one of the tutors of the College.

Mr. J. N. Langley, F.R.S., Lecturer in Physiology, has been approved for the degree of Doctor of Science.

T.R.H. the Grand Duke of Hesse and Prince Henry of Prussia have presented to the Museum of Zoology the skeleton of a wild boar.

The following have been appointed Electors to the undermentioned professorships: Chemistry, Prof. Thomson; Plumian (Astronomy), Sir G. G. Stokes; Anatomy, Downing (Medicine), Surgery, and Pathology, Prof. Foster; Botany and Physiology, Prof. Allbutt; Geology, Dr. Phear; Mineralogy, Prof. Liveing; Zoology, Mr. J. W. Clark; Experimental Physics, Prof. Clifton; Mechanism, Mr. Horace Darwin.

A MEETING was held at Cardiff last week to start a public subscription in aid of the erection of new buildings for the University College of South Wales. A sum of £20,000 is required to meet the conditional grants made by the Treasury and the Drapers' Company. Contributions amounting to £13,000 were promised at the meeting. Lord Windsor, who presided, will contribute £2500, and a substantial sum has also been promised by Lord Tredegar. It is expected that £30,000 will be raised. Mr. Alfred Thomas, M.P., contributes £1000, and Mr. John Cory a like amount.

Science announces the following gifts to education in America: The University of Pennsylvania has received a gift of 5000 dols. from Mr. Charles M. Swain, and of 5000 dols. anonymously, the money to be used without restrictions. The will of the late Martin Brimmer, of Boston, to take effect on the death of his wife, bequeaths 50,000 dols. to Harvard University. Ground has been broken for the first of the four buildings of the new biological school of the University of Chicago, which is to be erected with part of the 1,000,000 dols. recently given by Miss Culver. It is proposed to erect special buildings for zoology, botany, anatomy, and physiology, instead of one biological building, as planned before the receipt of Miss Culver's gift.

PRINCIPALS of Technical Schools and others who assist in deciding the character of instruction in chemistry, would do well to take to mind the lesson contained in the following extract, referring to the work of the Chemical Department, from the programme just received from the Central Technical College: "The object aimed at in this part [first year] of the course will be to encourage habits of accuracy and thoughtfulness, and to teach the art of experimenting with a logical purpose rather than to impress mere facts. . . . As soon as students have acquired the necessary proficiency as analysts and sufficient skill in preparing pure substances, they will be encouraged to undertake an original investigation, in order that they may learn to apply their knowledge, as well as develop their powers of observation and reasoning: and thus become fitted to solve problems which are continually presenting themselves in practice, and to improve and advance the industry with which they may be connected. The importance to students of thus devoting themselves, sooner or later, to the higher branches of chemistry cannot be too strongly insisted on; in no other way is it possible for them to acquire the breadth of view and the power of grappling with new problems, as they arise in practice, which are required of the technical chemist."

DR. H. E. ARMSTRONG has been for some time trying to instil a little scientific spirit into the School Board for London. In an address recently delivered at the Borough Polytechnic Institute, and printed in full in the *Technical World*, he described the excellent results attained by the introduction of the scheme of instruction in scientific method, drawn up by a Committee of the British Association. The Board has every reason to be proud of what its science demonstrators have done to promote the reformed methods of science instruction, of which Dr. Armstrong is the most active exponent. The methods have been proved to be practicable, and the results obtained by following them are most satisfactory. It remains for the School Board to recognise this by extending to all its schools in the metropolis (girls' as well as boys' schools) the teaching which has been so successfully carried on in one of its districts. If that were done, a great advance in education would be assured. Those who are engaged in the work of technical education are agreed, as Dr. Armstrong pointed out, that it is all but impossible at the present time to give true technical education in this

country, owing to the extraordinary defective condition of our preliminary school training. But if children in elementary schools were taught to appreciate the main principles of scientific method, it would be possible for them afterwards to properly avail themselves of the higher training which is offered to them, and which alone can render them competent as industrial and domestic workers. It is to be hoped, therefore, that the School Board will see its way to extending the work of scientific education begun under its auspices six years ago.

IN a preliminary report recently prepared for the Technical Education Board of the London County Council, Dr. C. W. Kimmins gives the following statistics to show the progress that has been made, especially in the teaching of physics and chemistry, in the secondary schools assisted by the Board.

	1893–4.	1894–5.	1895–6.
Number of pupils receiving theoretical instruction in physics	1867	1899	2266
Number of pupils doing practical work in physics	215	433	1576
Number of pupils receiving theoretical instruction in chemistry ...	2091	2287	2647
Number of pupils doing practical work in chemistry...	630	1101	1814
Percentage of those receiving theoretical instruction in physics, taking practical work in this subject	11·5	22·9	69·5
Percentage of those receiving theoretical instruction in chemistry, taking practical work in this subject	30·1	48·1	68·5

Dr. Kimmins points out that the statistics show that there has been a general advance in the number receiving instruction in experimental science at these schools, and that the proportion doing individual practical work has increased to a far greater extent. He reports that the general introduction of practical teaching in elementary physics is producing excellent results. A marked improvement is also to be noticed in the teaching of chemistry; the practical work is of a much more rational kind, and bears a closer relation to the class teaching. Qualitative analysis is rapidly ceasing to occupy the important position it has held in the laboratory in former years.

SCIENTIFIC SERIALS.

THE *Journal of Botany* commenced its enlarged issue with the present year, and the two numbers already published indicate that its editor will have no difficulty in filling its pages with matter of value to the English botanist. An interesting paper, by Mr. E. A. L. Batters, describes several new British seaweeds, including two new genera, *Colaconema* and *Traillicila*, both belonging to the *Florideæ*. Mr. J. H. Burkill contributes a paper on the variation in the number of parts of the flower of *Parnassia palustris*. Mr. A. H. Praeger proposes a division of Ireland into botanical districts, accompanying his paper by a map. There are a number of other papers on various departments of descriptive botany. The plates illustrate two new forms of British pond-weed described by Mr. A. Fryer, and new African plants described by Mr. A. B. Rendle and Mr. E. G. Baker.

Bulletin of the American Mathematical Society, vol. ii. No. 3, December 1895.—Prof. F. Morley, in a notice of Gundelfinger's Vorlesungen aus der Analytischen Geometrie des Kegelschnitte, classes it with two other recent analytic works on conic sections, for which one is very thankful; the other two are the works by the late Prof. Casey and Miss Scott. He states the plan of Gundelfinger's treatise to be to systematically develop the theory by means of homogeneous coordinates, while bringing out the fact that the elementary (x, y) system is merely a case to which we can descend when so minded. This latter may seem a minor point; pedagogically it is not so, and it is certainly not well explained in many books. The development of the theory is really analytic, though one feels that the analysis is under the control of a masterly geometric insight. Prof. Morley's review is a long one, and enters into many details of the work which has been edited by Dr. Dingeldey. Short notes follow, viz. on divergent series, by Prof. A. Chessin, and a simple proof of a fundamental theorem of substitution groups, and several applications of the theorem, by Dr. G. A. Miller.—Dr. James Pierpont contributes an interesting note on an undemonstrated theorem of the *Disquisitiones Arithmeticæ*. This ends with two theorems relating to the construction of a polygon of n sides by a series of *rational* conics, *i.e.* conics whose coefficients are rational in the current domain of rationality, and gives in three rows the polygons, constructible by rule and compass, known to the Greeks (twenty cases); then the polygons of this class discovered by Gauss (five cases); and, in the last row, the *additional* polygons which can be constructed when *rational* conics can be employed (thirty-five cases). The table is limited to constructible regular polygons of sides $\overline{\gtrless}$ 100.—Notes and new publications close the Number.

Bollettino della Società Sismologica Italiana, vol. i. 1895, No. 7.—Ernesto von Rebeur-Paschwitz, by A. C.—The first instant of the great earthquake-shock of May 18, 1895, noted in Arcetri (Florence), by A. Abetti.—On the Florentine seismic centre, by M. Baratta. A topographical discussion of the three principal earthquakes felt in the neighbourhood of Florence in the present century, those of 1812, 1887, and 1895. The centres of the meizoseismal zones, though very near one another, are not quite coincident; but this, it is suggested, may be due to a variation in the depth of focus, or in the intensity of the original disturbance.—Notices of earthquakes felt in Italy (May-June 1895), by M. Baratta. The most important are the Florentine earthquake of May 18, the Spoleto earthquake of May 20, and the Rovigo earthquake of May 25.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, January 16.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read:—The acetylene theory of luminosity, by V. B. Lewes. The adverse criticism of the acetylene theory of luminosity by Smithells does not affect the considerations upon which the theory is based; these are (1) that the unsaturated hydrocarbons in the inner region of the flame are largely converted into acetylene before luminosity commences; (2) that pure acetylene develops luminosity when flowing through a heated tube; (3) that the temperature necessary to decompose acetylene with evolution of light does not raise to incandescence the liberated carbon; and (4) that in luminous hydrocarbon flames of sufficiently high temperature, the luminosity varies directly with the amount of acetylene present at the point where luminosity commences.—The action of sodium alcoholate on certain aromatic amides, by J. B. Cohen and W. H. Archdeacon. Many of the aromatic amides form addition compounds with sodium methor eth-oxide; thus, acetanilide yields a substance of the composition PhNHAc, MeONa.—Note on the electrical conductivity of formanilide and thioformanilide, by T. Ewan.—The action of sugar on ammoniacal silver nitrate, by J. Henderson. A definite factor can be assigned expressing the action of glucose, lævulose, and galactose on ammoniacal silver nitrate under standard conditions, but no such factor can be obtained in the case of lactose or maltose, owing to secondary reactions. Canesugar, starch, and dextrin do not act on the ammoniacal solution under the standard conditions.—Solution and diffusion of certain metals in mercury, by W. J. Humphreys.—On some of the ethereal salts of active and inactive monobenzoyl, dibenzoyl, diphenylacetyl, and dipropionyl glyceric acids, by P. Frankland and J. MacGregor. The physical properties of these salts have been determined. and the relation between the rotatory power and the constitution of glyceric acid derivatives is discussed.—On the rotation of optically active compounds in organic solvents, by P. Frankland and R. H. Pickard. As a result of cryoscopic and rotatory power determinations of methyl dibenzoylglycerate and ethyl diacetylglycerate in various solvents, the authors find that when the substance has a low molecular weight, the specific rotation is high, and *vice versâ*; the bearings of these results are discussed.—Note on the action of hydrogen chloride on ethyl alcohol, by J. C. Cain.—Transformation of the alkylammonium cyanates into the corresponding ureas, by J. Walker and J. R. Appleyard. Measurements of the rates of transformation of the alkylammonium cyanates into ureas, and *vice versâ*, indicate that the cyanates are dissociated into two ions in aqueous solution. On certain phenylthiocarbamates, by H. L. Snape.—The available potash in soils, by T. B. Wood.

Linnean Society, January 16.—Mr. C. B. Clarke, F.R.S., President, in the chair.—Messrs. O. V. Aplin and William Cole were elected Fellows of the Society.—On behalf of Mr. G. H. Adcock, of Geelong, Victoria, Mr. A. B. Rendle exhibited and made remarks upon some photographs of *Hakea grammatophylla*, F. Muell, a little-known species of the Proteaceæ, of local distribution in South Australia.—Mr. G. F. Scott Elliot exhibited specimens of bark cloth from Uganda and the shores of Lake Tanganika, and gave an account of the mode of its preparation from the bark cloth fig, and of the fleshy Euphorbias and Acacias of British East Africa, illustrating his remarks with lantern slides from photographs taken by himself. Mr. Elliot remarked that the native cloth manufactured on the shores of the Tanganika was made on the same sort of rough loom which he had seen employed near Sierra Leone, and that as the Tanganika is ethnologically and botanically part of the west coast, it was interesting to find that the methods employed in countries so far apart were so similar in detail. A discussion followed, in which Messrs. Rendle, Holmes, T. Christy, and W. Carruthers took part.—On behalf of Mr. W. R. Ogilvie Grant, Mr. Harting exhibited some land shells and eggs and skins of two rare Petrels from the Salvage Islands, lying between the Canaries and Madeira. These islands were stated to be of volcanic origin faced with steep rocks from 100 feet to 300 feet in height, and covered with loose sandy soil, the vegetation consisting chiefly of the wild tomato *Lycopersicum esculentum*, the ice-plant *Mesembryanthemum crystallinum*, *Asparagus scoparius*, and *Cistanche lutea*. Amongst the shells collected were *Helix ustulata*, peculiar to the Salvage Islands, *H. pisana*, *H. Macandrewi*, *H. polymorpha*, *Rumina decollata*, *Littorina striata*, *Cerithium rupestre*, and *Nassa conspersa*. *Helix paupercula* was said to furnish the chief food of the Tarantula spider (*Lycosa maderiana*), and entire shells of *Helix pisana* had been found in the stomach of a Kestrel hawk shot on one of the islands. The Petrels exhibited with their eggs were *Pelagodroma marina*, and *Oceanodroma cryptoleucura*, which were found nesting in burrows after the manner of the Shearwater (*Puffinus kuhli*), of which great numbers were also breeding there. Mr. Howard Saunders offered some critical remarks on these birds, referring chiefly to what was known of their geographical distribution.—Mr. George Murray exhibited full-grown complete specimens of some giant Laminarians from the Pacific, *Nereocystis*, *Egregia*, and *Macrocystis*, and some very fine specimens of *Postelsia*, collected by Mr. W. E. Shaw on the coast of California. He made some remarks on the distribution of Californian *Laminarieæ*, and illustrated some points in the structure of their reproductive organs.—A paper was then read, by Prof. T. Rupert Jones, F.R.S., and Mr. Frederick Chapman, on the relations of the fistulose *Polymorphianæ* and the *Ramulinæ*, with the view of showing the existing evidence for or against the suggestion that several specimens referred to the latter of these two sub-families may really belong to the former.

Geological Society, January 22.—Dr. Henry Woodward, F.R.S., President, in the chair.—Mr. W. W. Watts, in the absence of Prof. Lapworth, called attention to three specimens of sandstone and limestone containing specimens of some species of *Hyolithes*, which Prof. Lapworth had found in the higher part of the Cambrian quartzite at Nuneaton in Warwickshire.—The following communications were read:—On the Speeton series in Yorkshire and Lincolnshire, by G. W. Lamplugh. Further work on the Speeton section, while extending the knowledge of the palæontological details, had fully sustained the results of the author's previous investigations. The rapid attenuation and final disappearance of the Speeton series in a westerly direction in Yorkshire was discussed, and though the available evidence was held to be insufficient to demonstrate the exact conditions, it was stated that, contrary to the accepted view, the lower zones were probably the first to die out and were overstepped or overlapped by the higher divisions, since at Knapton, fourteen miles inland, only the upper zones of the coast-section can be proved to occur. In Mid-Lincolnshire all the palæontological zones of Speeton were identified and traced, the presence of the leading zonal types of the cephalopoda readily establishing the general correlation proposed by Prof. A. Pavlow and the author. The President said that it was hardly possible when mapping in the field to do more than follow those petrological changes in the character of beds over any given area which are patent to the observer. The point discussed by the author was that the life-line did not follow the line of the same sedimentation, but life-forms may transgress, and did transgress, over sediments of different character when they happened to be accumulated at the same time. It was hoped, however, that the case propounded by the author was exceptional, and that, as a rule, the sediments and the fossils followed one another on the same lines.—On some Podophthalmous Crustaceans from the Cretaceous formation of Vancouver and Queen Charlotte Islands, by Dr. Henry Woodward, F.R.S.—On a fossil octopus, *Calais Newboldi* (J. de C. Sby., MS.), from the Cretaceous of the Lebanon, by Dr. Henry Woodward, F.R.S.—On transported boulder clay, by the Rev. Edwin Hill. The "mid-Glacial" sands of the cliffs between Yarmouth and Lowestoft are overlain at Corton by chalky boulder clay. But farther north than Corton some masses of the same clay occur in the interior of the cliffs, surrounded by the sands in undisturbed stratification, but passing into them by strings and patches such as suggest the melting off of enveloping ice. They had probably been floated and dropped there. The observations suggest that chalky boulder clay was being manufactured in one locality simultaneously with "mid-Glacial" sands in another.

Mineralogical Society, February 4.—W. W. Watts in the chair.—Mr. L. J. Spencer gave an account of some of the results he had obtained in the course of an examination of various massive and fibrous forms of calcite and aragonite.—Mr. F. Rutley read a paper relative to associated globular and rhombohedral forms of rhodochrosite and chalybite from Cornwall.—Mr. G. T. Prior described the microscopic characters of certain rocks, allied to Monchiquite, collected by Mr. Ridley in Fernando Noronha, Brazil.—Mr. W. J. Pope explained a method of determining the optic axial angle for the case where the faces of the investigated plate are oblique to a bisectrix, and demonstrated the phosphorescence of saccharin crystals on fracture.

Zoological Society, February 4.—Dr. A. Günther, F.R.S., Vice-President, in the chair.—Mr. G. A. Boulenger, F.R.S., read a report on the second portion of the reptiles and batrachians collected by Dr. A. Donaldson Smith during his recent expedition to Lake Rudolph, the first portion having been already described. In the present report forty-two species of reptiles and five of batrachians were catalogued—of which two lizards were described as new, under the names *Agama smithi* and *A. lionotus*.—Dr. A. Günther read a report on the collection of fishes made by Dr. Donaldson Smith during his expedition to Lake Rudolph. From Lakes Rudolph and Stephanie examples of eight species of fishes had been obtained. Of these, five were species also found in the Nile-basin, and mostly of wide distribution in Africa; while one (*Distichodus rudolphi*) was new to science. Two other species were also described as new, and named *Clarias smithi* and *Synodontis smithi*, after their discover.—Mr. Martin Jacoby offered some remarks on the system of coloration and punctuation in the beetles of the genus *Calligrapha* of the family Chrysomelidæ.—Mr. F. E. Beddard, F.R.S., read a paper on the oblique septa in Passerine and other birds, in which he pointed out a new character of Passerine birds.—A second paper, by Mr. Beddard, contained a note upon the syrinx and the ambiens muscle of an African stork (*Dissura episcopus*), and comprised some remarks upon the classification of the Herodiones.—A communication from Mr. R. Lydekker, F.R.S., contained a note on the mode of progression of the sea-otter.—A communication from Dr. St. George Mivart, F.R.S., contained a description of the hyoid bones of *Nestor meridionalis* and *Nanodes discolor*.

PARIS.

Academy of Sciences, February 3.—M. A. Cornu in the chair.—Notice was received from the Minister of Public Instruction of the approval, by the President of the Republic, of the election of M. Rouché.—On the equilibrium of an ellipsoidal envelope, by M. L. Lecornu. The problem of a flexible inextensible surface submitted to a given system of forces gives rise to a system of partial linear equations, the integration of which, in general, is not possible. The particular case, however, of an ellipsoidal membrane, which is of considerable practical value on account of its application to the theory of aerostats, can be dealt with by the use of elliptical coordinates, and the results of the integration are given.—The measurement of a section of the Paris base line, with the apparatus of Jäderin, by M. d'Abbadie. By the use of wires of steel and of bronze, of known coefficients

of expansion, a base line can be measured at the rate of 2500 metres *per diem*, as against 400 metres when bars are used as the standards of length.—Solar observations made at the observatory of the Roman College during the second half of 1895, by M. P. Tacchini.—On the complete solutions of the equation

$$x_1 \tan^{-1}\frac{1}{\kappa_1} + x_2 \tan^{-1}\frac{1}{\kappa_2} + \ldots + x_n \tan^{-1}\frac{1}{\kappa_n} = k \cdot \frac{\pi}{4},$$

by M. C. Störmer. A continuation of a note presented to the preceding meeting of the Academy.—On the energy dissipated in magnetisation, by M. Maurain. An attempt to measure the energy dissipated by iron and steel wires in a closed magnetic cycle when the variations in the strength of the field are very rapid (see p. 350).—Resistance of thin metallic sheets, by M. Ed. Branly.—Observations on a recent note, by M. G. Le Bon, on the "dark light," by M. G. H. Niewenglowski. A repetition of M. Le Bon's experiment, carried out in complete darkness, still gave a similar result, showing that the image is due to stored-up luminous energy.—Photography with dark light, by M. Gustave Le Bon. In further experiments made on this subject especial care has been taken to eliminate the possible influence of heat, and of light stored up in the plates.—New properties of the X-rays, by MM. L. Benoist and D. Hurmuzescu. The X-rays discharge a gold-leaf electroscope, and this offers a ready method for examining the permeability of various substances to these rays.—Experiments on the Röntgen rays, by M. A. Nodon. These rays are clearly distinguishable from the ultra-violet rays by the fect that the latter, obtained from a powerful arc lamp, fail entirely to affect a sensitive plate protected with several thicknesses of blackened paper. The Röntgen rays readily affect the plate under these conditions.—Transparency of metals for the X-rays, note by M. V. Chabaud. In sheets of 0·2 mm. thickness, platinum and mercury alone are perfectly opaque, while lead, zinc, copper, tin, steel, gold, silver, and aluminium are more or less transparent. In sheets of ·01 mm. thickness, platinum also ceases to be perfectly opaque.—The photography of metallic objects through opaque bodies, by means of the brush of an induction coil, without a Crookes' tube, by M. G. Moreau.—On the acid fluorides, by MM. Meslans and F. Girardet. The method employed is to act on the corresponding chloride with the fluoride of either arsenic, antimony, silver, or zinc. The fluorides of propionyl and of benzoyl were prepared and their properties examined.—Method of preparation of acid fluorides, by M. A. Colson. The acid anhydrides, treated with hydrofluoric acid, give the corresponding acid fluoride and acid. The chlorides of acetyl and propionyl are very easily obtained in this way.—On a hydride of lithium, by M. Guntz. Lithium, at a low red heat, absorbs about seventeen times its volume of hydrogen without any change of appearance; at about a red heat further absorption commences, and on cooling the lithium is seen to be covered with a layer of hydride. This was prepared in a pure state, and proved to be LiH.—The negative reaction and the centre of the retina, by M. Aug. Charpentier.—Researches on the embryonic nervous system of the Nauplius and of some larvæ of marine animals, by M. N. de Zograf.—On an Ophidian of the cretaceous earths of Portugal, by M. H. E. Sauvage.—Physiological researches on the respiration of fishes (*Ammodytes tobianus*), by M. J. B. Pieri. This fish was able to completely extract the oxygen from a solution of air in water, although it could not take out all the oxygen from a solution rich in the gas. Asphyxia is never instantaneous, even when the *Ammodytes* is introduced into water completely freed from dissolved oxygen. This fish can exist without inconvenience in water containing a considerable quantity of dissolved carbon dioxide.—Observations on the cephalic vesicle of insects of the family Muscides, by M. A. Laboulbène.—*Mucor* and *Trichoderma*, by M. Paul Vuillemin. Some remarks on a paper of M. J. Ray on the parasitism of a *Trichoderma* on a supposed new species of *Mucor*.—On the geological characters of the auriferous conglomerates of the Transvaal, by M. L. de Launay.—On the bed of eruptive and metamorphic rocks of the basin of Lavol, by M. D. P. Œhlert.—Petrographic study of the Albitophyres of the Laval basin, by M. Michel Lévy.—The effects of the solar displacements, considered by themselves, on the barometric pressures of the zone 10° to 30° N., by M. A. Poincaré.—On a meteor seen at Baleine on January 6, 1896, by M. Doumet-Adanson. This meteor, the appearance of which was noted to the Academy on January 13, was seen at Baleine at 5.7 p.m. (Paris time), passing horizontally, about 25° above the horizon.

BERLIN.

Meteorological Society, January 7.—Prof. Börnstein, President, in the chair.—Prof. Kremser spoke on the duration of sunshine over Europe, basing his remarks on the data available from the various stations. The mean duration increases from the north towards the south, being least in Scotland and greatest in Spain. There is also a distinct increase from the west eastwards. It is less on mountains than over open plains, except at very high stations which are frequently above the level of the clouds and mist. All stations show a yearly minimum in the winter solstice, and a maximum in the summer; the latter occurs as early as May in Scotland, in June over Germany, and in July over Spain. There is no such annual variation observable at the highest stations. The amplitude of the annual curve is less when based on the percentage of observed to possible duration of sunshine. The curve of daily variation rises sharply in the morning, is then steady for some time, and falls again sharply towards the evening. At high stations the daily maximum occurs in the afternoon.

AMSTERDAM.

Royal Academy of Sciences, November 30, 1895.—Prof. Van de Sande Bakhuyzen in the chair.—Prof. Engelmann treated the following subjects. (1) The influence of the pulse frequency upon the physiological conductive power of the ventricular muscle. (2) A means of rendering extra-polar electric impressions upon muscles and nerves impossible.—Prof. Lorentz read a paper on Poynting's theorem concerning the transfer of energy in the electromagnetic field, and on two general propositions in the theory of light. After showing how Poynting's theorem may serve to calculate the energy of a magnetised body and the development of heat due to magnetic hysteresis, the author discussed a more general formula, already used by Volterra. The application of this equation to the propagation light (homogeneous and of constant intensity) leads in the first place to a well-known law of reciprocity (viz. a relation between the vibrations at a point A, caused by a source of light at B, and the vibrations at B, produced by a source at A) and in the second place to a generalisation of "Huygens' principle." If, in a system of conducting or dielectric, isotropic, or anisotropic bodies, surrounded on all sides by the ether, a closed surface be arbitrarily chosen, so, however, that all sources of light are external to it, then a definitive distribution of sources of light over this surface may be indicated, which would give rise at all internal points to the same vibrations as are produced by the external sources.—Prof. Kamerlingh Onnes communicated Dr. Zeeman's further measurements on the absorption of electrical waves in different electrolytes. The results are: (1) the intensity of electrical vibrations (wave-length 6·5 m.) decreases to one-third of its original value when the vibrations pass a layer of a solution of sulphate of copper, 5 per cent. c.m. in thickness, the resistance being $3340 \cdot 10^{-10}$ that of mercury. (2) Different aqueous solutions of the same conductivity absorb vibrations of the same frequency in the same degree.—Dr. W. van Bemmelen has drawn the lines of equal secular variation of the magnetic declination for the period 1540–1880. The values of the yearly variations have been determined by measuring the inclination of the curves on his map, which shows the curves of the secular variation for 8 x 18 intersections of meridians and parallels (meeting of September 28).—The maps for 1780 and 1880 show that Bauer's isoclinal poles lie in the immediate vicinity of the lines of maximum variation; whilst the whole system of maps points out the fact that in the tropical zone these lines and the agonic lines accompany each other. The mean yearly rates of shifting of the poles, the agonic lines and the maximum lines, viz. 0°·194, 0°·184 and 0°·21, agree very closely.

December 28, 1895.—Prof. van de Sande Bakhuyzen in the chair.—Prof. W. Kapteyn gave a new treatment of a problem on *Analysis situs*.

GÖTTINGEN.

Royal Society of Sciences.—The third part of the *Nachrichten* (physico-mathematical series) for 1895 contains the following papers communicated to the Society:—

May 25.—On the development of *Dadocrinus gracilis* (von Buch) and *Holocrinus Wagneri* (Ben.), and their relation to other crinoids, by A. von Koenen.

June 15.—On the integration of the partial differential equation $\Delta u + k^2 u = 0$ on Riemann's surfaces, by A. Sommerfeld.—The hypsographic curve of the earth's crust and the relations of Romieux ,by Hermann Wagner.

July 6.—On certain regularities in the spectra of solid bodies, and on a new determination of the sun's temperature, by F. Paschen.

July 20.—Researches (ii.) from the Göttingen University Laboratory: (1) On new instances of isomerism and abnormal molecular refraction in certain cyclic ketones; (2) on pulegon, by O. Wallach.—Report on the scientific memoirs issued from the Göttingen University Pathological Institute in the session 1894–95, by J. Orth.

October 19.—(1) Contributions to the theory of algebraic numbers; (2) the unimodular substitutions in an algebraic *Zahlenkörper*, by A. Hurwitz.—On a geometrical representation of the ordinary development of a continued fraction, by F. Klein.—On the regions of discontinuity of the groups of real linear substitutions of a complex variable, by Robert Fricke.—On the foundations of the theory of "ideals," by Ph. Furtwängler.

November 2 (Commemoration-day).—On the "arithmetisation" of mathematics, by F. Klein.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, FEBRUARY 13.

ROYAL SOCIETY, at 4.30.—On the Behaviour of Argon and Helium when submitted to the Electric Discharge: Dr. J. N. Collie and Prof. Ramsay, F.R.S.—On the Generation of Longitudinal Waves in Ether: Lord Kelvin, F.R.S.—On the Discharge of Electricity produced by the Röntgen Rays, and the Effects produced by these Rays on Dielectrics through which they pass: Prof. J. J. Thomson, F.R.S.

EMBRYOLOGY.

Text-book of the Embryology of Invertebrates. By Dr. E. Korschelt and Dr. K. Heider. Part I. Translated from the German by Edward L. Mark and W. McM. Woodworth. Pp. xvi + 484. (London: Swan Sonnenschein and Co., 1895.)

EMBRYOLOGY "is one of the most important subjects in the whole round of Natural History." So says Darwin, and so say all zoologists who have the knowledge to appreciate, and the training and patience to deal with, the innumerable facts which constitute that most fascinating branch of their subject.

Formerly the view was held—it is even now held by some zoologists—that embryology is a subject apart from the other branches of zoology; that a man might be a complete zoologist without any knowledge of it; that it could throw but little light upon those great questions of structure which it is the ambition of comparative anatomy to solve; and that it was a study which, if it did not actually narrow the mind, took it away from that pure and sympathetic contemplation of nature, which it was the object of all true zoological teaching to call forth. To such zoologists embryology was of but small importance.

And the reason for this attitude is not far to seek. In the good old days the equipment required by the zoologist was but slight, and the facts lay bare for every one to note. A collecting-box and a bottle of spirits, a pocket-lens and, by the more advanced, a pair of forceps and a scalpel were all that were required. With such simple instruments, combined with a certain power of observation and a love for nature, which had often more of an æsthetic than a scientific character, a man might go far. But this delightful time is past—the unaided pocket-lens is now of little service, the forceps and scalpel have revealed almost all that they are capable of revealing, and the bottle of spirits requires to be supplemented by a whole complement of elaborate reagents. And if this is true of the material requisites, how much more true is it of the intellectual. In addition to the elaborate technique, the complicated instruments and the whole routine of the modern laboratory, there are the immense accumulations of knowledge which must be mastered if nature is to be questioned with any hope of success. It is this training which is often irksome; it is these instruments which cannot be used without patience and practice; which bewildered the older zoologists, and which make the way so hard for those younger men who, with a collector's or an æsthetic's love for nature, wish to pose before the world, after the manner of their fathers, as experts in an important branch of science.

But to return to our question: What is the relation of embryology to the other branches of zoology? Clearly it is an integral part of the well-known and respected science of comparative anatomy; it is the part of that science which deals with the anatomy of the organism before the attainment of sexual maturity, and, inasmuch as most animals pass through several stages of structure during their growth, the study of it is, to the scientific anatomist at least, as important as the study of the adult. One would have thought that this position would have been conceded on all hands, and that there would have been no necessity to call attention to it here. But it is not so; for there are anatomists who hold that, in solving anatomical problems, the structure of the embryo is of very small importance indeed as compared with the structure of the adult.

But embryology is more than this. It has caused the use of methods and instruments which have extended the bounds of comparative anatomy; it has brought into the field men who, in their love of nature, in their capacity for patient labour, and in their powers of accurate observation, are at least the equals of the older naturalists; and it has brought to light facts of natural history which, but for it, would have remained in darkness, and which even that zoological butterfly, the amateur naturalist, would not pass by. To mention only a few such. What more wonderful phenomena can be mentioned in the whole round of natural history than the larval development and metamorphosis of the Echinodermata; the detachment and digestion of the brain and sense organs of the larva of Phoronis on the attainment of sessile life; the growth of the worm within the larval skin of the Pilidium; the double sexual life of the Ctenophora.

Of the relation of embryology to the evolution theory, we can only shortly refer. Apart from the construction of phylogenetic histories, to which unfortunately there appears to be no end, our science is of supreme importance as affording the most unanswerable, indirect corroboration of that theory which it is possible to obtain.

But embryology has wider bearings even than these. The systematist is powerless without it. He may ignore it, he may neglect it; but if he do so, he can have no true insight into the relations of the great groups. Until embryology was a science, the Tunicata were grouped near the Mollusca; and without its aid the great Cuvier himself was led into the error of placing the Cirrepedia in the same phylum. Nor can the student of species avoid his fate. To-day he may rejoice that he at least can pass by on the other side, and leave embryology to the embryologists. But, alas! it will not be so for long; even now embryonic characters are beginning to assert their claims for recognition, and in the near future a knowledge of development will be as indispensable to the species-monger as to any other kind of zoologist.

It would thus appear that embryology has a classificatory as well as an anatomical value, and should be dealt with in works on zoology. But while in works on anatomy it is quite impossible to ignore the facts of development, it is unfortunately true that in zoological treatises, systematic embryology is either entirely neglected or else treated in such a sketchy way as to be useless, or nearly so, to the student. But in saying this, we desire to impute no blame to zoological authors, who are already overburdened with the immense mass of facts which they have to treat. Hence the necessity for books specially dealing with the subject—books which had their model and initiator in the great work on comparative embryology by F. M. Balfour. The book before us may, indeed, almost be regarded as a second edition of that work, so closely are Balfour's plan and

method followed. And surely no greater praise could be given to it. Not only is the method of treatment almost identical, but the points of view from which the facts are looked at is almost exactly the same as that adopted by Balfour more than fifteen years ago. The passage—"In the group Metazoa or germ-layer animals, on the contrary, there always results a multicellular organism (cell-community or cell-corm), in which the single cells give up their independence for the good of the community, and accommodate themselves to a division of labour, in consequence of which there is brought about a diversity in the structure and function of the cells of the Metazoan organism" (Introduction, p. 1)—shows that the cell-theory in its modern form is the key-note of the work, and that the germ-layer hypothesis of Huxley and Kowalevsky still holds the prominent position assigned to it in Balfour's work. And we are very far from blaming the authors for thus adhering to the old faiths of the seventies; for though much may now be urged to diminish the importance of these hypotheses, which in their day have done yeoman's service to the furtherance of anatomical science, and though it might be argued, as has lately been done in more than one quarter, that they are moribund and powerless to lead us further in the intricate task of unravelling structure, still it would be foolish, to say the least of it, to cast them on one side in a didactic work of this kind, until some better, some more penetrating guide has been found to replace them.

After this, it is hardly necessary to say that it is our opinion that the authors are men of sound judgment, a fact which is shown in every chapter of their work. But we have said enough to indicate our admiration for the work. The authors are scholars in the best sense of the word. Their erudition is profound, their accuracy is minute, their industry and patience must be marvellous, and their critical powers are quite first-rate. In soundness and impartiality their judgment leaves nothing to be desired. So far as our knowledge goes, credit is always well apportioned, and conflicting statements are handled, if not with the consummate skill of Balfour, still in a manner which is unusual in works of the kind.

The volume before us is part i. of the German work, and deals with the Porifera, Cœlenterata, Platyhelminthes, Nematelminthes, Annelida, Echinodermata, Rotifera, Chætognatha and Enteropneusta, treated entirely in a systematic manner.

Parts ii. and iii., of which a translation is promised, complete the treatment of the invertebrata. In the authors' preface, a general part is spoken of, but so far as we know it has not yet appeared; and the vertebrata are expressly excluded from the scope of the work. This omission we hold to be a defect. The authors defend it on the ground that that department of the subject has been adequately treated recently by other hands. We entirely differ from this view; for not only do we hold that no entirely satisfactory treatment of the vertebrata has appeared since Balfour's work, but that no satisfactory treatment is possible apart from the rest of the animal kingdom. Moreover, though the phylum vertebrata is only one phylum of the animal kingdom, no scientific treatment of the subject as a whole is possible without at least a consideration of the facts of vertebrate embryology. One might as well, in a scientific treatise on chemistry, omit all reference to carbon and its compounds. We sincerely hope that the authors will change their minds, and will, when they issue the general part, append an account of vertebrate embryology.

In a work of this magnitude there must be a certain number of small mistakes and slips; but we have found surprisingly few of them. We might, however, call attention to two, which bear on subjects having a certain amount of general interest. On p. 3, it is stated that the "ectoderm germ-layer presides over the animal functions (sense, perception, locomotion)." This is of course an error; for not only are the most important muscles often endodermal in origin, but, if certain observations are to be trusted, it is highly probable that the main nervous tracts arise *in situ* in the mesoderm. On p. 31, a series of diagrams showing the structure of the canal-system in certain sponges is described as "a diagram of the development of the canal system in various sponges." This is obviously a loose statement. What the authors probably mean is, that the diagrams illustrate various conditions of the canal-system, which are actually met with in different sponges, and which may be supposed hypothetically to represent permanently stages of structure through which the more complicated canal systems have passed in phylogeny. This slip is of more importance than at first sight it may appear to be, because phylogenetic speculations, if they are to have any value at all, and not to be mere hindrances, must be described in the most precise language, and based upon the most exact ideas. It is very important at the present time, when so many loosely-conceived and worthless phylogenetic hypotheses are constantly being put forward, that the necessity for precision and clearness of thought at least should be regarded as indispensable in all attempts to trace the ancestry of living animals.

With this one exception, which is obviously a slip, this volume is happily entirely free from all blemishes of the kind. The phrase, "embryonic connective tissue," though no doubt sanctioned by usage, is one to which we take exception. The tissue so described has almost, if not quite always, nothing whatever in common with connective tissues as ordinarily conceived, but is a germinal or growing tissue which gives rise to most important organs.

The translators have performed their task with skill. There are short notices, made for the most part by the authors, of the more important memoirs which have appeared since the publication of the original in 1890. The German idiom is quite got rid of, and the book in its English form is eminently lucid and readable. The translators are to be congratulated on their work, and have earned the gratitude of all English zoologists. But, alas! there is one serious blemish. If the translators were Englishmen, we should call it an error of taste; but being Americans, we must make allowances, and put it down as another example of the curious incompleteness of their knowledge of the English language, which some Americans are known now and again to display. We all know how frequently the word *anlage* is used in German works on embryology; and we all know that some authors, notably those writing in America, refusing to use the English equivalent, have attempted to add this word to the English language. The translators of this work have

not taken this course—we almost wish they had—they have decided to use an English equivalent. But instead of using the English word *rudiment*, a well-known word, a respectable word, one might almost say a classic word in the ears of English zoologists—a word which well covers the meaning of the German word "anlage," and the use of which in this sense can be productive of no confusion, they have invented a new rendering; and—O ye gods!—what a rendering!

We would pardon the ignorance of one who did not know that the first and most common meaning of the word *rudiment* is the "original of anything in its imperfect form." But the editors have not stopped short at this: they have fallen from Scylla into Charybdis; they have employed a word with the meaning of which every schoolboy is familiar—often painfully familiar—a word which has only one usage in English, and that a usage which, to all people with a sense of humour, would entirely unfit it for the present purpose, even if it were required. They have displayed an ignorance which is almost incredible in men who speak the English language, an ignorance which, while it may help us to understand certain peculiarities observable in some of their countrymen, is fraught with the most ludicrous results in the present instance. We sincerely regret that we are obliged to call attention to this blemish. It is hard upon the authors to have their work served up to the English public with such a grotesque ingredient. We feel that the publishers, who at any rate are Englishmen, should have seen to the matter, and we sincerely hope that the pages of parts ii. and iii. of this most valuable work will not be defaced by such a misuse of a well-known and old-established English word.

It only remains to say that the book is well got up. The printing is good, the illustrations are excellent, and the size is convenient.

THE EVOLUTION OF CULTIVATED PLANTS.

Plant-Breeding: being Five Lectures upon the Amelioration of Domestic Plants. By L. H. Bailey. Pp. 293. Figs. 20. (New York and London: Macmillan and Co., 1895.)

WHEN, in 1859, Darwin's "Origin of Species" first saw the light, naturalists were astonished at the large number and variety of illustrations the author derived from cultivated plants. This feeling was accentuated in 1868, when the "Variation of Animals and Plants under Domestication" appeared. Previous to that time botanists had, for the most part, ignored the productions of the horticulturists, or looked upon them as so many sources of annoyance and confusion. With the publications just mentioned, there dawned upon the minds of thinkers the notion that what was done in nature slowly and gradually had been, and was effected by the gardener rapidly and, relatively, with equal certainty.

Variation, selection, adaptation, progressive evolution were seen to constitute the basis of the work of the gardener and the "florist" in their attempts to gain new and improved varieties. Cross-breeding and hybridisation had been practised for generations. The first artificially-produced hybrid on record was raised in the beginning of the eighteenth century by Fairchild—a gardener. It was a hybrid Pink. After him came Bradley, Logan, Philip Miller, who each and all carried on their experiments on evolutionary lines. With Thomas Andrew Knight and Dean Herbert, we are brought down to modern times. They were great gardeners. Assuredly they were great evolutionists. And the work is going on day by day with more activity than ever. In addition to the constant improvement recognised in the case of agricultural and garden plants, the evidence of which may be seen in the seedsmen's trial-grounds and in the experimental garden of the Royal Horticultural Society at Chiswick, there is a positive production of new forms, so different from pre-existing ones, that were the history not known they might be thought to constitute new genera, or, at any rate, new sections. Take the tuberous Begonia, for instance. Thirty years ago or so, there was nothing like it either in nature or in gardens. Now, by the blending of various species, entirely new races have been produced; and these, to a large extent, are reproduced from seed. From the seedlings selection is made, and so the progress goes on. But some will say, Will they not die out if not looked after by the gardener? Of course they will; but are there no such things as retrogressions and extinctions in nature? The Begonias in question would doubtless die here if uncared for, as they are not suited to the climatal environment; but they would at least have a very good chance if removed to the Andean forests, whence their progenitors sprang.

The gardener, moreover, is often in a position to demonstrate the hybrid origin of some wild plants. There are now numerous cases in which certain wild orchids have been supposed, from the blending of morphological characters which they present, to have had a hybrid origin. Some botanists have hesitated to accept this kind of evidence, though we may say incidentally, that it has been borne out, in other genera, by Dr. Macfarlane's histological researches. More to the point is it to say that certain of these hybrid orchids have been actually artificially produced in Messrs. Veitch's nurseries by crossing the species that were reputed to be the parents of the supposed natural hybrids. The evidence is complete; and it alone is sufficient to show to the evolutionist what a vast and fertile field lies open to him in the observation, and especially in the experimental investigation of ordinary cultivated plants.

The reader will find numerous valuable hints and suggestions on the subject in Prof. Bailey's little book. It contains the substance of five lectures on variation and its causes, and on their application to the practical purposes of the cultivator. The most successful hybridisers and selectors act on a preconceived plan, according to their requirements; but since so much attention has been directed to the subject, there has been—indeed there always has been—much indiscriminate, haphazard experiment. Prof. Bailey cautions experimenters against such unscientific procedures, and supplies directions whereby the aim and purpose may more surely be attained.

The fourth lecture is largely a reprint from Carrière's paper on bud-variation, and from Focke's work on the hybridisation of plants; whilst the fifth contains practical instructions as to the methods of crossing employed by experimenters. A glossary and an index terminate a book which, if it contains little that is not familiar to experts, will be extremely serviceable to beginners, and will furnish the naturalist, who wishes to gain a general survey of the matter, with just the information he requires. For this latter purpose, a fuller bibliography would be an improvement in a new edition.

MAXWELL T. MASTERS.

OUR BOOK SHELF.

Die Haustiere und ihre Beziehungen zur Wirtschaft des Menschen. Eine geographische Studie von Eduard Hahn. Large 8vo, pp. 581, and a map. (Leipzig: Duncker and Humblot, 1896.)

THIS volume is an important contribution to our knowledge of the relations existing between domestic animals and human economy. It forms a large octavo volume of nearly 600 pages, compiled from all sources, and of its interest the reader may form some idea from the following summary of its contents. After a brief introduction, we have our domestic animals considered from a zoological standpoint; here the interesting questions of hybridisation and of the returning of once-domesticated animals to a feral state, are investigated. Next the subject of the profitableness of such animals is considered, the author alluding but casually to the fact that some animals were decidedly domesticated, without an eye to profit; he cites the case of some South American aborigines keeping a "grylla" in their houses for the perfume, but has apparently overlooked the case of the Greeks domesticating the cigale. He on purpose omits the subject of animals in connection with "worship," quoting Tylor, that "it is a subject not wanting in interest, but is one abounding in difficulties."

The list of domesticated animals (using this term in the widest sense of animals kept for the use or service of man) given is a long one, comprising not only such familiar forms as the dog, horse, ass, horned cattle, sheep, goats, reindeer, &c., but also the yak, gaur, llama, guinea-pigs, and ferrets. The list of birds is extensive; reptiles are not mentioned, save the axolotl in an appendix; and among the fishes we find the carp, the gold-fish, and the paradise-fish. Bees and several silk-spinners are mentioned among the insects.

The concluding portion of the work is devoted to economic geography, and is illustrated by a map, in which an attempt is made to mark out the world into areas characterised by aboriginal industries. Certain regions are coloured as being those of the hunters and fishers, then of the several divisions of mankind living upon tubers and cereals, or further advancing to the culture of such plants as sugar-cane, tobacco, and the like; still greater progress is indicated by the type of gardening as practised, for example, by the Chinese. Of the various regions of the world alluded to, that of Australia is the one most unsatisfactorily treated; there is scarcely an allusion to the wonderful culture of vegetables by the Maoris, for a very good knowledge of which we are long since indebted to the labours of Colenso and others. The subject treated of in this volume is of the widest range—in space covering the known world, in time going back to days of indistinct tradition, and for its complete investigation requiring some knowledge of an immense range of literature, this work is a contribution towards this history, and as such is a most useful one.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Velocity of Propagation of Electrostatic Force.

LORD KELVIN, in his letter published in NATURE, February 6, says that "it is an abuse of words to speak of the 'elastic solid theory of electricity and magnetism' when no one has hitherto shown how to find in an elastic solid anything analogous to the attraction between rubbed sealing-wax and a little fragment of paper . . . or between two wires conveying electric currents."

It has, no doubt, escaped Lord Kelvin's notice that in 1884 a paper was published in the *Cambridge Philosophical Transactions* (vol. xiv. p. 45), in which I showed that two spheres pulsating in an elastic medium will, if pulsating in opposite phases, attract each other as sealing-wax attracts paper, and if in the same phase will repel just as like electrified bodies do, the action being propagated in the medium with a finite velocity.

In a subsequent paper, published in 1885 (*Camb. Phil. Trans.*, vol. xiv. p. 188), I have shown that two straight oscillatory twists placed in an elastic medium will, if in the same phase, attract each other as like electric currents do, and if in opposite phases will be repelled. In fact, if the vibration of the surface of a solid placed in a vibrating elastic medium is resolved into normal and tangential vibrations, the normal vibrations will, as pointed out in these papers, cause the solid to exhibit several of the phenomena of statically electrified bodies, while the tangential vibrations will cause it to behave as if carrying a current and acted on by a magnetic field.

I only venture to mention these results because it appears from Lord Kelvin's letter that they are not generally known. They should, I believe, assist in forming a conception of a possible explanation of electric action, based on the supposition of an elastic medium which resists changes of volume and shape.

Firth College, Sheffield, February 11. A. H. LEAHY.

In making the statement quoted, I had fully taken into account all such considerations as those referred to in Prof. Leahy's letter. The rigidity of the solid absolutely prevents any phenomenon, analogous to the attractions by rubbed amber or lodestone, from being exhibited in an elastic solid. No such barrier exists if the elastic medium be fluid; and §§ 733-740 of article[1] xli. of my "Electrostatics and Magnetism" contain conclusions of hydrokinetic theory regarding mutual forces between movable tubes or rings with cyclic motion of an incompressible liquid through them, showing magnitudes identical with, *but directions exactly opposite to*, those of the forces in electro-magnetic analogues consisting of movable conductors conveying electric currents. The remainder of that article contains remarks on Guthrie's interesting paper[2] "On Approach caused by Vibration," and "On the Attractions and Repulsions due to Vibration, observed by Guthrie and Shellbach," from which the following (§ 744), being an extract from a report, in the *North British Daily Mail*, of an address by myself to the Philosophical Society of Glasgow on December 15, 1870, may possibly be read with interest in connection with Prof. Leahy's letter:—

"The speaker began by stating that interesting papers had recently appeared in the *Proceedings* of the Royal Society and the *Philosophical Magazine*, by Prof. Guthrie, in which some very curious hydrokinetic phenomena were described. From hints and suggestions in his paper, it seems that Prof. Guthrie connected, in his own mind, these phenomena with possibilities of explaining some of the more recondite actions in nature; and he (the speaker) believed that what gave the great charm to these investigations for Prof. Guthrie himself, and no doubt also for many of those who heard his expositions and saw his experiments, was, that the results belong to a class of phenomena to which we may hopefully look for discovering the mechanism of magnetic force, and possibly also the mechanism by which the forces of electricity and of gravity are transmitted. The speaker, however, did not lay any stress at present upon the possibility of applying these results directly to explain magnetism. He believed, on the contrary, that the true kinetic theory of mag-

[1] First published in the *Proc.* Roy. Soc. Edinb. for Feb. 1870.
[2] *Proc.* Roy. Soc., August 26, 1869.

netism (and the ultimate theory of magnetism is undoubtedly kinetic)[1] involves quite a different class of motions from those to which the beautiful phenomena discovered by Mr. Guthrie are due. He rather wished to point out the close connection that existed between the laws of some of these actions and the laws of magnetism, which, while involving some remarkable coincidences, involves certain contrasts decisive against any hypothesis, such as the ingenious one[2] of Euler, explaining magnetism by fluid motion directly comparable with that which forms the subject of the present communication." KELVIN.

The University, Glasgow, February 13.

The Stress in Magnetised Iron.

I AM glad to see from Dr. Taylor Jones' letter that he and Mr. Nagaoka contemplate a discussion of the *magnitude* of the magnetic stress really existing in iron under, I hope, natural conditions. A complete discussion of the sort would, I think, be of much value. It seems to me somewhat doubtful what is the true nature of the assumptions latent in Maxwell's work, vol. ii. arts. 630–646. I am uncertain whether his conclusions are strictly applicable to any case other than that of an infinite homogeneous medium in which the permeability is unity. In the ordinary case of a magnetic bar, some lines of force traverse the surrounding air, and complications also arise from the "free" magnetism at the ends. When, as in previous experiments on the magnitude of the stress, a magnetic bar or ellipsoid is cut in two, the stress measured is presumably that exerted across a minute air-film separating the opposed surfaces. Under such circumstances the formula $B^2/8\pi$ is, according to Dr. Taylor Jones' own experiments (*Phil. Mag.* for 1895, p. 254), a close approximation to the stress when the permeability of the bar is large.

Prof. Ewing's letter also calls for some comment at my hands. The view I advocated is hardly that he attributes to me. I expressed no opinion as to the correctness of the measure $B^2/8\pi$, assumed by Dr. More and others, for the *intensity* of the magnetic stress. Neither did I say the stress system reduced to a *simple* longitudinal tension. It is, I believe, in general considerably more complicated, and is accompanied by strain perpendicular to, as well as along the lines of force. Avoiding complications unessential to the point at issue, I simply supported the view that the magnetic stress along the lines of force is a tension, and that the associated strain in the metal along this direction is an extension.

Again, Prof. Ewing says that the case illustrated by me in p. 270 is a "special one." The illustration in question is, however, just as applicable to the case of an endless ring, to which he specially refers, as to that of a long rod. It is really based on three hypotheses or assumptions, as valid in one case as in the other: (1) that the magnetisation is uniform; (2) that the air gaps, real or imaginary, are narrow compared to the length of the element; (3) that the existence of an indefinitely thin air gap, such as may be found between two attracting pole faces in contact, does not affect the *sign* of the stress.

Now (1) is merely a definition, and (2) a mathematical expedient to simplify the proof, so that (3) alone remains. As regards (3), I merely followed Prof. Ewing in § 145 of his "Magnetic Induction," except in so far as I did not assume the existence of a narrow gap to be wholly immaterial. As Prof. Ewing admits that the stress in the case of my illustration is a *tension*, we should, if he adhered to his original views regarding (3), be now on the same side. He has, however, apparently completely altered his views, for he says: "Make the iron continuous by closing up the gaps, and the tensile stress disappears." This seems an explicit declaration that there is no such thing as a "Maxwell stress," and that consequently neither extension nor compression can be assigned to such a cause. Prof. Ewing's new view implies a sudden large discontinuity between the state of close juxtaposition of magnetic material, when the stress he admits is large, and that of absolute continuity, when the stress he says is nil.

It would, I think, be premature to do more than call attention to this apparent discontinuity until the arguments in favour of the new view are produced.

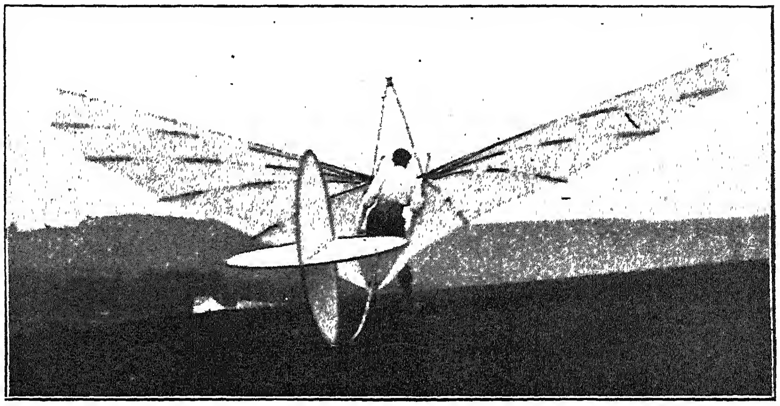
Prof. Ewing's remarks about the pulling and pushing of magnetised rings, indiarubber bands, &c., suggest that he experiences a difficulty in imagining any complete, homogeneous, isolated ring under conditions such that the normal stresses over all cross-sections are tensions. The consideration of the elastic stress system produced in an anchor ring by rotation about a perpendicular to the plane of its circular axis (line of centres of cross-sections) through the centre will be found, I think, to aid such a conception.

I must decline, I fear, to follow Prof. Ewing into the clothes-basket he refers to, though doubtless the experiment must be a fascinating one—for spectators. C. CHREE.

Kew Observatory, February 11.

Experiments with Soaring Machines.

AT the end of the article on Herr Lilienthal's soaring experiments, in your issue of January 30, reference is made to my trials, with somewhat similar apparatus, at Cardross, and it is said that so far I have not been very successful.



I do not consider this to be the case. I think that, so far as I have gone, my work has been rewarded with as much success as could possibly have been hoped for.

I only commenced to build my first machine just a year ago, and being very busy with other things, was not able to take the machine out to practise till June.

At first my wings were, as is stated, very much raised, so that the machine should have transverse stability of its own in flight, just as a kite is stable sideways when it is of this shape, or as a sheet of paper folded to a V-shape will always fall on the folded edge.

There is, however, a great practical difficulty with the raised wings, and that is, that if one stands not exactly head to wind, the machine tends to "pay off" from the wind, which then comes more on one side, and rolls the machine over.

With the wing tips lowered more as a gull's wings are, if the wind (virtual or real) is not ahead, through a squall or any other cause, the machine has very little tendency to raise on the windward side, and so be turned over by the wind.

Not appreciating this, certainly caused me some delay and breakages; but when I realised how great is the objection to the raised wings in such a squally place as Cardross, I curved the wings as shown in the second photo which I enclose, and with this original apparatus have been picked up by a puff of wind over and over again, sometimes as much as 12 feet above the spot I was lifted from, and put down again on exactly the same place. At other times, when there has not been so much wind, I ran to meet the wind with the front of the wings depressed somewhat, so that my weight is only partially taken by the wings, and in this way I am, strange as it may appear, able to run very

[1] "Electrostatics and Magnetism," § 290 (Roy. Inst. Friday Evening Lecture, May 18, 1860); "Electrostatics and Magnetism," § 546 (*Proc.* Roy. Soc., May 10, 1856).

[2] "Electrostatics and Magnetism," § 573.

much faster than without the wings; then raising the front edge a little, I am able to take a long soar down a slight incline. The only slopes on which I was able to practise, were not steep enough to make it possible for me to soar for any great distance; and therefore I have at times, on days when the wind was fairly steady, attached a string to the front of the machine, with which a boy has run and kept me in the air for about half a minute. I never used a line when there was enough wind to pick me up without forward movement, on account of the strong winds at Cardross being so very squally.

I had to stop experimenting at the end of September; but when I left off, I was pretty sure of my balance in the air, and was able to land without damage and without falling, even when soaring over the ground very fast. And this was the whole object of my work, so that I should be pretty sure of my balance before putting motive power into the machine to make horizontal flight possible. This I hope to do this year, with a petroleum engine, either working the screw propeller in the front of the machine, or two screws, one placed under each wing, so that the machine will then practically become a Maxim machine of the smallest size possible for one man to fly with.

Mr. Maxim has shown most clearly that his large machine at Bexley will rise on the underneath side of rails put down to prevent its rising further; and what is possible for this large machine, is just as possible for a small one. And I am confident that I could maintain horizontal flight with wings similar to those I have been using, or, better still, similar to those I am now making, which vary chiefly only in mechanical detail from the first, if driven forward as I propose.

Herr Lilienthal, who most kindly showed me his apparatus, and let me see him practise last April, has kept me informed of what he has been doing.

Mr. Lawrence Hargrave, of New South Wales, kindly wrote to me suggesting that I should use double surfaces, and advocated the construction he uses in his cellular kites, as being simple and light.

Although with the double surfaces now used by Herr Lilienthal a machine with the same area of sail can be made of less extreme dimensions, and a considerable saving can probably be made in weight, it has the disadvantage of having less area to act as a parachute in the event of speed through the air being lost, either by a sudden lull in the wind, or through want of skill on the part of the flyer. And I am as yet not at all sure that the upper surface with a puffy wind would not, from the very fact of its high position, prove a source of danger rather than the reverse.

My reason for saying this is because I tried a machine at Cardross with the wings just above my head, but found the machine with the low wings very much more easy to handle, especially when the wind was puffy; but in order to make more sure of this, I shall probably make a double surface machine at once.

It is quite possible that what is best at Herr Lilienthal's ideal practising place, where he has his cone-shaped hill and flat country for miles round, so that his wind is unbroken and steady, is not best in the proverbially squally district of the Clyde, where I have had to experiment.

The accompanying illustration will probably make my letter more clear.

PERCY S. PILCHER.

Science and Morals.

A HABIT has been growing of recent years among certain scientific men, which many of those with whom I have discussed the subject join with me in regretting. It is this:—After the announcement of an interesting discovery, a number of persons at once proceed to make further experiments, and *to publish their results*. To me it appears fair and courteous, before publication, to request the permission of the original discoverer, who probably has not merely thought of making identical experiments, but who has in many instances made them already, and has deferred publication until some grounds exist for definite conclusions.

The late President of the Chemical Society, Dr. Armstrong, has sought to justify such conduct. On p. 225 of the *Proceedings* of that Society for 1894, these words are reported as having been used by him:—"After having been told so much, chemists could not be expected to remain under the imputation that they had been eyeless for a whole century, and they would undoubtedly inquire into the matter. Although no one would seek to take the discovery out of the hands of those who had announced it, chemists unquestionably had the right, not only to exercise entire freedom of judgment, but also to critically examine the statements which had been made."

These words related to the discovery of argon by Lord Rayleigh and myself; and, as we were otherwise occupied, no notice was taken of them. Events, I think, have justified the course which we then took. But now that all personal element has been removed, I feel free to raise the question—Is this recommendation precisely consistent with the highest view of scientific morality.

An analogy will perhaps help. If a patent has been secured for some invention capable of yielding profit, and some person repeats the process, making profit by his action, an injunction is applied for and is often granted. Here the profit of the business may be taken as the equivalent of the credit for the scientific work completed; no original idea, undeveloped, is of much value; before it produces fruit, much work must be expended; and it is precisely after the publication of the original idea, that sufficient time should be allowed to elapse, so as to give the author time to develop his idea, and present it in a logical and convincing form.

Should such trespassing on newly-sown ground come to be the rule, instead of, as I fervently hope, the exception, the result will be this:—Scientific men will provide their private laboratories with a good lock; they will communicate their ideas to none, until they are worked out; and the pleasant and friendly intercourse, which is now universal, must be abandoned. Such a state of matters would be greatly to be regretted; and it is obvious that the progress of scientific discovery would be not immaterially hindered, if every scientific man were obliged to protect himself against what, after all, comes near to a breach of the Eighth Commandment. WILLIAM RAMSAY.

University College, February 14.

The Former Northward Extension of the Antarctic Continent.

MR. BEDDARD, in NATURE for December 12 (p. 129) has called attention to a new fact, "loading still further the already over-weighted scale which now dips so deeply in favour of the Antarctic continent." Permit me to add another fact bearing on the question, but whose significance has been quite overlooked hitherto.

The most characteristic of types which occur in the cold and temperate fresh waters of the southern hemisphere is the genus *Galaxias*—a type whose representatives are popularly known as trout in New Zealand, Tasmania and Australia. Species nearly related (in one case claimed to be identical) are found in South America, and furnish the most cogent testimony in favour of a former connection of the several now isolated areas. None have been found elsewhere, and none were looked for from Africa; but in 1894 a species was described by Dr. Steindachner (*Sitzungsb. k. Akad. Wiss. Wien*, ciii., abth. 1, p. 460, pl. 3, f. 2) as *Galaxias capensis*, and there is no apparent reason to doubt that the generic allocation is correct. The geographical range of *Galaxias* is then somewhat analogous to the worm genus *Acanthrodilus*, which is the theme of Mr. Beddard's note. His remarks are applicable with even greater force to the fish genus. "It is clear that, if the former northward extension of the Antarctic continent is not believed, some explanation of these remarkable facts is much wanted; on that hypothesis they are perfectly explicable."

Lest some may think the argument in question is invalidated by the so-called *Galaxias indicus* of Day, I may add that I do not think that fish has any relation to the genus to which it was referred. THEO. GILL.

Washington, January 24.

Children's Drawings.

THERE are two little boys in my circle (nephews, in separate families), who at an early stage in their attempts at drawing, have drawn things *upside down*. Thus a locomotive would be drawn with funnel pointing downwards, and wheels at the top of the figure. Has this peculiarity been noticed before, and is it common? It seems to me interesting in relation to the subject of erect vision, for the retinal image is, of course, *inverted*.

A lady who had lived in India mentioned, in this connection, that she had often noticed natives, after taking up a photograph to look at it, replace it upside down. One of those two boys, looking at pictures, preferred to hold them upside down.

A. B. M.

Lecture Experiment on the Nodes of a Bell.

REFERRING to Mr. Taylor's letter on the above subject (January 23), the method he describes requires, in the first place, a bell-jar of very wide edge—at least half an inch—and the result, when obtained, would only be visible to one or two persons at a time. May I suggest the following method, although, very probably, by no means new.

An ordinary bell-jar with a plain edge (not welted) is fixed firmly in an inverted position; from a metal ring, arranged above it, are suspended eight small beads by fine threads, in such a manner that they rest lightly against the outside of the edge of the jar. It is convenient (though not necessary) to so arrange the beads that they touch the circle of the jar at equidistant points. On then bowing, the beads are all jerked out from their positions, and can be heard rattling against the glass as they fall back; and it is easy to note that at the nodes the disturbance is comparatively slight, while it is more violent in the ventral segments.

H. G. WILLIAMS.

Middle School, Ipswich.

THE PLANET VENUS.

THE planet Venus, as every observer knows, is a difficult and, at the same time, a tantalising object for observation, for when she is in that part of her orbit nearer to us, and therefore greatest in size, she presents us with only a small illuminated crescent, from which it is impossible to gather much from her surface markings as a whole. Although at her greatest distance from us she presents her whole disc, yet the latter appears so small that even in this case satisfactory observation is not obtainable. We have to content ourselves, therefore, with observations made between these two stages, and when her apparent disc is thus semi-illuminated.

That such an important question as the time of rotation of the planet about her axis is not yet definitely settled, is quite sufficient to indicate that the observer has not everything his own way.

In a former number of NATURE (vol. xlvi. p. 469), a summary was given of the valuable observations made by the late M. Trouvelot at Cambridge, United States, and Meudon, extending over the years 1877-1891. The chief points to which reference there was made were the two kinds of spots, white and grey, one specially prominent in size having appeared on September 3, 1876; the snow caps at the poles, and the bright specks which appeared at their southern extremities; the varying shape of the terminator, which occurred sometimes in the space of a few hours; and, finally, the period of rotation. Trouvelot found that the whitish and greyish spots were very difficult to observe, even under favourable conditions. The former were situated near the terminator, and produced on it slight deformations, which seemed so to alter it as to suggest that these spots are at a higher level than the other parts. The greyish spots, on the other hand, when situated in about the same positions, also deformed the terminator to a small extent, but in an opposite way to those just mentioned, suggesting that these spots lie at a lower level than the parts near them. Another peculiarity of these two kinds of spots which he remarked was their size. The white ones seemed to assume a round or slightly oval form, and were nearly always small, while the grey spots were generally of an elongated shape and of large dimensions, forming sometimes straight bands. That the spots were not necessarily of long duration was also remarked, and they were analogous in their formation to "taches des couches nuages continues de notre atmosphère précédant les pluies, et qu'un simple jeu de lumière fait naître ou disparaître." Their contours were described as very vague, those of the white spots being less brilliant, and those of the grey spots less dark.

In the observations that were made at the Catania Observatory and at Mount Etna (*Astr. Nach.*, Bd. 139, No. 3329), and to which a brief reference is here made, the observer, Sig. A. Mascari, describes in detail the appearances of the spots during the years 1892–1895. He also differentiates between the two kinds of spots. "Le macchie oscure si presentano ordinariamente sotto forma di leggiere velature grigie a contorni mai netti, molto deboli, senza alcun limite deciso, ed è assai raro e fortunato quel momento in cui si può arrivare a distinguere con precisione qualche contorno netto." The second type, "Le macchie chiare si rilevano per un maggiore splendore rispetto a quello del resto del pianeta.

FIG. 1.—October 12, 1892.

From the series of twenty drawings which accompany the observations in the communication referred to above, the surface markings can be clearly followed.

Fig. 1, which is one of a series of four drawings made in the months of October and November 1892, gives the general appearance of the surface as it was then observed. The three dark patches, A, B, and C, were nearly always visible; *a* was not always so prominent as is shown in the drawing. The terminator was also at times irregular in shape, being specially so on November 14. The edge of the south polar cap, near the terminator on October 13, assumed a somewhat similar appearance to that which Trouvelot recorded on September 27, 1876. The observations of the latter indicated that the most striking

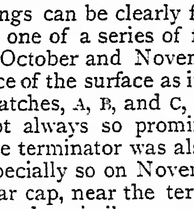


FIG. 2.—September 25, 1893.

irregularities were found at the extremities of the terminator close to the edge of the pole-caps, where deep notches were often recorded. They were of different sizes and shapes, and underwent rapid changes in periods of sometimes a few hours. These facts led Trouvelot to believe in a short period for the rotation of the planet. In the observations for 1893, the terminator was directed towards the east.

Fig. 2 shows the planet for September 25, 1893, from 13h. 50m. to 14h. 52m. The bright spot, H, is bounded on the east and west sides by dark, well-defined contours, *e*, *f*, and *m*. The region about G was somewhat obscure; the area enclosed by *i*, *m*, *n* was bright and sometimes circular, being bounded, for the most part, by dark indistinct contour lines.

Fig. 3 shows this more clearly. This drawing, made on October 13, seems to be more typical of the appearance of the disc for this year. The six comparatively large whitish spots, H, I, G, N, M, L, are here clearly shown. H is somewhat varied by an incursion of the dark contour line on the east side; I is also sometimes partially bisected by a dark streak, as was the case on November 27, 16h. 50m. (Fig. 4).

The different shapes which the terminator underwent during this year's observation were very prominent, that on November 27 being the most noticeable.

The disc in March 1895, the terminator being directed towards the east, presented the appearance shown in Fig. 5. One can easily recognise the large white spots, H, I, G, N, M; I appears, however, no longer divided,

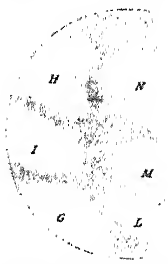

FIG. 3.—October 13, 1893.

while L seems to have more or less disappeared, giving place to a prominent circular spot a little more to the eastward. The detail observed during the months of July and August can be best seen by examining Fig. 6, which can be conveniently compared with Fig. 3 or Fig. 4.

With regard to the length of period of rotation of this planet, the difficulties of identifying the spots after brief intervals of time have rendered this point doubtful. Leo Brenner on this point writes (*Astr. Nachr.*, No 3300, p. 197): Obgleich ich bisher 107 Beobachtungen der Venus zu verzeichnen habe, konnte ich doch erst 22 Zeichnungen anfertigen, weil die wahrgenommenen Flecken gewöhnlich so schwach und unbestimmt sind,

FIG. 4.—November 27, 1893.

dass ein gewissenhafter Beobachter Bedenken trägt, ihre Wiedergabe zu versuchen, weil er fürchten muss, entweder ein Opfer von Selbsttäuschung zu werden oder die Ausdehnung der Flecke nicht richtig aufzufassen. Deshalb halte ich auch die Berechnung der Rotation aus Flecken, die so unbestimmt sind, für ganz und gar unmöglich. Anders verhält es sich aber mit Erscheinungen, welche so deutlich sind, dass sie ins Auge fallen und über deren Wirklichkeit mithin kein Zweifel bestehen kann."

It is at present uncertain whether a rotation is performed in, roughly, twenty-four hours, or whether it is accomplished in about 225 days. Trouvelot, from his numerous observations, gave a period amounting to nearly twenty-four hours; while Schiaparelli still adheres to 225 days. Quite lately also Tacchini, from observations made during last summer at the Collegio Romano, favoured Schiaparelli's view that the rotation period is equal to the sidereal revolution; and his observations (*Atti Reale Acad. Lincei*, vol. v. p. 3) towards the end of 1895, have led him to the same conclusion. The observations of Mascari seem, however, to have led him to adopt the longer of the two periods. Cerulli also, from observations made in July, August, and November of last year (*Astr. Nach.*, No. 3329) is inclined to adopt Schiaparelli's length of period. Writing in *Astr. Nachr.* (No. 3310, p. 368), he says: "Onde si conchiude che la configurazione delle ombre di Venere si mantiene sensibilmente invariabile per molti giorni, e non rivela nessun movimento conciliabile con rotazioni di breve durata."

FIG. 5.—March 23, 1895.

Leo Brenner, on the other hand (*Astr. Nach.*, No. 3314), is decidedly in favour of the shorter period, and so is therefore of the same opinion as Trouvelot. The former argues that if the spots preserve their positions, then those near the terminator would be for some length of time under the same conditions of illumination, and therefore would appear the same. This he maintains is not the case, and is not even borne out by the drawings of Schiaparelli and other observers.

It may be remembered that Trouvelot determined his value of 23h. 49m. 28s. from the observations of certain spots, but he also stated that many of the general features visible on the planet's surface, such as the rapid deformations of the horns and of the terminator, &c., a

FIG. 6.—July 26 to August 5, 1895.

suggested a short period of rotation, and were "inconciliable avec la période de rotation, si lente et si inattendue, déduite par l'éminent astronomie de Milan."

Brenner, who has observed Venus some 275 times, says that the spots move with a velocity of $15^{\circ}\cdot030$ in one hour, thus indicating a period of 23h. 57m. 7·5459s. In fact, he seems so convinced of the accuracy of his observations, that he has published a map of the surface of Venus, and finds that drawings by numerous observers agree well with it. He maintains, also, that the dark spots are true appendages on the planet's surface, and are not connected with the cloudy atmosphere. (See *Astr. Nachr.*, No. 3300, p. 198, in which he refers to a peculiar shaped spot situated near the South Pole, and a communication from Stanley Williams.

He accounts for the idea of a long period of rotation having been and still being upheld, on the ground that between 320° and 150° longitude there are several spots which are somewhat alike, six of which lie in a north and south direction, and two in higher latitudes in an east and west direction.

For this reason, if an observer does not steadily watch the planet from morning till evening every day, but simply makes an occasional observation, he can then easily mistake one spot for another, and imagine that he is observing the same one when he is really observing another, and thus conclude that no apparent motion of the spot is noticeable.

Whether this be so or not is, however, the question, but one does not feel quite at liberty to state definitely that therein lies the cause of Schiaparelli's, Tacchini's, &c., deductions of a long period, for certainly they must have convinced themselves thoroughly that such a rapid rotation, which according to Brenner is so apparent, was nevertheless to them very difficult of observation before they committed themselves to definite statements.

The following, but somewhat incomplete, list gives some idea of the views held by observers regarding the time of rotation of the planet under discussion. Column I. gives the names of those who advocate the short period of about 24 hours; column II., with one exception, those who are inclined to the period of, roughly, 225 days, and column III., those who are doubtful. The dates against some of the names refer to the times at which the respective observations were made.

I. Short period.	II. Long period.	III. Doubtful.

During the first few months of this year the planet will be a morning star. From the middle of January to the middle of May, her time of rising before the sun diminishes from three hours to half an hour, her apparent diameter decreasing during this time from 16″ to 10″. After August she will become an evening star, her apparent distance from the sun increasing. In the middle of November she will set one hour and a half, and towards the end of December three hours, after the sun; her apparent diameter at this latter epoch being 15″.

W. J. S. L.

THE SEEBOHM COLLECTION.

THE British Museum has always owed much to the generosity of private donors, and this has been exceptionally true in the case of the collection of birds, which is now the finest in the whole world. It is difficult for ornithologists of the present day to imagine what the collection was like five-and-twenty years ago in its old quarters at Bloomsbury. Its principal value then consisted of the type-specimens which it had received from the earlier voyages, and the celebrated Nepalese collection of Mr. Brian Hodgson; but the great series of Australian birds obtained by John Gould had been allowed to go to Philadelphia, apparently without a protest from any public body in England, and to the great regret of Gould himself. He had offered the collection to the nation on reasonable terms, which were afterwards eagerly accepted by Dr. Edward Wilson, who transferred the whole series, with its priceless types, to Philadelphia.

The birds' skins in past years were kept in an underground vault, in wooden boxes, so that if any particular specimen was wanted by a student, the whole lot had often to be turned out on the table, to render possible a search for the skin required. The time thus wasted was considerable, the damage to the specimens enormous, as they were heaped one upon another in the boxes, and every skin became more or less ruffled and spoilt as time went on. As regards the mounted collection, the absurd idea obtained that the public liked to see all the rare birds, and thus all the valuable types and priceless specimens were stuffed and exhibited, there to wither with the dust and exposure to light, and decay with age. Many specimens of great value, known to have been in the collection of the British Museum at the beginning of the century, are now no longer to be found there; they have doubtless fallen to pieces from decay, and have been thrown away. Even with the utmost care, I find it difficult now to preserve some of the old Montagu collection, the skins never having been properly preserved, and having been mounted with most of the bones inside them. In this way also were preserved the specimens of Captain Cook's voyage, most of which have vanished since the time that Latham described them, and they have doubtless crumbled to pieces.

It is quite certain, therefore, that twenty-five years ago the collection of birds in the British Museum was of small repute, and probably did not exceed 40,000 specimens. Little encouragement was given to travellers to help the national collection, and, excepting in the case of the Antarctic Expedition, and a few of the same kind, the specimens received from explorers on sea and land were few and far between. The best series were in the hands of private collectors. Thus, for the study of Palæarctic ornithology, students visited my collection and that of Mr. H. E. Dresser, or that of Mr. Henry Seebohm, already then commencing to loom large. For Ethiopian birds, my own collection and that of Captain Shelley were always available for the purposes of study, and far exceeded that of the British Museum in number of specimens. For Indian birds, that of the late Marquis of Tweeddale was the one generally consulted, and in India the influence of Mr. Hume was at work, and his collection was already assuming large proportions. The collection formed by the late Consul Swinhoe was the best as regarded Chinese birds, and Dr. A. R. Wallace still retained in his hands the chief set of the specimens obtained by him during his travels in the Malay Archipelago, with all the types. The best collection of Australian birds was that in the possession of Messrs. Salvin and Godman, though Mr. Gould had a large number of valuable specimens, gathered together during the previous thirty years, since the sale of his original collection. As regards American birds, the absolute dearth of species in the national collection can be estimated from a glance at the late George Robert Gray's "Hand-list of Birds," published in 1869–71, then the authentic record of what the Museum possessed, where genus after genus is scantily represented, and the series of species is lamentably defective. With regard to those of the Neotropical region, no great Museum, in the year 1872, probably stood at a greater disadvantage than the British Museum. The majority of the types of American Passeres were in the collection of Dr. P. L. Sclater, and, for a general series, nothing in Europe could surpass that of the Salvin-Godman cabinet.

In 1896 it is interesting to note the present location of the above-mentioned private collections. They are *all* in the British Museum. With the acquisition of the Wallace collection in 1874, commenced that era of improvement in the ornithological collection which has steadily progressed, and is still progressing at the present day. The Gould, Sclater, Shelley, and Sharpe collections, with many others of greater or less importance, have passed into the hands of the Trustees. Then came, in 1885 the, magnificent donation of Mr. Allan Hume, followed by that of the Tweeddale collection

presented by Major Wardlaw Ramsay, to whom it had been bequeathed by his uncle, the Marquis of Tweeddale. Messrs. Salvin and Godman not only gave their unrivalled set of American birds, but Mr. Godman supplemented this splendid present by employing a staff of collectors to work out the ornithology of Mexico, and presented the results of their expeditions to the Museum. He also purchased the celebrated Henshaw collection, and gave it to the nation. Many other collections have since been acquired by him, and likewise presented to the Trustees of the British Museum. Only lately can it be said that we possessed in England a representative set of North American birds.

Meanwhile, although the series of Indian, African, Australian, and American birds had become adequate and representative, the ornithology of the Palæarctic region was but feebly illustrated. Through the exertions of Lord Walsingham and other English ornithologists, the nesting-habits of our British birds have been successfully demonstrated by the well-known series of groups in the Natural History Museum; but the birds of Europe and Northern Asia were poorly represented in its cabinets. By the splendid bequest of Mr. Henry Seebohm, this vacuum in our Palæarctic collections has been filled, though there is no one in the Museum who does not feel that this addition to the strength of its ornithological section has been attained only through the loss of one of the truest friends of the institution which his dying wishes have enriched. There has not yet been time to register and incorporate the specimens of the Seebohm collection, but we know that we have now received the principal collection of Palæarctic birds of modern times.

A few years ago Mr. Seebohm presented his collection of eggs, and, with this as a basis for the work, the entire series of oological specimens in the Museum was set in order and arranged under his own supervision by my daughter, Emily Mary Sharpe, till it was found that, with the Hume and Salvin-Godman collections, the British Museum could boast of a series of 48,000 eggs of birds.

In the same generous spirit, he freely gave the type-specimens of any birds he possessed, that the value of the "Catalogue of Birds" might be enhanced thereby; and now, by leaving the contents of his Museum to the nation, the British Museum becomes possessed of several invaluable additions to its ornithological collection. Thus are added: the Swinhoe collection of Chinese birds, the Pryer collection of Japanese birds, the series of specimens obtained by Holst in the Bonin and Loo-choo Islands, and Formosa; and last, but not least, his own European and Siberian collections, the result of his travels in all parts of Europe, and of his expeditions to the valleys of the Petchora and the Yenesei. Of his collection of *Charadriidæ*, he had already presented hundreds of specimens to the Museum, but by his bequest is added the series which formed his special series of the plovers and snipes, on which, indeed, was founded his great work on the geographical distribution of the *Charadriidæ*. He had, moreover, in contemplation a "Monograph of the Turdidæ, or Family of Thrushes," and in pursuance of this object he had amassed a large collection of thrushes, which now passes into the ornithological collection of the British Museum. Nests and skeletons of birds are in plenty, and a set of the Layard collection of Oceanic birds and others from the Whitehead expedition to Kina Balu, the Prjevalski and Severtzov expeditions in Central Asia, make up one of the most important donations which the Trustees of the British Museum have ever received. His series of skins of the *Phasianidæ* was one of the finest in the world, and the value of the osteological collection cannot be over-estimated, as it formed the material on which was founded his many essays on the "Classification of Birds."

In this necessarily imperfect sketch of the contents of the Seebohm collection, of which a fuller account will only be possible when it has been arranged and registered in the archives of the British Museum, it is impossible to give a detailed history of the various collections which constitute its importance to ornithologists. I feel, however, that I cannot close this article without expressing my opinion of the great loss which ornithology in general, and this country in particular, have sustained by the death of Mr. Seebohm, for, had I space to tell, it would interest naturalists to know how the great collection of birds in the Natural History Museum has been built up, by the help of such men as Henry Seebohm and the other munificent, though unostentatious, donors whose names I have recorded above. I believe, however, that under the enlightened sway of its present Director, the Museum has a still greater future before it than it has enjoyed in the past, and that when the common people have the opportunity to "read, mark, learn, and inwardly digest" the lesson which the Museum is trying to teach, the nation at large will still more fully appreciate the work of such men as Henry Seebohm.

R. Bowdler Sharpe.

MOVEMENT.[1]

Some of the results of the researches of M. Marey on the movements of men, horses, and fishes, have appeared from time to time in English papers. The skill and originality displayed by M. Marey in experimental work, involving great difficulties, must have astonished many, at a time when the idea of taking a rapid succession of photographs of a moving object was new.

The method of determining time-periods by means of a continuous chain of photographs appears to be due to Mr. Jansen, who used it in 1874 to record the transit of Venus across the sun's disc; he also suggested that the method might be applied to the study of animal locomotion. The subject of intermittent photography was attacked by Mr. Muybridge, who discovered, by means of a method different from that suggested by Jansen, the analysis of the locomotion of men, horses, and other animals. Mr. Muybridge took successive photographs of moving animals, using a battery of cameras and lenses, each plate being exposed automatically at the required instant; he also produced photographs of pigeons in flight. The end aimed at by Marey was to use a succession of photographs for chronographic purposes: photographs so taken have been called chronophotographs; his method of procedure is as follows. The object to be chronophotographed performs its movements in full sunlight before a black background of unilluminated velvet. The camera employed is furnished with a slotted disc (*disque fenêtre*) which can be uniformly rotated; as each slot cuts the beam of light reflected from the moving object, the sensitive plate receives an impression, which gives the exact form and position of the object at the instant, the duration of exposure being $\frac{1}{500}$th of a second, and the interval between the formation of each image $\frac{1}{10}$th of a second. A chronometric dial is so placed that the position of its revolving pointer is recorded on the same sensitive plate; this instrument serves to indicate both the time of exposure and the time between successive exposures, the pointer of the chronometric dial being driven at a known uniform velocity.

Provided with this instrument, and the photographic gun (which is described on pp. 108–115), and certain other special arrangements for the chronophotography of fishes, the excellent results shown in "Movement" have been obtained.

Mr. Eric Pritchard, assisted by his sister Mrs. Chalmers

[1] "Movement." By E. J. Marey. Translated by Eric Pritchard, M.A., M.B., B.Ch. (Oxon.) 323 pp., 200 illustrations. (London: William Heinemann, 1895.)

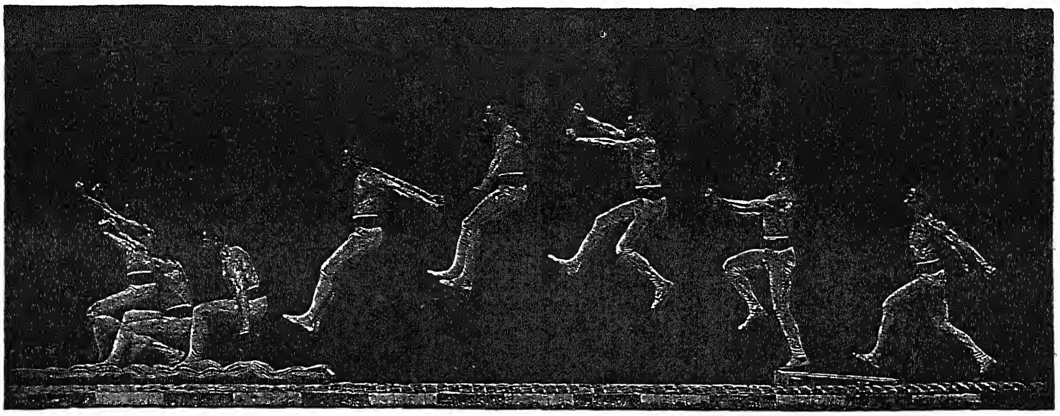
Mitchell, has produced an excellent translation of "Le Mouvement," by E. J. Marey (G. Masson, Paris), on which they may be much congratulated. The work will be most acceptable to a large number of readers widely differing in their lines of study. In many cases the details of the construction of the apparatus and its use are so clearly given, that but little difficulty should be experienced by any of those who wish to use chronophotography in researches on the movements of any animals, from elephants to microscopic insects. The translators have reproduced a large number of plates, amongst which the following seem to be good illustrations of chronophotography.

The flight of the heron (p. 233).

The arrangement of apparatus for taking three simultaneous chronophotographs of a flying bird from three points of view—from the front, the side, and from above (p. 236). By means of these chronophotographs, bas-reliefs have been constructed, showing the successive attitudes of the bird during flight.

Different figures of rotation (Figs. 15-24); amongst which that of a certain sphere (p. 30) is most curious. "The inner and outer surfaces of this sphere can be seen at one and the same time."

Fig. 92. Successive phases of a long-jump; this should be of interest to the tyro in athletics, as by it the exact position of the champion athlete may be seen at any instant.



Successive phases of a long jump. (Chronophotography on a fixed plate.)

It is much to be regretted that several plates in the French edition have been omitted, notably that of the camera and revolving disc, which shows at a glance the disposition of the different parts of one of the most important instruments; and that of the print, at the end of the French edition, called "Escrime au Bâton," which is full of life and energy, and would certainly appeal much both to the scientific and to the artistic reader.

F. J. S.

THE NEW MUZZLING ORDER.

SINCE Darwin, in his "Journal of Researches," wrote of the occurrence of hydrophobia in Central and South America, much has been learned of the nature of this disease. He says: "In so strange a disease, some information might possibly be gained by considering the circumstances under which it originates in distant climates; for it is improbable that a dog already bitten should have been brought to these distant countries." It is now known that such a possibility must receive careful consideration. In the first place, it has now been placed beyond doubt that hydrophobia is a specific infective disease, which so far as can at present be ascertained, does not originate *de novo*, but can only be introduced into a district or country by being passed on from animal to animal, different species of which, however, are affected in very varying degree. In the second place, the disease may remain latent for a long period after an animal has been infected—through a bite, usually; for this reason it is sometimes a very difficult matter to trace the infection to its source, with the result that the method of spread of the disease was for long very imperfectly understood, although the means for preventing its extension, when once it had obtained a foothold in a district, had long been elaborated and found to be thoroughly efficient when properly applied.

In this country our statistics relating to the localisation of rabies are now so full and trustworthy, that it seems to be little short of a public health scandal that the disease has not long ere this been completely eradicated from our midst. Let us take this new muzzling order, which is undoubtedly a step in the right direction. For some time past it has been perfectly well known that an outbreak of rabies was not only imminent, but had actually occurred in the north of London. The disease has made its way apparently from Essex to Middlesex, or it may be from the north, but up to the promulgation of the muzzling order, which came into force on Monday, no definite effort had been made to circumscribe the disease. We may expect that the regulations now brought into force will very soon have the desired effect of diminishing the number of animals returned as rabid; but from the experience of the Berlin authorities, we cannot expect to stamp out the disease even in London so long as Middlesex, Surrey, and the surrounding counties of Essex, Sussex, and Hampshire return cases of rabies, and any one of them fails to enforce a muzzling order. In Berlin, up to July 1853, there was no muzzling order, and in 1852 there were 107 cases of rabies reported, and up to July 1853, 85 cases. After this there was a marked fall in the number of cases; but so long as the law was merely municipal, the disease had still to be reckoned with. Since, however, the Prussian Animals Diseases Acts, 1875 and 1880, were passed (relating to the whole of Prussia), the disease has become rare, and *only occurs along the French and Russian borders*.

It is to be noted that rabies in England and Scotland is at present confined entirely to certain populous counties and centres, and that it is especially common in those districts in which dogs are favourite domestic companions or pets. On examination of the Rabies Chart for the year 1894, it is found that the majority of cases occur in Lancashire, the West Riding of Yorkshire, then, *longo intervallo*, Cheshire, London, Ayr, Lanark, and

Renfrew, and then Dumbarton and Edinburgh in Scotland, and in England, Derby, Warwick, Essex, Middlesex, Surrey, Hants, Sussex and Cornwall. The disease is strictly localised in four very definite centres, each, with the exception of that in which Cornwall is situated, containing a group of five counties. These counties are, of course, under different local authorities, so that it is impossible, in some cases at least, to obtain combine action in the matter of taking measures to stamp out the disease. It is objected that each authority must take this matter into its own hands, and act as it thinks best; but where the welfare of adjacent districts is so closely involved, as in such a case as this, some central authority might surely bring pressure to bear in order to ensure conjoint action. The Board of Agriculture, for instance, might, either by diplomacy or financial argument, compel joint action on the part of the counties situated in the above infected areas, leaving the uninfected areas free to act as they think proper. A muzzling and registration order so enforced for a couple of years would, in all probability, bring about the disappearance of rabies from our island. It is sometimes objected that the muzzle is a cruel apparatus. We have it on the authority of the most eminent veterinarians, that the cage muzzle, when properly fitted so as to allow the animal to lap water and eat grass, but not to bite, causes little or no discomfort to the dog, but that the strap muzzle, which is recommended by some of those who pose as the "friend" of the dog, is not only an uncomfortable but actually an unhealthy apparatus, as it keeps the animal from opening its mouth and getting the free use of its tongue. In Norway, Denmark and Sweden, rabies is little known; a system of quarantine is insisted upon, so that none but valuable dogs, and therefore animals constantly under observation, can gain access to these countries. Once the disease has been stamped out, it would be a comparatively easy matter to prevent its reintroduction. Even Darwin, in his time, observed that there was no hydrophobia in Van Dieman's Land and Australia, and that it only made its appearance in South America in 1803, and that it had then apparently made its way south from Central America. In the old days of long passages to these places, dogs were for long under observation before they were introduced into the new countries, and in the case of America the disease must have first appeared in the north, being introduced after a comparatively short voyage, and then gradually making its way south. Muzzling, and the taking up of unmuzzled dogs, when properly carried out, has been so successful hitherto, not only locally in this country, but generally in other countries, that the new order will be warmly welcomed by all who have studied this matter carefully, as the first step towards a really efficacious measure—combined action on the part of the authorities in the rabies areas.

NOTES.

"THE Diffusion of Metals" is the subject of the Royal Society's Bakerian Lecture, which is to be delivered to-day by Prof. Roberts-Austen, C.B., who has obtained some singular experimental results connected with the mobility of solid metals. Many experimenters in this country, especially Prof. Graham and Lord Kelvin, have studied the diffusion of gases and saline solutions, and Prof. Roberts-Austen has measured the rate at which certain metals will penetrate each other. He finds that solid gold, for instance, will diffuse into, and move about slowly in lead, even at the ordinary temperature of the air, and with considerable rapidity if the lead be warmed, though far from melted. Evidence as to the presence of wandering atoms in a solid, possesses much interest now that views as to the nature of metals and other solids have been extended by the discovery that certain rays of light will penetrate them.

THE announcement of the attainment of the North Pole by Dr. Nansen has been received with great popular interest and even enthusiasm. According to Prince Kropotkin, the correct text of the telegram which was received at St. Petersburg concerning Nansen was as follows:—"Irkutsk, January 31 (February 12).—The contractor for Nansen, Kushnareff, through the Kolymsk *ispravnik* (chief of police) Kandakoff, by mail from Yakutsk to Kirensk, and thence by telegraph, informs the *Eastern Review* that Nansen has reached the Pole, has discovered land, and returns." M. Kandakoff appears not to be the chief of the police of the Verkhoyansk district, but a "councillor to the Provincial Government of Yakutsk and a member of the Yakutsk expedition," which fact gives a much greater weight to the news. The Russian Government immediately took steps to have the truth of the report tested, but some time must necessarily elapse before authoritative confirmation is received. The absence of date and of any hint as to whether a direct message from Nansen or his crew had been received, lead us to suspect that the report may be a rumour similar to that which reported the *Fram* in the ice east of Greenland last autumn. It seems rather late in the season, even allowing for the slow rate of travelling in North-eastern Siberia, for information to come from the New Siberian Islands; while if Nansen had landed himself on the Asiatic coast, it is difficult to believe that his own dispatches should not have reached the telegraph as soon as the vague report. On the other hand, it is necessary to remember that there is nothing improbable in the news. If land intervened and stopped the drift of the *Fram*, a land expedition would certainly have been made, and the ship afterwards taken south by the clearest route irrespective of destination. She might have been frozen up at the beginning of winter somewhere within reach of the New Siberian Islands, and it is possible enough that she was visited by native hunters, who may have carried a message. While, therefore, we fully recognise the possibility of the news being authentic, and it becomes more probable as the source of the information is inquired into, we must await further information before believing that the past record of Arctic exploration has really been so brilliantly surpassed.

MR. WILLIAM W. ROCKHILL, whose journeys through Mongolia and Tibet, and his works upon them, have earned him distinction among geographers, has been promoted to the assistant-secretaryship in the State Department at Washington.

MISS CATHERINE W. BRUCE has recently made another addition to her numerous benefactions to astronomy in both Europe and America, by presenting to the University of Chicago the sum of one thousand dollars, to be used for the purpose of providing illustrations for the *Astrophysical Journal*.

THE death is announced of M. Jules Reiset, member of the Section of the Rural Economy of the Paris Academy of Sciences, and the author of many valuable contributions to agricultural chemistry and animal physiology.

A LECTURE will be delivered, on Thursday next, at the Royal Artillery Institution, Woolwich, by Dr. G. H. Bryan, F.R.S., on "Flight and Flying Machines."

THE Ethnographical Survey Committee of the British Association would be glad to receive offers of assistance from persons capable of making the requisite measurements of individuals belonging to rural populations. The Committee would supply instruments and full information. It is requested that competent observers might find it interesting to occupy themselves during some part of the Easter vacation in this manner. Applications may be made to the Hon. Sec., Mr. E. S. Hartland, Highgarth, Gloucester.

PROF. D. KIKUCHI informs us that on December 28, 1895, an Imperial Ordinance was promulgated by which a new standard time was established in Japan. The ordinance read as follows: (1) The standard time of the Empire hitherto in use shall henceforth be called the Central standard time. (2) The time of the meridian of 120° east longitude shall be the standard time of Taiwan (Formosa), Hōko group (the Pescadores), and Taeyama and Miyako groups, and shall be called the Western standard time. (3) This ordinance shall come into effect on January 1 of the twenty-ninth year of Meiji (1896).

THE Hayden Memorial Medal of the Philadelphia Academy of Natural Sciences has been awarded to Prof. Karl von Zittel, whose services to the sciences of geology and palæontology extend continuously over a period of thirty years. Born in 1839, Prof. von Zittel was, at the age of twenty-four, appointed to the Professorship of Mineralogy at Karlsruhe, and three years later to the Professorship of Palæontology at the University of Munich, a position, jointly with that of Director of the Palæontological Museum, which he still holds. His published works cover a large range of personal investigation, not the least important of which are the researches into the structure and physiography of the Libyan Desert and the Sahara, and his monumental work, "Handbuch der Paläontologie," which has not long been completed.

THE work of the Marine Biological Association at Plymouth has, for a number of years, been carried on under great difficulties, owing to the want of a suitable steamboat capable of working in the Channel. We are glad to be able to announce that this difficulty has now been overcome by the purchase of the steam fishing yacht, *Busy Bee*, from Mr. C. E. Treffry, of Fowey. The vessel is 56 feet long, with a registered tonnage of 7·9, and is a good sea-boat, capable of going anywhere in the English Channel. With the increased facilities for marine work which will thus be offered, it is hoped that a still larger number of naturalists will visit the Laboratory. Applications for the use of tables during the Easter vacation, including, when desired, participation in the dredging and trawling work to be carried on by the new yacht, should be sent without delay to the Director.

WE regret to notice the death, on Sunday, of General J. T. Walker, C.B., F.R.S., whose work as Superintendent of the Great Trigonometrical Survey, and Surveyor-General of India, is widely known and appreciated. From an obituary notice in the *Times* we learn that he was born in 1826, and entered the Bombay Engineer Corps in 1844. He joined the Trigonometrical Survey in 1852, and, except for a short time during the Mutinies, he was incessantly employed on work connected with it, under Sir Andrew Waugh, until he succeeded that officer as Superintendent in 1861. He held this post for twenty-two years, combining with it during the last five years the Surveyor-Generalship and the charge of the Revenue Surveys. He continued and completed the original scheme of the Great Trigonometrical Survey, and conducted numerous collateral operations connected with it. General Walker's labours were not confined to geodesy. He was in the first rank as a geographer. On retiring from India in 1883, he became an active member of the Council of the Royal Geographical Society, and was an authority on all questions relating to Central Asia. Last July he took a leading part in the geodetical business of the International Congress, and was doing useful geographical work up to within a short time of his death.

WE cordially welcome the *Centralblatt für Anthropologie, Ethnologie und Urgeschichte*, edited by Dr. G. Buschan, as supplying a real need. Other sciences, such as zoology, botany, or chemistry, have journals the aim of which is to keep their readers abreast with the literature of their respective subjects. Till now the very comprehensive study of anthropology has been without such a necessary journal, although several anthropological serials make a point of giving some idea of current literature. Dr. Buschan has secured the co-operation of a large number of colleagues, which will ensure catholicity in the selection of notices. There are to be a few quite short original articles, and various items of general interest and personal notices. This first number contains short, clear notices of 112 papers and books. We hope that the "bibliographische Ubersicht," which is promised, will give the current literature as exhaustively as is possible. If this is done, the new journal will be of the greatest value to all those interested in the study of man.

AT the annual meeting of the Royal Astronomical Society, on Friday, the gold medal of the Society was awarded to Dr. S. C. Chandler for his many astronomical investigations, and especially for his work in connection with the variations of latitude.

THE successive deaths, following so soon one after the other, of the two great American systematic botanists, Dr. Asa Gray and Dr. Sereno Watson, suspended the publication of their great Synoptical Flora of North America, of which two parts were published, and were reissued by the Smithsonian Institution in 1886. Arrangements have now been made for carrying on the publication, and a fascicle of upwards of 200 large octavo pages is published, under the editorship of Dr. B. L. Robinson. It comprises the orders of Polypetalæ from Ranunculaceæ to Frankeniaceæ.

ACCORDING to the recent investigations of Dr. R. F. Kaindl (*Globus*, lxix., 1896, pp. 69, 90), the Huzulen retain many primitive customs; these people are Slavs who inhabit the Galician Carpathians, and are nominally Roman Catholics. Everywhere one comes across wooden crosses erected over buried brandy-bottles. In 1894 a "Brandy-prophet" appeared; he was a simple peasant who waged a successful warfare against brandy-drinking. The zeal of the people constrained the clergy to bury the spirit with ceremonies; and now in this country the use of brandy has ceased; and the words of an old Huzulen may be true, that at the present time only those drink brandy who are worth nothing. A gypsy, who had sent his wife away, bought the daughter of a Huzulen for fifty florins; he was had up by the magistrate, but that had no effect; in a year he was tired of her, and then he hired the wife of another Huzulen for sixty florins: again the law was powerless, and at the end of the year the husband came for his wife. There are two remedies for back-ache—one is for the priest to walk on the patient's back in church, and the other is to let a bear walk on it. Weasels, snakes, frogs, puppies, and kittens may not be killed, and there are numerous charms against the two first. For three days before the Huzulen moves into a new house he throws a black hen on it, so that snakes may not nest there. Black cattle are lucky. The mentioning of certain words for simmering and boiling is prohibited when applied to milk, lest harm should come to the cows. The grave-diggers and coffin-makers wash their hands over a grave to signify that they are not to blame for the sorrow, and the relatives ask the latter not to be angry with the dead for the trouble he has caused them, and not to ask for payment from him in the next world. Several original sketches illustrate this article.

GEOLOGY and agriculture, as well as meteorology, writes Prof. Abbe in the *Monthly Weather Review*, are interested in the part played by the small quantity of carbonic acid gas that exists in the atmosphere. The leaves absorb and assimilate a portion; the falling raindrops and the surface water of the ocean absorb

another portion; it is exhaled from the lungs, and given off in still greater quantities from every burning substance. It may accumulate temporarily in some regions, but the slow diffusion and swifter winds carry it away. It ought to diminish as we ascend above the earth's surface, but the rapidly rising and falling currents of air tend to preserve a fairly uniform mixture very much as they do in the case of aqueous vapour. Evidently there is a general balance between the production and absorption of carbonic acid gas, so that, like the temperature of the air and the quantity of rain or any other meteorological element, we find no great progressive secular increase or diminution. An article in *Wollny's Forschungen* (1895, vol. xviii. p. 409) reviews the latest additions to our knowledge of the distribution of carbon dioxide in air. A comparison of the proportion of the gas in samples of air obtained near the earth's surface with that of samples collected by S. A. Andrée at various altitudes, failed to prove any diminution of carbon dioxide with altitude up to the highest point, 4300 metres, obtained in the balloon ascensions. On the other hand, the percentages of the gas by volume throughout the different strata of air, are very much the same as those observed at the surface of the earth. An apparent dependence upon the wind was, however, suggested by the results, and when the percentages were discussed from that point of view, the general conclusion arrived at was that a descending mass of air brings with it a higher percentage of carbonic acid gas, which is subsequently diminished by absorption near the earth's surface, so that the ascending current has a smaller percentage. The question here raised is one of great importance in the theory of the interaction of the atmosphere and the earth, and it can only be brought to a definite solution when the greatest possible number of investigations into the percentages of carbonic acid gas in the atmospheric strata are carried out by means of balloon voyages.

UNDER the sensational title of "Longitudinal Light," a paper by G. Jaumann appears in *Wiedemann's Annalen der Physik und Chemie*. It is based upon the law of electric discharge enunciated by the same writer in 1888, according to which electric waves impinging at right angles upon a kathode surface favour the dissipation of the charge upon it. This was proved experimentally by Hertz in the case of ultra-violet light, and by Elster and Geitel in the case of ordinary light impinging upon a liquid electrode in a vacumn. Wanka also proved it in the case of electro-magnetic waves. Hence, so the writer argues, light vibrations must have a component in the direction of propagation; they must, in fact, contain longitudinal as well as transverse waves. That this is so, is made extremely probable by the analogy of kathode rays. The latter have the vibration period of waves in wires, and are therefore pretty certainly longitudinal. Now comes the question how Maxwell's electromagnetic equations, which do not admit of any but purely transverse vibrations, can be made to agree with these conclusions. Jaumann gives a simple answer. Let it be admitted that the specific induction capacity of a medium and its magnetic permeability are affected by the oscillations themselves. These "constants" will then be variable, and when introduced as such into the equations, longitudinal vibrations are at once seen to be possible. Each pencil of light will then be vibrating transversely along its centre line, and towards the outer edge the vibrations will become more and more longitudinal. This theory is a distinct innovation; but the author claims that it affords a natural and simple explanation of a large number of discharge phenomena. Thus the curious diffused reflection of kathode by a plane surface is easily reduced to the fact that Huyghen's principle of reflection no longer holds good.

ALTHOUGH we may still identify a particular disease with a particular microbe, yet there can be no doubt that the part played by other microbes associated with pathogenic germs is of very great importance in determining the course pursued by the disease. The co-operation of bacteria is, therefore, a subject which is gradually more and more occupying the attention of bacteriologists, and in the last document issued by the Russian Imperial Institute of Preventive Medicine, M. Maschevsky has published a very extensive series of investigations on the effect upon the cholera bacillus of cultivation in the presence of other microbes. Several varieties of bacteria were isolated from the intestinal tract of man and animals, as well as from apples and cucumbers, and with these the cholera bacillus was then grown. The number of bacteria from these sources in themselves proved to be harmless, but which served to exalt the virulence of the cholera bacillus, appears to be very considerable. Perhaps one of the most interesting results is the discovery that cholera bacilli which had lost their virulence, regained it completely when associated with perfectly harmless bacteria isolated from apples and cucumbers. M. Maschevsky considers, therefore, that he has discovered a scientific basis for the popular prejudice which condemns the consumption of uncooked fruit and vegetables during epidemics of cholera. Prof. Metchnikow has already dwelt at considerable length upon the effect produced by the nature of the bacterial flora present in the intestine upon the virulence of cholera bacilli, and seeks to explain in this manner what may be described as some of the "vagaries" of cholera epidemics. The whole subject is one of great importance, but one which, involving as it does experiments of the most extensive and laborious nature, still requires an immense amount of work to place on a satisfactory basis. M. Maschevsky's investigations must be regarded as an important contribution in this direction.

MESSRS. CROSBY LOCKWOOD AND SON have nearly ready for publication a volume entitled "Light Railways for the United Kingdom, India, and the Colonies," by Mr. John Charles Mackay.

TO the Hand-list of Orchids cultivated at the Royal Gardens, Kew, which has just been issued, is prefixed a preface giving an interesting historical sketch of the cultivation of orchids in this country. In the year 1890 as many as 766 species belonging to the order flowered in the Gardens.

THE first part of a "Géométrie Descriptive," by M. A. Gouilly, dealing with the geometry of points, straight lines, and planes, has been published jointly by MM. Gauthier-Villars and G. Masson, in the Aide-mémoire Series. The second volume of the work will be concerned with the sphere, cone, and cylinder of revolution, and conic sections; while changes in planes of projection and rotation will form the subject of the concluding volume.

THE *International Journal* of Microscopy and Natural Science, the fifth volume of which (third series) has lately been issued, contains many important contributions to the knowledge of nature in the animal, vegetable, and mineral worlds. The *Journal* is the organ of the Postal Microscopical Society, and is edited by Mr. A. Allen, with the assistance of three associate editors, viz. Prof. V. A. Latham (Chicago), Mr. J. S. Brown (Montreal), and Dr. F. Vicentini (Chieti). Naturalists generally, and workers with the microscope, will find much interesting and serviceable information in the new volume.

WHEN the Austrian Government took over the administration of Bosnia and Herzegovina in 1879, meteorological observations were commenced at a few stations, the number of which has now increased to seventy-seven; three of these are of the first order, or provided with complete self-recording instruments. The Government of these Provinces has recently published its first volume, containing hourly observations and curves for

Sarajevo and Mostar, daily observations at four stations, and monthly and yearly results at all the stations, for the year 1894. A fully-equipped mountain observatory has also been established on the Bjelasnica (lat. 43° 42′ N., long. 18° 15′ E.), at an altitude of about 6800 feet; the publication of these results will commence with the next volume.

THE Kew *Bulletin of Miscellaneous Information* often furnishes us with material for notes; and in looking through the volume containing the numbers published during 1895, we are struck with the large amount of valuable information to be found in its pages. Kew has trained and sent out botanists to botanic gardens in most parts of the world, and it is chiefly due to them and the Director of the Royal Gardens, that the *Bulletins* are able to do so much to extend the knowledge of economic plants. The services thus rendered to the national welfare, by the publication of exact information with reference to botanical enterprise and the potentialities of newly-explored regions, cannot be over-estimated. All who wish to see how science can assist in developing the resources of our colonies, are advised to turn to the 1895 volume of the *Bulletin* of the Royal Gardens, and they will not be disappointed.

THE "Electrical Trades' Directory and Handbook for 1896" (14th year), published at the office of *The Electrician*, furnishes wonderful evidence of the extent of electrical industries at the present time. It consists of over five hundred pages of handbook matter, and nearly seven hundred pages of directorial information. The volume is invaluable to all who are concerned with the production and supply of electricity. Another handy book for electrical engineers and contractors is "The Universal Electrical Directory," published by H. Alabaster, Gatehouse, and Co. This publication, which has now reached its fifteenth year, contains a complete record of all the industries directly or indirectly connected with electricity and magnetism, and the names and addresses of manufacturers at home and abroad.

THE *Quarterly Statement of the Palestine Exploration Fund* (January 1896) contains the usual detailed record of careful exploring work. Of more general interest is the adventurous expedition of Mr. and Mrs. Gray Hill to the isolated and remarkable Crusaders' Castle of Khauranee, of which photographs are given. Lieut.-Colonel C. M. Watson has attacked the problem of the position of the Temple of Jerusalem. He states his views with much plausibility; his method is the scientific one of first considering the historical written evidence, and then the levels of Mount Moriah as it originally existed before Solomon began to build the Temple; and he has drawn his plans in accord with the historical documents, and also with what exploration has shown to be the actual facts. Lieut.-Colonel Conder has an essay on the Syrian language and the history of Samâla.

DR. G. BROWN GOODE's report upon the condition and progress of the U.S. National Museum, under the direction of the Smithsonian Institution, during the fiscal year ending June 30, 1893, has come to hand. The report is especially noteworthy on account of the description Dr. Goode gives of the development, organisation, scope, and work of museums generally, and the National Museum in particular. The description is lavishly illustrated by full-page plates reproduced from photographs of objects and cases in the museum. Bound up with the report are ten papers describing and illustrating collections in the National Museum, among them being "The Poisonous Snakes of North America," by L. Stejneger; "The Onyx Marbles," by G. P. Merrill; "The Cowbirds," by Major C. Bendire; "The Weapons and Wings of Birds," by F. A. Lucas; and "Ethnology of Tibet," by W. W. Rockhill. These papers, which are accompanied by numerous full-page plates, are most valuable contributions to knowledge. The papers, together with Dr. Goode's report, fill nearly eight hundred pages, and the whole stands as striking evidence of the liberality of the Smithsonian Institution in matters of publication.

THE third annual report (vol. iv.) of the Iowa Geological Survey, dealing with the work accomplished under the auspices of the Survey during 1894, has been received. The report shows that a large amount of valuable information was accumulated with reference to the geological structure, and geological products of economic importance, in several counties of the State of Iowa. The method followed by Dr. Samuel Calvin, the State geologist, is to give reports of the geological features of each county separately. He recognises, of course, that this involves following an artificial subdivision of the State; for county boundaries have no relation to the distribution of geological formations. But, at the same time, he points out that the present citizens, as well as prospective settlers and investors, think not of naturally-defined areas, but of counties in which they become interested; and they will turn to the geological report of the several counties under consideration for information concerning the resources of them. Dr. Calvin reports that the work of the Survey continues to demonstrate that the Iowa coal-measures are far richer than they have been believed to be. The report is illustrated by numerous maps and figures, and is standing evidence of the vigour and thoroughness with which the work of the Survey is carried on.

AMONG the many interesting articles and notes in the number of the *Asclepiad* just issued (No. 44, vol. xi.), is a biographical paper on Dr. Thomas Young, by Sir B. W. Richardson, accompanied by a fine autotype portrait of him. Dr. Young is perhaps better remembered by his optical observations than for his medical researches. His mind was turned towards natural philosophy, and it was in that domain rather than in his profession that he earned distinction. He did, however, make some contributions to medical science. About the year 1813, he wrote an essay on the medical facts of climate, containing a large amount of valuable information. In the same year he prepared an introduction to medical literature, including a system of practical nosology, and his essay on consumption attracted considerable attention. Throughout his life he was a close student of vision and of the eye, and in the Bakerian Lecture which he delivered before the Royal Society in the first year of this century, he entered largely into the dimensions and refractive qualities of the eye, and the size of the pictures which are developed on the retina. It was in physical investigations that Young excelled, and especially in connection with interference and the wave-theory of light. He died in May 1828, after just completing his fifty-sixth year.

The current number of the *Berichte* contains an interesting historical note, by Dr. G. W. A. Kahlbaum, on the origin of the "Liebig's Condenser." The inventor of this indispensable piece of apparatus appears to have been C. E. Weigel, Professor of Chemistry and Botany at Greifswald. The account of this apparatus, with diagram, a facsimile of which is reproduced in the *Berichte*, first appeared in 1771, thirty years before Liebig was born. It should be noted, however, that Liebig never described this condenser as his own, but called it Göttling's; and the latter, again, who seems to have made these condensers for Liebig, distinctly refers its invention to Weigel. On these grounds, Dr. Kahlbaum thinks it should be henceforth known as "Weigel's Condenser."

THE chemistry of the simpler organic fluorine derivatives, after a period of comparative neglect, has during the last few years been vigorously followed up, more especially in France. At the meeting of the French Academy of Sciences on February 3, two papers were presented on the acid fluorides, one

by MM. M. Meslans and F. Girardet, the other by M. A. Colson. In the first paper, the method previously used with success by M. Meslans in the preparation of other organic fluorine derivatives, the treatment of the corresponding chloride with metallic fluorides, was employed. M. Colson used a rather different method, the action of the halogen acid upon the organic acid in presence of a dehydrating agent. With hydrogen fluoride, the anhydride of the organic acid gives the best results; thus with acetic anhydride the reaction is

$$(CH_3.CO)_2O + HF = CH_3.CO.F + CH_3.CO.OH.$$

The operation, which must be carried out in a freezing mixture in a metallic flask, gives a theoretical yield. Acetyl fluoride boils at 20°·8 under a pressure of 770 mm., and its density at 0° is 1·0369. Propionyl fluoride boils at 44°, and is lighter than water, its density at 15° being about 0·972. Benzoyl fluoride, which has already been prepared by M. Guenez, is best obtained by acting with benzoyl chloride upon dry zinc fluoride, and is a liquid of extremely irritating odour, boiling at 154°.

THE additions to the Zoological Society's Gardens during the past week include a Common Viper (*Vipera berus*), British, presented by Mr. S. Ockenden; four Japanese Teal (*Querquedula formosa*, ♂ ♂ ♀ ♀) from North-east Asia; two Smews (*Mergus albellus*, ♂ ♂), European, a Black Lark (*Melanocorypha yeltonensis*) from Siberia, purchased; a Purplish Death Adder (*Pseudechis porphyriaca*), a Punctulated Tree Snake (*Dendrophis punctularia*) from Australia, deposited; a Hybrid Pheasant Antelope (between *Tragelaphus gratus*, ♂, and *Tragelaphus spekii*, ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

PERRINE'S COMET.—A telegram from Kiel announces the re-discovery of Perrine's comet by Dr. Lamp, on February 13. At 17h. 40m., Kiel mean time, it was in R.A. 19h. 44·8m. and decl. −2° 22'. The R.A. agrees well with the ephemeris published in NATURE on January 23, but the south declination is about a degree greater than that predicted.

A NEW COMET.—Another telegram from Kiel is as follows: "New comet Perrine Lamp, February 15, 17h. 28·6m., Kiel mean time; R.A. 19h. 26m. 44s., decl. −1° 1' 56"; daily movement in R.A. 7m. 36s., in declination 2° 57' towards the north: bright." The new comet is thus in the immediate neighbourhood of the original Perrine's comet, but it has a much more rapid movement. Both comets are in the constellation Aquila, rising about 4 a.m.

THE ZODIACAL LIGHT.—During the last three years the zodiacal light has been very carefully observed by E. Marchand, under the advantageous conditions afforded by the observatory of the Pic du Midi, at an altitude of 2860 metres (*Bull. Soc. Ast. de France*, February). Ordinarily this phenomenon is best seen during the evenings of spring or in the mornings of autumn; but in the absence of the moon, when the sky is clear, it is seen at all times of the year from the mountain observatory, completely encircling the celestial sphere. The limits of the luminosity have been plotted on charts, and taking the mean positions of the boundaries, it is found that the width of the belt of light is about 14°, and that it is very nearly a great circle inclined 6° or 7° to the ecliptic, with a longitude of about 70° for the ascending node. Now the inclination of the sun's equator is about 7°, and the longitude of the ascending node is about 74°; hence, it is concluded that the central plane of the zodiacal light coincides with the plane of the sun's equator.

The observations support the idea that the attenuated cosmical matter of which the zodiacal light is probably composed extends all round the sun, in the form of a very flattened ellipsoid of revolution, to a distance well beyond the earth's orbit.

In the part of the sky opposite to the sun, the brightness of the light is not greater than that of the most feeble parts of the Milky Way, but it becomes much more intense as the sun is approached. The increase of brightness in the direction of the sun, however, is more rapid than can be accounted for merely by the increased thickness observed, so that a greater condensation of cosmical matter in the neighbourhood of the sun seems probable. Near the horizon, the width of the zodiacal light seems generally greater than that which traverses the sky; but it is pointed out that this may be due to the same cause as that which makes the sun, moon, or constellations appear larger when near the horizon. The "Gegenschein," or counter-glow, does not appear to have been noted.

SURFACE DRIFT OF JUPITER.—A useful summary of the various determinations of the rotation period of Jupiter in different latitudes is given by Mr. Stanley Williams (*Monthly Notices*, lvi. No. 3). Nine distinct currents can certainly be recognised, and their boundaries are pretty sharply defined, though possibly varying slightly in position from time to time. These currents, with the exception of that including the red spot, completely encircle the planet, travelling due east and west, and giving little or no indication of any movement towards or from the poles. In the following tabular statement the number of the zone or current is followed by the zenographical latitudes of its boundaries; then follows the average rotation period of the zone expressed in time and in terms of the equatorial period.

Zones.	Lat.	Period. In time. h. m. s.	Period. In terms of equatorial period.
I.	+85° to +28°	9 55 37·5	1·0089
II.	+28 ,, +24	9 54 30	1·0071
		9 56 30	1·0104
III.	+24 ,, +20	9 48 0 9 49 30	0·9973
IV.	+20 ,, +10	9 55 33·9	1·0089
V.	+10 ,, −12	9 50 20	1·0000
VI.	−12 ,, −18	9 55 40	1·0090
VII.	−14 ,, −28	9 55 40	1·0090
VIII.	−18 ,, −37	9 55 18·1	1·0084
IX.	−37 ,, −55	9 55 5	1·0081

There is a remarkable want of symmetry in most of the currents. In the northern hemisphere the drift is nearly uniform from the pole to lat. 28°, and there is nothing equivalent to the red spot (zone VII.); in the southern hemisphere there is no counterpart of the region about lat. 25°, which is such a prominent feature in the northern hemisphere. It is suggested that atmospheric circulation in a north and south direction may take place through the narrow rifts which have been seen to traverse obliquely some of the belts and clear zones.

THE TEMPERATURE OF AIR AND THE PROBLEM OF AN ICE AGE.[1]

THE mean temperature t of the air is determined by the balance of radiations received from the sun and from the soil with that given up towards the sky, and is ruled by the action of meteorological factors. According to Maurer's and Trabert's discussion of nocturnal temperatures, air radiation in the atmosphere is a *linear* function of its temperature; so radiations from soil and towards sky are expressed as proportional to the differences $[(t_s - t), (t - t_c)]$ of t from the mean temperature t_s of soil, and from the mean temperature t_c of an ideal stratum, the radiations of which would be equivalent to that of the whole atmosphere and of all the celestial bodies except the sun. This temperature t_c I call *temperature of the sky*.

Similarly, the mean temperature t_s of soil is determined (if we abstract from meteorological agents, that is in *solar climate*) by the balance of its radiation towards the sky [which is proportional to $(t^s - t_c)$] with that fraction of mean solar heat which is bestowed upon heating the surface considered. The mean annual solar heat received by unity of surface at the limits of the atmosphere (which is 0·305 of the solar constant at the equator) diminishes with the latitude λ, not as cos λ, but, according to Wiener's computations, as the cosine of an auxiliary angle ζ, which is 0° at the equator, and 65° 31' at the poles, and which repre-

[1] I beg permission to briefly review the assumptions upon which Section II., III. of "Le Cause dell' Era Glaciale" (Pavia, 1865) is based, and which the reviewer of the book in NATURE (No. 1348, vol. lii. p. 412) judged as far from satisfactory.—LUIGI DE MARCHI.

sents zenithal distance of a fixed sun, the intensity of which would be 3/10 of the true intensity, and the annual effect of which would be equivalent to that of the true sun. At sea-level this quantity of solar heat is supposed to reduce itself, according to Bouguer's law, from 1 to $p^{\sec \zeta}$, where p is the mean transparence of the atmosphere.

Upon these assumptions, the *annual solar temperature* of the air on a *continental* globe is expressed (omitting here a little term for diffused heat) by a formula $t_1 = t_c + k_s \cos \zeta \frac{p^{\sec \zeta}}{m_s}$ where m_s is the transparence of the atmosphere for the earth's radiations, and k_s is a coefficient proportional to the *heating power* of solar radiation for soil, and depends then upon the physical constitution of the latter. On the sea the effect of solar heat is most complicated, but, abstracting from currents, arguments are given for accepting on *oceanic* globe a formula $t_0 = t_c + k_a \frac{p^{\sec \zeta}}{m_a}$, where m_a, k_a are the analogues of m_s, k_s for sea. Forbes expresses the mean temperature of each parallel by $t = t_0 + x(t_1 - t_0)$, when x is the fraction of parallel occupied by continents; but the same formula may express the mean temperature of every point on continents, if x means its *continentality*, whose expression by annual range e $\left(x = \frac{e - e_0}{e_1 - e_0}\right)$ is discussed.

The calculation of coefficients in the complex formulæ so obtained is very much simplified by comparison with known empirical formulæ. Mendeléef's formula for vertical distribution of temperature leads to the fundamental fact that the mean temperature of the sky, t_c, is a constant for all points at sea-level, and from evaluations of Mendeléef's constant by Woeikof I assume it as $-45°\cdot4$ C. ($-49°\ 7$ F.). So is numerically expressed what Mr. Culverwell calls the *blanketing* function of atmosphere, and its function of conforming temperature on the earth's surface; and Croll's fallacy of evaluating effects of solar heat by differences from a hypothetical temperature of space is placed in evidence. Values of t_0, t_1 at equator, discussed from Forbes' formulæ, give values of $\frac{k_s}{m_s}$, $\frac{k_a}{m_a}$; p is assumed as 0·60.

Solar temperatures so obtained give a very satisfactory representation of facts; their differences from true temperatures are a striking reflex of the distribution of meteorological and physical agents (sea and air currents, convective motions, shore-ice, &c.) not accounted for in deduction of formulæ.

An attempt is made for a theory of annual range, where Wilson's principle of the constancy of nocturnal cooling of bodies, whatever may be the temperature of the air, allows the assumption that the temperature of the sky follows in its variations temperature of soil. Comparison of theory with facts indicates the enormous smothering influence of meteorological agents.

Discussions of astronomical and geographical theory of an Ice Age, in the light of the formulæ given, accounts for variability of physical and meteorological agents. None seems to me to satisfy either the theory or the actual conditions for variation of climates, as developed *on facts* by Brückner's classical work on "Klimaschwankungen." These conditions seem to the author to be satisfied by the suggestion of a small *diminution* in the transparence p, attended by a proportional, or by a smaller, diminution of m_s, m_a. So the difference $t - t_c$ is diminished, less at low latitudes, more at higher, above all at 70° Lat., the variation diminishing further. Diminution is greater on sea and less on continent, so diminishing at high latitudes thermic difference between earth and sea, what is, according to Brückner's demonstration, the capital condition for a rainy period on continents, and indirectly for glaciers pushing forward. Also the difference between equator and poles is strengthened.

Inversely, an increase of p and m_s m_a would bring, as in Tertiary periods, a more equal distribution of temperature between equator and poles, by increasing for several degrees the temperature in higher latitudes. Mars is probably in a similar condition, as polar ice-caps do dissolve, notwithstanding that the intensity of sun is there much less than on earth; but the Martian atmosphere is extraordinarily more transparent than ours. Annual range would be strengthened; but the flora of East Siberia suggests that also Heer's polar floras might have sustained severe winter, provided that summer's heat was sufficient to support them, and that abrupt variations were avoided.

THE RÖNTGEN RAYS.

THE field of investigation opened up by Prof. Röntgen's researches on the new actinic rays has attracted explorers from all parts of the civilised world. So numerous are the communications being made to scientific societies that it is difficult to keep pace with them, and the limits of our space would be exceeded if we attempted to describe the whole of the contributions to the subject, even at this early stage. It may assist, however, in the organisation of the facts if we bring together a few of the results obtained since the publication of Prof. Röntgen's paper.

The most important British communication on the subject was made by Prof. J. J. Thomson to the Royal Society on Thursday last, in the following paper, on the "Discharge of Electricity produced by the Röntgen Rays, and the effects produced by these Rays on Dielectrics through which they pass."

"The Röntgen rays, when they fall upon electrified bodies, rapidly discharge the electrification, whether this be positive or negative. The arrangement I have used to investigate this effect is as follows: The Ruhmkorff coil and the exhausted bulb, used to produce the rays, are placed inside a large packing case covered with tin plate; this is done to screen off from the electrometer any electrostatic disturbance due to the action of the coil. The needle of the electrometer is suspended by a quartz fibre; thus, as there is no magnetic control, the needle of the electrometer is not affected by changes in the magnetisation of the core of the coil.

"The exhausted bulb is placed so that the phosphorescent part of it is about $1\frac{1}{2}$ inches from the top of the box, and a hole about an inch in diameter is cut in the lid of the box just over the bulb, so as to allow the rays to emerge from the box: a thin plate of either aluminium or tinfoil is used to cover up the hole. The electrified plate, which is a little larger than the hole, is placed outside the box about two inches above the hole in the lid, so that the Röntgen rays which passed through the hole fall upon the plate. This plate is kept permanently connected with one of the quadrants of a quadrant electrometer; the greatest care is taken with the insulation of this plate and of the quadrants of the electrometer. The insulation was so good that there was no appreciable leak when the coil was not in action. The following is the method of making the experiments: The two pairs of quadrants are connected together, and the plate charged to a high potential by an electrophorus, or by temporary connection with a large battery of small storage cells. All the quadrants of the electrometer are now at the same potential. The two pairs of quadrants are now disconnected; if the insulation is good the potentials will remain the same, and there will be no deflection of the electrometer; in our experiments the leak is so small that under these circumstances the movement of the spot of light is hardly perceptible. If, now, the Rontgen rays are directed on to the plate a violent leakage of electricity from the plate occurs, the potential of the quadrants connected with the plate changes, and in a few seconds the spot of light reflected from the mirror of the electrometer is driven off the scale. This leakage of electricity occurs whether the plate is positively or negatively electrified; if the plate is uncharged to begin with, I have not been able to detect that any charge is acquired by the plate by exposure to these rays. When the potential to which the plate is raised is high the leakage from the plate is a most delicate means of detecting these rays, more so than any photographic plate known to me. I have found these rays produce distinctly perceptible effects on a charged plate after passing through a zinc plate a quarter of an inch thick. The charged plate and electrometer are much more expeditious than the photographic plate and more easily adapted to quantitative measurements.

"To determine how the radiation of the Röntgen rays depended upon the degree of exhaustion of the bulb, the bulb was kept in connection with the pump and the leakage was observed at different degrees of exhaustion; no leakage could be detected until the pressure was so low that phosphorescent patches appeared on the bulb, and. even after the phosphorescence appeared, the leakage was small as long as there was any considerable luminosity in the positive column; it was not until this had disappeared that the leakage from the charged plate became rapid.

"If the greatest sensitiveness is required, it is, of course, advisable to charge the plate as highly as possible. The leakage due to

the rays, however, occurs when the potential of the plate does not exceed that of the tin-plate cover by more than 3 or 4 volts, and I have not yet met with any phenomena which suggest that there is a lower limit of potential difference below which leakage does not take place.

"This leakage differs from that produced by ultra-violet light, the laws of which have been unravelled by Elster and Geitel, in several essential features, in the first place ultra-violet light only discharges a negative charge, while the Röntgen rays discharge both positive and negative. Again, the effect of ultra-violet light is only considerable when the electrified body is a strongly electro-positive metal with a clean surface. The effects of the Röntgen rays are, on the other hand, very marked whatever the metal, and take place when the electrified plate is surrounded by solid or liquid insulators as well as when surrounded by air. I have embedded the plate in solid paraffin wax, in solid sulphur, placed it inside a lump of ebonite, wedged it in between pieces of mica, and immersed in a bath of paraffin oil; in each of these cases, though the insulation was practically perfect when the insulator was not traversed by the Röntgen rays, and the potential of the plate differed from that of the metal covering of the box by from 10 to 15 volts, yet, as soon as the Röntgen rays passed through the insulator, the charge of the metal plate leaked away. I have found that the electricity leaks from the plate even when the space between it and the nearest conductors connected to earth is entirely filled with solid paraffin; hence we conclude that when the Röntgen rays pass through a dielectric they make it during the time of their passage a conductor of electricity, or that *all substances when transmitting these rays are conductors of electricity*. The passage of these rays through a substance seems thus to be accompanied by a splitting up of its molecules, which enables electricity to pass through it by a process resembling that by which a current passes through an electrolyte. By using a block of solid paraffin in which two pairs of electrodes were embedded, the line joining one pair being parallel, that joining the other pair perpendicular, to the Röntgen rays, which were kept passing through the block, I found that there is but little difference between the rate of leakage along and perpendicular to the rays."

Prof. Thomson has investigated the question of longitudinal vibrations in connection with the recent discoveries. In a paper read before the Cambridge Philosophical Society on January 27, he discussed the theory of longitudinal waves from the point of view of the electro-magnetic theory of light, and showed that on that theory longitudinal waves can exist (1) in a medium containing moving charged ions; (2) in any medium, provided the wave-length is so small as to be compared with molecular dimensions, and the ether in the medium is in motion. It was shown that it follows from the equations of the electro-magnetic field that the ether is set in motion in a varying electric field. These short waves would not be refracted, but in this respect they do not differ from transverse waves which on the electro-magnetic theory would not be refracted if the wave-length were comparable with molecular distances. The properties of the longitudinal waves were developed in the paper. Prof. Thompson exhibited a number of photographs which had been taken at the Cavendish Laboratory by Prof. Röntgen's method, and experiments made on the Röntgen rays were described. In one of these experiments the photographic plate was placed inside the vacuum tube so as to intercept the rays between the kathode and the walls of the tube; in this case the plate was not affected, showing that the fluorescence of the glass is necessary for the production of these rays. Other experiments were made to see if they could be excited by fluorescence without a kathode; the ring discharge was produced in bulbs, and caused a vivid phosphorescence; a plate protected by cardboard when exposed to the bulb for an hour was not affected, nor was any greater effect produced when the bulb was filled with a gas such as oxygen, which phosphoresces under the discharge. It thus appears that both a kathode and a phosphorescent substance are required for the production of these rays, and that one without the other is inoperative. A series of experiments were made by taking photographs through tourmaline plates, (1) with their axes parallel, (2) with their axes crossed; it was hoped by this method to get some evidence as to whether the rays were longitudinal or transverse. A considerable number of photographs were taken in this way, but no difference could be detected in the obstruction offered to the rays by the tourmaline plates in the two cases. Another method of investigating the same question was described, based on Elster and Geitel's discovery of the influence of the plane of polarisation of light on its power to discharge electricity from a metallic surface. The experiments, which were not concluded until the day after the meeting of the Society, show that these rays exert the most powerful effect in discharging electricity, whether positive or negative, from an insulated electrified metal plate exposed to their influence. A bulb separated from the charged plate by a board three-quarters of an inch thick covered with several layers of tinfoil exerted a most powerful effect, and it was not until the thickness of the metal between the bulb and the electrified plate was nearly quarter of an inch that the effect ceased to be perceptible. The electrified plate is a much more delicate detector of these rays than the photographic one, and is more suitable when measurements are required. These results, though by no means conclusive, are in favour of the vibrations being longitudinal.

We have already mentioned, in our abstracts of the *Comptes rendus*, and in notes, the many papers which have been read before the Paris Academy descriptive of developments of Röntgen's work. In France, both the chemical and surgical sides of the discovery are being studied. As recorded in our issue of February 6 (p. 324), Prof. Lannelongue, assisted by MM. Barthélemy and Oudin, have demonstrated to the Academy of Sciences the applicability of the discovery to surgery, and observations made by Prof. Lannelongue since then bear out his conclusions that in diseases where there is an actual loss of substance in the bone, or an abnormal growth of bony tissue, photography by means of Röntgen's rays will be a valuable aid to diagnosis. The current number of the *Comptes rendus* contains several papers dealing with the chemical properties of the rays. M. Meslans has studied the influence of the chemical nature of substances on their transparency to the rays. He has found that the varieties of carbon —diamonds, graphite, and charcoal—and their compounds are easily traversed by Röntgen's rays, as also are compounds of hydrogen, oxygen, and nitrogen. Alkaloids are also transparent, but sulphur, iodine, and silicon are opaque. M. Charles Henry has found that by coating coins opaque to the rays with phosphorescent sulphide of zinc, photographic impressions of substances beneath the coins can be obtained, metals coated in this manner appearing to lose their opacity to the Röntgen rays. M. Henry has also found that phosphorescent sulphide of zinc emits, in addition to green light, a large number of the new actinic rays.

The properties of Lenard rays—that is, kathode rays which have travelled outside the tube in which they had been produced—are also being investigated. A note in the *Chemical News* states that Prof. Slaby, of Charlottenburg, has obtained good photographs by means of Lenard rays. Dr. J. Joly has also been successful in this direction of work. At the Dublin University Experimental Science Association, on February 11, he showed photographs of various objects taken after the manner of Röntgen by the Lenard rays. One of a pair of spectacles within its case showed well the transparency of wood and cardboard and the comparative opacity of glass, and the still higher opacity of the heavy metals. Experiments on refraction of the rays have in the case of paraffin oil given no evidence of refraction. This substance proved very transparent. Experiments upon the reflection of the rays have, however, yielded positive results. The rays were reflected by a silvered copper mirror on to a sensitive plate. The plate was in the geometrical shadow of a thick lead shield, the rays passing through a slot in the shield and through thick millboard before reaching the mirror, which was inclined at an angle of about 45° to the plate. Exposures of two hours gave distinct photographic effects. Reflection from a concave mirror placed behind the plate and facing the sensitive film, did not give any trace of a focus, but a darkening of the full diameter of the mirror, and rather more marked at the edge; thus suggesting irregular reflection of the rays. The experiment of Prof. J. J. Thomson on the discharge of a charged electroscope by the rays was also shown by Dr. Joly, and, at the conclusion of the meeting, it was demonstrated that this effect was not obtained at short distances from the tube, the electroscope then becoming positively electrified.

Several important letters on the subject of Röntgen rays have come to us. Lord Blythswood communicates the following, in continuation of his letter published last week:—

"Since I last wrote to you, I, at the suggestion of Lord Kelvin,

placed my sensitive plate in a metal zone with an aluminium window in it. The whole was well earthed. This precaution was taken to prevent any sparking inside the zone. The zone was placed between the poles of my Wimshurst machine, and photographs of various objects taken. This is, I think, conclusive that the influence at work is not the ordinary electrical waves or discharges. For in a carefully-closed metal zone there can be no electrification, neither do the photographs of metal objects show any trace of discharge or sparking."

The following important communication on "Photography through Opaque Bodies without Crookes' Tube" has been received from Dr. John Macintyre:—

"At the demonstration given by Lord Blythswood and Dr. J. T. Bottomley before the Glasgow Philosophical Society on Feb. 5, I was requested to show some results in shadow-photography obtained by the use of comparatively simple apparatus. My remarks were then intended to show that as we became familiar with this new art the apparatus would become less complicated. As the present notes are written for another purpose I simply mention the fact that the experiments noted below were made with the same apparatus exclusive of Crookes' rube. It consisted of an induction coil giving not more than a two-inch spark, the primary coil of which was excited by four small secondary cells giving two volts each; a very small Tesla coil made by Messrs. Baird and Tatlock; and a Crookes' tube selected from the stock of an instrument-maker, but not specially prepared.

"Lord Blythswood on that occasion described the experiments published in the last issue of NATURE by means of which he was able to demonstrate that photographs could be taken without Crookes' tubes. Mr. Sydney D. Rowland in his interesting contribution to the subject in the same issue raises the question of the possibility of a 'contact phenomenon' being the explanation of Mr. Gifford's results, and not Röntgen's rays at all. As the same doubt was suggested to my mind as the result of my own experience I should like to record the following experiments which were made by me with a view of confirming the extremely interesting results recorded by Lord Blythswood. In doing so I wish it clearly understood that I do not suggest that the photographs taken through opaque bodies by Lord Blythswood were not the result of Röntgen's rays; my statements simply bear upon my own experience and the results I have been able to obtain.

"In my first experiment the sensitised paper was enclosed in a mahogany box, the sides of which were three-sixteenths of an inch thick, and the object to be photographed was a perforated zinc plate; bromide paper was substituted for glass plates in order to do away with resistance, and the whole was placed between the terminals of the small Tesla coil. The current coming from the negative pole before reaching the positive had therefore to pass through the following structures: (1) Three-sixteenths of an inch of mahogany, (2) a sheet of aluminium one-sixteenth of an inch thick, (3) the zinc plate, (4) the bromide paper, (5) some black cardboard for packing, (6) the other end of the box, also three-sixteenths of an inch. The box was insulated from the earth and held between the poles for ten minutes. On developing, a distinct image of the plate was obtained, the perforations showing black on the paper, while the part upon which the zinc rested had not been acted upon at all. It was clear from this experiment that I had obtained a photograph without a Crookes tube, and a negative—that is to say, had it been printed from the bromide paper we would have had a reproduction of the original perforated plate.

"The second experiment was different from the first inasmuch as I placed a metal plate behind the bromide paper, and consequently there was the following arrangement proceeding from the negative to the positive pole: (1) The end of the mahogany box, (2) the aluminium plate, (3) the zinc perforated plate, (4) the bromide paper, (5) a copper disc, (6) black cardboard for packing, (7) the other end of the mahogany box. This was again placed between the terminals of the Tesla coil for the same time, and the bromide paper developed in the usual way. This time the perforations did not mark the paper, but I had a distinct impression of the zinc; in other words, I had obtained a positive, because, had I printed a copy, the perforations would have appeared black, quite the reverse of the last experiment.

"It will be observed that in neither case had I, like Mr. Sydney Rowland, connected the positive pole of the coil with the metal plate behind the sensitised surface.

"On submitting these results (which were obtained previous to the date of Mr. Sydney Rowland's letter) to Lord Kelvin and Dr. Bottomley they agreed with me that the picture had possibly not been taken by means of Röntgen's rays at all; and Lord Kelvin suggested the following third experiment, in which the sensitised paper was enclosed in a metal box. In this experiment the following structures were placed in definite order between the negative and positive pole: (1) The front of the mahogany box, (2) several layers of black paper, which formed a covering for the metal box, (3) the front of the metal box, (4) the zinc perforated plate, (5) the bromide paper, (6) the metal plate, (7) the back of the metal box, (8) the black paper surrounding the metal box, (9) the other end of the mahogany box.

"It will be noticed that in this experiment the metal plates in front and behind the bromide paper were enclosed in a metal case which attracted the current round it. The result was as we had anticipated, because repeated attempts with different and prolonged exposures failed to produce any impression whatever upon the bromide paper.

"Had the photographs been obtained by the X-rays, one might have expected that while the current was conducted past the sensitised paper some impression would have been got by the Röntgen's rays piercing the metal box. As yet, however, I have not been able to obtain this result, although I have tried to with thin aluminium sheets in contact with each other at the edges and enclosing the metal plates and bromide paper.

"I should like to point out that Lord Blythswood's experiments differ from the above in many respects. He used glass sensitised plates; the apparatus was exceedingly powerful; and the objects were not placed between the terminals of the machine, but at some distance below the line of the sparks.

"From the above-mentioned experiments it is clear (1) that photographs may be taken without Crookes' tubes; (2) that different results may be obtained according to the conditions to which the sensitised surface is subjected. And I would suggest the following questions as suitable for further investigation:—(*a*) Are they not the result of a force different from the Röntgen's rays? (*b*) what is this force which is now described as a 'contact phenomenon'—a term, of course, which does not explain the actinic power? (*c*) what is the actinic power which we have hitherto considered to be a property of ordinary light? (*d*) were Röntgen's rays not generated between the metal plates?

"There is one point in this experiment which has not been touched upon by other writers, and which I should like to allude to in conclusion. It is quite clear, whether the photographs produced without Crookes' tubes were obtained by means of Röntgen's rays or not, that a current may be conducted through metal plates to a sensitised surface and impressions obtained thereon. In Mr. Sydney's Rowland's letter he makes no mention of metal plates having been placed in front of the sensitised plates. I have placed three plates of different metals in front of the object to be photographed during the time of exposure and obtained a picture, so that we have here a method of photographing certain objects through opaque bodies in the form of metal plates, and, theoretically speaking, the thickness would be a matter of comparatively little importance."

Prof. J. Wertheimer, Principal of the Merchant Venturers' Technical College, Bristol, has, at the suggestion of Mr. C. A. Morton, Surgeon to the Bristol General Hospital, taken a radiogram of an amputated foot into which Mr. Morton had introduced nine foreign bodies (bullets, splinters of needles, and glass wedges). Six of these were plainly seen on the radiogram, although Mr. Morton found that a fellow-surgeon could only locate one by palpation.

Prof. Wertheimer says: "Two points of interest arise on examination of the radiogram. Mr. Morton had endeavoured to place a fragment of needle through the last joint of the great toe on its plantar aspect. On dissecting the foot, after the radiogram had been taken, he found that the fragment had penetrated the inner corner of the distal end of the first phalanx, and had passed *beneath* the bone, leaving a small portion embedded in the phalanx itself. This fragment shows up plainly in the radiogram, and, as the foot rested on its plantar aspect, the rays must have passed through the whole thickness of the bone. The radiogram does not, however, show that the needle is *beneath* the bone. It appears, therefore, that in such cases two radiograms will be needed—one taken with the dorsal, and the other with the plantar aspect uppermost, the conditions being other-

wise precisely alike. A comparison of these should show whether the foreign object is nearer the dorsal or the plantar aspect of the foot.

"The second point refers to the three objects not seen clearly in the radiogram. The tube used was the ordinary 'shadow of the cross' one, and, though the cross was bent back, the shadow of its supports was visible; two of the objects were directly under this shadow. The third lay parallel and very close to a bone, and hence is not plainly distinguishable."

Photographs have been obtained by utilising other sources of luminosity than high vacuum tubes. The following experiments, performed by Messrs. Wm. Wallace and H. C. Pocklington in the Physical Laboratory of the Leeds Central Higher Grade School, are of interest:—

"A cheap German incandescent lamp of low candle-power was used in place of a Crookes' tube, a piece of tinfoil applied to the outside serving as one electrode, and the filament as the other. The current employed was the high frequency one obtained from a Tesla coil actuated by a large Ruhmkorff. The sparking distance of the Tesla was about 5/8 inch. This apparatus gave a vivid green phosphorescence of the glass, which soon grew less, and in fifteen minutes had almost disappeared. Three exposures were made in succession, each of fifteen minutes: the first when the lamp was new; the second immediately afterwards, the lamp being tired by the previous exposure; for the third, the tinfoil electrode was shifted round about 90°, so as to utilise a fresh part of the surface of the glass. The three negatives were developed simultaneously; the first was good, the other two were under-exposed to about the same extent. In the last experiment, the green phosphorescence, though not as brilliant as in the first, was much more brilliant than in the second. This seems to show that the production of X-rays is due to some cause different from that which produces the phosphorescence."

Mr. J. W. Gifford has obtained photographs by Röntgen's methods, and also by means of the ordinary discharge of an induction coil. Replying to a suggestion that results obtained by him with metal discs were due to a "contact" phenomenon, and not to Röntgen's rays, he says:—

"I notice in your issue of February 13, p. 340, that Mr. Sydney D. Rowland thinks that he has evidence to prove that my results without a Crookes' tube were not due to the 'Röntgen rays.' I have already replied to his observations elsewhere (*British Medical Journal*); but will you allow me to say that I think the evidence he advances entirely turns on whether the electrograph was a shadow or an impression, or, in other words, whether surface markings of the objects electrographed were reproduced, or not. Now, the discs I used bore numbers stamped on them, but in no case were these numbers, or any surface markings whatever, to be found in the resulting negative, a print of which I enclose.

"With regard to what Mr. Rowland says about the objects, in his case, being behind or in front of the film, I would suggest that the discharge from a coil is an oscillatory one, and that glass is fairly transparent to the 'Röntgen rays,' almost as transparent as aluminium, in fact. But conditions are often so different, that I do not feel justified in criticising another man's work without having seen his experiments myself. I must, however, most emphatically disclaim any positive assertions in the present stage of the inquiry. I have, as far as I am aware, only mentioned tentatively what seem to me the general indications of my experiments up to now, and feel that in investigations of this kind the balance is generally in favour of one's first impressions being wrong.

"I do not know if you have observed that when Crookes' tubes are employed for the purpose, after about an hour's use they become coated, both above and below, with a thin layer of dust. This happens, at least, time after time in my own laboratory."

Mr. W. A. D. Rudge, writing from the Science, Art and Technical Schools, Plymouth, says that he has obtained a radiogram of a crayfish, and found the exoskeleton to be as transparent to the new radiations as glass and aluminium.

Our United States correspondent sends us descriptions of work being done in America, in continuation of Röntgen's discovery. He says very successful photographs have now been obtained by Prof. A. W. Wright, of Yale. Prof. Wright has photographed a piece of metal having a fracture which had been welded, but showed no flaw or line of puncture to the eye. The photograph, however, revealed the fracture. This last result was considered by ordnance officials of the Government to be of profound significance, as indicating a means of testing armour for hidden defects and discovering hidden flaws in machinery. Prof. John Trowbridge, of Cambridge, Mass., has also obtained some results. He arranged strips of glass an eighth-inch thick in a wooden box of inch board, and passed the rays through the board, thus obtaining a photograph of the strips of glass. By passing the rays through prisms of wood and of vulcanite he has confirmed the observation that they were not refracted.

THE MANUFACTURE OF ALUMINIUM BY ELECTROLYSIS.

At the ordinary meeting of the Institution of Civil Engineers on Tuesday, February 11, a paper was read on "The Manufacture of Aluminium by Electrolysis, and the Plant at Niagara for its Extraction," by Mr. Alfred E. Hunt. The author's description of the ores of aluminium best fitted for electrolytic reduction to the metallic state, and of the general principles governing the extraction of the metal from its compounds, makes interesting reading.

The Hall process, which is that adopted by the Pittsburg Reduction Company, involves the direct electrolysis of the sesquioxide, alumina, dissolved in a molten bath of the mixed fluorides of aluminium, calcium and sodium. One cubic foot of the solvent serves for an hourly production of one pound of metallic aluminium, the bath used being capable of dissolving one-third of its own weight of alumina. The electrical energy required for extracting this amount of metal is 3730 watt-hours for the decomposition of the alumina, with a further supply to maintain the bath at the temperature necessary for the molten condition. The fluorides remain unchanged, so that the operation is continuous. The bath is made either from a mixture of fluorspar and cryolite, or from the artificial fluorides; and it may be fused in a separate vessel when starting work, or in the bath by the current itself. Alumina is added at frequent intervals to prevent too great a variation in the resistance of the bath, and the aluminium, as it is produced, is siphoned from beneath the layer of fluoride, where it collected, without interference with the progress of the operations. The oxygen of the alumina is liberated at the carbon anode, which, at the temperature of the bath (980° C.) oxidises to carbon monoxide. Outside the bath this is burnt at once to carbon dioxide, and is allowed to escape into the working apartment. The carbon anodes are consumed at nearly the same rate as the aluminium is produced, the amount being about two-thirds of the quantity actually used. The difference of potentials theoretically necessary for the separation of the constituents of alumina is about 2·8 volts, but a greater difference is due to the resistance of the bath. The pots employed are of iron with carbon linings, but these can be dispensed with if a high degree of purity is not required.

The chief impurities in the finished product are silicon and iron. These are derived from the alumina as well as from the carbon anodes. Aluminium can be produced containing 99¾ per cent. of the pure metal, and is regularly delivered with 99 per cent. The electrolytic baths are joined in series, the positive bar of the switch-board being joined to the carbon anode of one of the baths, and the last pot of the series being joined to the negative board of the switch-board. All the copper connections are necessarily very heavy, on account of the large currents employed.

The electrical energy is generated at the works of the Niagara Falls Power Company, and is conveyed, without the intervention of transformers, over a distance of about half a mile, by stranded copper cables 1¼ inches in diameter. The loss in transmission is about 1½ per cent. of the energy conveyed.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Mr. D. H. Nagel, Fellow of Trinity College, has been elected as a Delegate of Local Examinations in place of Mr. E. Chapman, Fellow of Magdalen College, resigned.

Mr. F. T. Richards, Fellow of Trinity College, has been re-elected a Curator of the Botanic Garden.

Mr. J. E. Marsh, M.A., Balliol College, has been reappointed Lecturer in Materia Medica and Pharmacology for the year 1896.

Cambridge.—Mr. J. E. Marr, F.R.S., Fellow of St. John's College, has been reappointed University Lecturer in Geology for five years.

The Council of the Senate propose to submit a grace for the appointment of a syndicate to consider what further rights or privileges (if any) should be granted to women students by the University, and in particular whether they should be admissible to degrees.

The Special Board for Biology propose that the arrangement subsisting for the last twenty years between the University and the Zoological Station at Naples should be renewed for a further period of five years. This arrangement secures for University students the use of a table in the laboratory and facilities for research, in consideration of an annual payment to Dr. Dohrn of £100 from the Worts Travelling Scholars Fund.

The Board of Agriculture has made a grant of £650 to the Glasgow and West of Scotland Technical College. The same amount was granted to the College last year.

In Paris the Société de Topographie is making an effort to establish topography as an ordinary subject of instruction, and has published a circular and syllabus for the purpose.

The Russian Government has, says the *British Medical Journal*, assigned an annual grant, equivalent to about £10,000, to the Medical School for Women in St. Petersburg. The city undertakes to provide £2400, and private munificence has raised an endowment fund of £70,000. Preliminary courses are already being given.

The following are among recent appointments abroad: Dr. Eigenbrodt to be Extraordinary Professor of Surgery at Leipzig; Dr. Lenhossék to be Extraordinary Professor of Anatomy at Tubingen; Dr. M. Valsilieff to be Extraordinary Professor of Theoretical Surgery at Warsaw; Dr. Eliza M. Mosher to be Professor of Hygiene in the University of Michigan.

The following announcements are made in *Science*:—Mr. Joseph Bannigan has given 4000 dols. to the Catholic University of America, and has made known his intention to donate for twelve years 4000 dols. a year for library purposes. By the will of the late Mrs. Doyon, the University of Wisconsin has received 5000 dols., the income of which is to be devoted to scholarships for young women. Two scholarships of 2000 dols. each have been presented to Tufts College, one by Mrs. A. B. Perkins, and the other by J. S. and H. N. White.

The disasters of the late war seem to be teaching the Chinese that the traditional attitude of distrust and exclusion of Western civilisation cannot any longer be safely maintained. It may be taken as a sign of the times that the Vice-Regent of Tientsin has entertained a proposal to start a university upon the European model. The university is particularly intended to foster the technical sciences, and will be connected with a preparatory school. Mr. Charles D. Jenney will undertake its direction, and the staff will be partly composed of foreigners. The autumn of this year is to see the opening of the school and university.

The Apprentices' Institution has recently instituted inquiries among a large number of trade societies and workmen's clubs with a view to ascertaining the opinion of working men themselves upon the apprenticeship system. From the standpoint of the advocates of technical education, the results of their enquiry are very satisfactory. A unanimous affirmative was given by all the trades to the questions—Is your Society of opinion that instruction for a number of years in the workshop is essential to the trained mechanic? But especially valuable and significant is the emphatic "No" to the question—Is your Society of opinion that the instruction afforded in the technical schools is sufficient training for a skilled mechanic with apprenticeship? Asked what they think, whether the instruction in technical schools should be given during apprenticeship or before it, the answer was in the large majority of cases "during apprenticeship." Putting side by side with this the remark of Mr. Reynolds, of Manchester, the Chairman of the Directors, and Organising Secretaries for Technical and Secondary Education, at their recent meeting, that the great difficulty the technical schools had to contend with was the want of preparation exhibited by the pupils who present themselves for instruction in the technical schools, it becomes abundantly manifest what policy ought to be pursued by the Technical Instruction Committees throughout the country.

As we recorded in our issue of February 14, 1895, the County Council of Hampshire resolved to devote £6000 of the surplus of the funds available for technical education during the preceding year to general purposes in the county. It would seem that they are not to be deterred from their retrograde policy by the unanimous protests of the various educational papers, for at the quarterly meeting of the Council, held on the 10th inst., a motion was proposed by the Chairman of the Finance Committee—"That the Finance and Technical Education Committees be instructed to meet together and report to the meeting in May 1896, their opinion upon the manner in which the balance remaining after the annual expenditure on technical education has been defrayed, shall be dealt with." It appears that, notwithstanding the transfer of £6000 from the technical education account towards the cost of the county buildings, up to December 31 last, and taking the estimate to the end of March next, there would be a balance of £12,000. Though the Chairman of the Technical Instruction Committee assured the Council there was no prospect of having a large balance to deal with in the future, evidently meaning that the Committee had every need of this money which they were reserving, the motion was put and carried. It would be supposed from an action such as this, that Hampshire is already well supplied with every kind of secondary education; but is it so? At Southampton, which it is true receives *its share* of the whole grant, there are at least two institutions which are in want of assistance. The Hartley Institution, which receives a county grant of only £75 per annum, is badly crippled for want of funds. The Grammar School similarly is greatly in want of help to develop the technical side of its work, and the same condition of things is true in many other of the local centres. In addition to all this, one hears repeatedly of the urgent need of Schools of Forestry in this country, and yet Hampshire, with the New Forest in its midst, has £12,000 for which it has no educational use!

Particulars are tabulated in the *Technical Education Gazette* of the principal scholarships which are awarded in London, giving free education or education at reduced fees—(1) at the public secondary schools; (2) at universities, university colleges, polytechnics, technical institutes, and other places of higher education; (3) at schools of art. The tables are intended to give some idea as to the opportunities that are offered to the inhabitants of London of obtaining education above the elementary grade, either entirely free or at greatly reduced cost. The total number of scholarships tenable at public secondary schools appear to be as follows: Boys—1240 per annum (of which all except 85 may be regarded as actually available for pupils in public elementary schools). Girls—543 per annum (of which all except 8 may be regarded as actually available for pupils in public elementary schools). Total—1783 per annum (of which as many as 1690 are actually available for pupils in public elementary schools). Taking the average number in attendance in public elementary schools (exclusive of infants) as 382,121, it is found that the number of scholarships available per 1000 children in attendance is 4·4, of which 1·5 per 1000 children are provided by the Technical Education Board of the London County Council. The majority of the scholarships tenable at universities, university colleges, polytechnics, and similar institutions, are restricted as regards the school previously attended, but unrestricted so far as residence is concerned, though some are confined to residents within the county of London. No notice is taken of the numerous scholarships and exhibitions offered by university authorities outside London, such as the colleges of Oxford or Cambridge, but an attempt is made to show the facilities for acquiring training of a university type offered to pupils who are educated or who reside in London. The table shows that the scholarships available in London for giving training of a university type are as follows: open to young men only, 240; open to young men or young women, 120; open to young women only, 40; making a total of 400. These scholarships do not include, however, those that are specially awarded by the City Companies.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xviii. No. 1, January, 1896.—"Sur la réduction à sa forme canonique de la structure d'un groupe de transformations fini et continu," by E. Cartan. This memoir occupies 61 pages. We state the most important results in the writer's own words: "On peut toujours par des

opérations *rationnelles* ramener le problème au cas où le groupe est *semi-simple*, et même reconnaître d'avance la *nature* des sous-groupes invariants simples qui *composent* le groupe. . . . Quant à la réduction à sa forme canonique de la structure d'un groupe simple, elle dépend d'une certaine équation algébrique dont le *groupe* de substitutions, au sens de Galois, est connu ; cette équation s'appelle *l'équation caractéristique* du groupe. Les différents groupes de substitutions qui s'introduisent ainsi ne présentent rien d'interessant et se relient immediatement aux groupes symétriques de n lettres. Néanmoins trois d'entre eux offrent un intérêt particulier et sont isomorphes, l'un avec *le groupe des* 27 *droites d'une surface du* 3^e^ *ordre*, l'autre avec *le groupe des* 28 *tangentes doubles d'une courbe du* 4^e^ *ordre*, le dernier avec le 7^e^ *groupe hypoabélien de* 120 *lettres*. Ce n'est pas un des résultats les moins intéressants et les moins inattendus de cette étude, que d'établir une relation entre ces groupes de substitutions de Galois et les groupes de transformations de M. Lie."—Mr. A. L. Baker writes upon algebraic symbols. The symbols considered are $+, -, i(\sqrt{-1})$, and $-i$. The closing sentences will indicate the line of reasoning. "In tri-dimensional domains we have $(\sqrt{-})^{\infty}x = x + iy + jv + ku$, a quaternion. Is this a hint that in the Calculus of Reals, Complex Functions and Quaternions, we have run the gamut of the Algebraic Calculi?" There is some (to us) novel notation in this article. To express the roots of the Solvable Quantics as symmetrical functions of homologues, is the title of an interesting algebraic article by C. H. Kummell. There is, it may be inferred, some stiff reading in these three articles.—Two short notes on singular solutions by J. M. Page, and on a point of the theory of functions by A. S. Chessin, close the number, which is adorned with a fine portrait of the French mathematician, M. Paul Appell.

Bulletin of the Mathematical Society, vol. ii. No. 4, January.—On the convergence of the series used in the subject of perturbations, by Dr. G. W. Hill. M. Poincaré ("Les Méthodes nouvelles de la Mécanique céleste") has recently insisted that certain series, in this subject, under a certain condition, are, in the rigorous mathematical sense, divergent. Dr. Hill thinks that the reasons brought forward to sustain this opinion are scarcely convincing, and so, without attempting to find a flaw in M. Poincaré's logic, he aims at pointing out a class of cases where the convergency can be shown in spite of the incommensurability of the component arguments.—Mr. R. A. Roberts contributes an article on the locus of the foci of conics having double contact with two fixed conics.—Note on the common tangents of two similar cycloidal curves, by Prof. F. Morley. This is the application of a new method, given by the writer in vols. xv. and xvi. of the *American Journal of Mathematics*, to a question proposed by Prof. Aiyar, in the *Educational Times* for November 1895.—The list of new publications is an extended one, and the notes, as usual, are of interest. There is, however, an error in the quotation from our pages. On p. 651 (vol. lii.) is given a list of names proposed for the Council of the London Mathematical Society, and at the end of the note it is stated that Mr. Jenkins and the late G. C. De Morgan were elected joint secretaries (in January 1866). The *Bulletin* says, "the late Prof. De Morgan." It is a matter of common knowledge that Prof. *Augustus* De Morgan was the first President. The Secretary was his son.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 23.—"An Attempt to Determine the Condition in which Helium and the Associated Gases exist in Minerals." By Prof. W. A. Tilden, F.R.S.

From the results of the experiments recorded in this paper, it seems that helium exists in the minerals in which it is found in a condition comparable with that in which hydrogen is associated with many metals, and carbonic oxide especially with iron. Whether this condition is rightly distinguished from ordinary chemical combination is a question which admits of debate. The stability of all dissociable compounds is influenced by pressure and by temperature in the same kind of way as "occlusion," which, like ordinary chemical combination again, is a phenomenon in which the bodies concerned exercise a power of selection.

The presence of hydrogen as well as carbon dioxide in granite, if already observed, is not known to geologists generally. From observation on variations in the critical point of carbon dioxide in minerals (*Journ. Chem. Soc.*, 1876, ii. 248), Hartley seems to infer that the incondensable gas present with carbon dioxide, is usually nitrogen. A passage in Geikie's "Text-Book of Geology," third edition, p. 110, refers to the presence of hydrogen in cavities ; but no information is given as to the evidence upon which this statement is based. The presence of hydrogen in such a rock as granite must be attributed to the existence of this gas in large proportion in the atmosphere in which the rock was crystallised. Whether this was the primeval atmosphere of the earth before the hydrogen had escaped or had been oxidised into water, or whether it resulted from the local action of water upon unoxidised metals or other materials in the interior of the earth, is a question which may be of some interest to the geologist. If the former hypothesis were adopted, it would perhaps be difficult to explain the absence of helium from the gas included in the rock ; and, on the whole, the latter view appears to afford the more probable explanation.

Experiments show that hydrogen is present in even larger proportion in the granite from the neighbourhood of Dublin, and it is proposed to examine some other examples of the ancient crystalline rocks in order to determine the nature of the gases enclosed in them.

Physical Society, February 14.—Annual General Meeting.—Captain W. de W. Abney, President, in the chair.—The Chairman, after referring to the position of the Society, called upon the Treasurer to read the balance-sheet. After a discussion on the financial status of the Society, in which a number of members took part, the ballot was held for the election of a President and Council for the ensuing year. The following gentlemen were declared duly elected: President—Captain W. de W. Abney, C.B., F.R.S. Vice-Presidents—Shelford Bidwell, F.R.S. ; Major-General E. R. Festing, F.R.S. ; Prof. J. Perry, F.R.S. ; G. Johnstone Stoney, F.R.S. Secretaries—T. H. Blakesley, 3 Eliot Hill, Lewisham, S.E. ; and H. M. Elder, 50 City Road, E.C. Treasurer—Dr. E. Atkinson, Portesbery Hill, Camberley, Surrey. Demonstrator—C. Vernon Boys, F.R.S. Other members of Council—Walter Baily, Dr. C. V. Burton; L. Fletcher, F.R.S.; R. T. Glazebrook, F.R.S. ; Prof. A. Gray, G. Griffith, Prof. G. M. Minchin, F.R.S. ; Prof. W. Ramsay, F.R.S. ; Prof. S. P. Thompson, F.R.S. ; and Prof. S. Young, F.R.S.—The Chairman read an obituary notice of the late Right Hon. T. H. Huxley.—A vote of thanks to the auditors was proposed by Prof. Carey Foster, seconded by Mr. Enright, and carried unanimously. A vote of thanks to the officers was proposed by Prof. A. Gray, seconded by Mr. Rhodes, and carried unanimously. A vote of thanks to the Chemical Society for the use of their rooms, was proposed by the Chairman, and carried by acclamation.—The meeting was then resolved into an ordinary science meeting, and a paper, on the determination of high temperatures by the meldometer, by Prof. Ramsay and Mr. Eumorfopoulos, was read by the latter. The meldometer—an instrument invented by Dr. Joly, of Dublin—consists essentially of a thin platinum strip which can be heated by the passage of an electric current. Small fragments of a solid substance are placed on the platinum strip, and the temperature at which they melt is deduced from the length of the platinum strip, which has been previously calibrated by means of solids of known melting-point. The authors have used gold for the purpose of calibrating the strip, and have assumed Violle's value, 1045° C., for the melting-point of gold. A number of measurements have been made of the melting-point of salts of sodium, lithium, strontium, barium, calcium, and lead. The results obtained, however, differ considerably from those of Heycock and Neville, and the authors have not been able to account for these differences. Prof. Ramsay said the chief advantage of the meldometer was that only a very minute fragment of the substance was required for the measurement, so that extreme purity of the sample could be secured. There was the disadvantage, however, that many substances undergo some change when heated in air. In reply to a question from Mr. Blakesley, Prof. Ramsay said that the property of the platinum which was used to measure the temperature was its expansion. Mr. Campbell asked whether the zero of the instrument was found to be constant. In Cardew voltmeters it often took several hours for the needle to come back to zero after heating. Mr. Eumorfopoulos, in reply, said that the zero was constant to within a quarter of a degree.—Prof. Ramsay also exhibited a small direct-vision spectroscope, in which the eye-piece is moved

in a plane perpendicular to the axis of the instrument by means of a micrometer screw. This form of spectroscope was found to be of great utility in verifying the position of lines in the spectrum.

Geological Society, London, February 5.—Dr. Henry Woodward, F.R.S., President in the chair.—On the Morte Slates and Associated Beds in North Devon and West Somerset.—Part 1, by Dr. Henry Hicks, F.R.S. In a paper read before the Society in 1890 the author stated that he had found the Morte Slates to be fossiliferous, and had come to the conclusion that they were the oldest rocks in the North Devon area and had been thrust over much newer rocks, producing a deceptive appearance of conformity; and that there was not a continuous upward succession in the rocks from the Bristol Channel to the neighbourhood of Barnstaple. Since that paper was read, the author has obtained much additional evidence bearing on the succession, which was described so far as the position and age of the Morte Slates in the Ilfracombe area are concerned.—Evidences of glacial action in Australia in Permo-Carboniferous Time, by Prof. T. W. Edgeworth David. The author, after summarising the work of previous observers, gave an account of recent observations made by himself. In Hallett's Cove, near Adelaide, the pre-Cambrian rocks were strongly glaciated, striæ being seen when the overlying glacial beds are removed, as sharply cut as though caused by recent glacial action, and trending nearly north and south, the ice having come from the south. The overlying glacial beds were in places fairly stratified, while parts contain abundance of well-striated boulders; these beds are from 23 to over 100 feet thick. Proofs were obtained that in this case the glaciation occurred in an age intermediate between Miocene and pre-Cambrian, and probably did not antedate the close of the Palæozoic period. In Wild Duck Creek, near Heathcote, Lower Silurian (Ordovician) beds exhibited strongly-grooved, polished surfaces, the grooves being from S. 5° E. to N. 5° W., the ice having probably come from the south. They were succeeded by Permo-Carboniferous glacial beds, consisting chiefly of mudstones with well-glaciated boulders. At Bacchus Marsh Ordovician beds were also well-striated and polished, and more or less *moutonnés*. There also the ice came from a southerly point. These beds were succeeded by Permo-Carboniferous glacial beds having an approximate thickness of at least 2000 feet, consisting of mudstones with well-glaciated boulders. It was extremely probable that the glacial beds of Bacchus Marsh, Wild Duck Creek, and Springhurst in Victoria were of homotaxial if not contemporaneous origin, and they may probably be correlated with the glacial conglomerates at Mount Reid in Tasmania, these correlations being mainly based on lithological evidence.

CAMBRIDGE.

Philosophical Society, January 27.—Prof. Liveing, Vice-President, in the chair.—On longitudinal vibrations in connection with recent photographic discoveries, by Prof. J. J. Thomson (see p. 379).—On the equilibrium of isotropic elastic solid shells of nearly spherical form, by Dr. Chree. Attention was chiefly devoted to the case of a thin shell exposed to uniform, but different, normal pressures over its two surfaces. The effect of external pressure, it was proved, is to increase, while that of internal pressure is to diminish the original departure from sphericity.—A harmonic analysis of the amount of solar radiation received at the different latitudes on the earth's surface, by Mr. R. Hargreaves. The amount of solar radiation falling on the earth's surface in any latitude is expressed by a harmonic series containing constant, annual, semi-annual terms, and so forth. The dependence of the coefficients on latitude, and also on the astronomical elements obliquity of the ecliptic, eccentricity, and longitude of perihelion, was fully discussed. Numerical results were given in connection with each point, showing the extent to which the present values may be modified by such secular changes as are known to astronomers; and complete numerical data are thus provided for the discussion of the question whether these astronomical changes are a *vera causa* in the explanation of changes of climate.

EDINBURGH.

Royal Society, January 20.—Rev. Prof. Flint in the chair.—Dr. Buchan read a paper on the recent great atmospheric pressure. So far, the highest reading had been that recorded at Ochtertyre, in Perthshire, where 31·107 inches was registered on the 9th. This place, curiously enough, had the "record" for low readings, a pressure of 27·333 inches having been recorded there in January 1884. This was the lowest ever recorded anywhere.—Prof. Crum Brown showed and discussed an experiment illustrating the modern theory of salt solutions.—Dr. A. Lockhart Gillespie gave statistics from the Infirmary records of the past fifty years, illustrating the relations of weather, influenza, and disease. Diseases of the respiratory system were more common during cyclonic weather, and cardiac troubles showed a marked increase after epidemics of influenza. The idea that influenza was more severe than it used to be was not borne out by facts.—Dr. John Murray and Mr. Robert Irvine contributed a paper, replying to criticism, on the chemical changes in marine deposits.—Prof. Tait illustrated the looped, concave-upward path of a rotating spherical projectile by means of a spherical india-rubber balloon.

January 27.—Prof. McKendrick in the chair.—By request of the Council, Mr. Frederick Ives, of Philadelphia, gave an address on the stereo-photochromoscope. The essential features of Mr. Ives' method are as follows. By means of a specially constructed stereoscopic camera, three pairs of negatives are taken at once. Each pair, by a suitable intervention of colour-filters, secures those parts of the object from which one of the Young-Helmholtz three primary colours is reflected. When the six positives are subjected to the synthetic action of the photochromoscope, a coloured, solid-looking, optical illusion is the result. Not the least interesting feature of the process, as was remarked at the meeting, is the light which it throws on the Young-Helmholtz theory of colour vision.

February 3.—Prof. Chrystal in the chair.—Prof. Tait read an obituary notice of Prof. Blackie by the Rev. Dr. Walter Smith.—Dr. W. W. J. Nicoll described experiments he had carried out on the behaviour of the iodine molecule in solution. His method was different from any yet tried, viz. the determination of the molecular volume of the iodine in different solutions, and his results agreed well with those of others approaching the problem from different sides. He found that the value of the iodine molecule in solution was about 85, and this whether it was of the form I_2 or I_4. His conclusion was that the molecules, in the gaseous form, and in dilute solution, were truly comparable.—In Dr. E. H. Barton's absence, Prof. Tait read a paper on the temperature-variation of the magnetic permeability of magnetite. His results, as exhibited graphically, showed that the permeability reached its maximum about 300°, suffered a very sudden decrease about 500°, and remained constant afterwards.—Prof. Tait gave a note on centrobaric shells. Thomson and Tait prove the proposition that a shell, whose density is inversely as the cube of the distance from an internal point, has a true centre of gravity, by considering the forces of attraction. Prof. Tait gave a demonstration of a very much simpler and shorter proof, which had since occurred to him, from the point of view of potential.

PARIS.

Academy of Sciences, February 10.—A study of uranium carbide, by M. H. Moissan.—Action of high frequency currents upon bacterial toxines, by MM. d'Arsonval and Charrin. In these experiments especial care was taken to eliminate, as far as possible, all electrolytic action of a chemical nature. Two different cultures were used (pyocyanic and diphtheric toxines), and in both cases these were found to have their virulence diminished after passage of the high frequency current. It was also noticed that this attenuated virus more or less protected the animals against further injections of the original virus.—On the application of the Röntgen rays to surgical diagnosis, by MM. Lannelongue and Oudin. An application to some diseases of the knee and thigh. The conclusion is drawn that although the application of the new light to surgery has not led to the discovery of any points previously unnoticed, yet it has in all the experiments given results in agreement with the clinical diagnosis.—Microbial associations and tuberculous suppurations, by MM. Lannelongue and Achard. A discussion of the conditions under which other microbes are associated with the tubercle bacillus.—On the structure of Mount Joly, near Saint-Gervais, by MM. Marcel Bertrand and E. Ritter. The view previously held about this mountain, that it had escaped the violent actions to which the neighbouring rocks had been subjected, and that foldings had not taken place, is shown to be untenable. This spot is, in fact, the region where the displacements of the strata have been pushed to the greatest extent.—On campholide, the reduction product from camphoric anhydride, by M. A. Haller. Camphoric anhydride reduced

with sodium amalgam in acid solutions gives the lactone campholide, $C_{10}H_{16}O_2$, not identical with the substance of the same composition obtained by Dr. M. O. Foster (*J. C. S.*, January 1896).—Copernicus and the geographical discoveries of his time, by M. Daubrée.—On the equation of the tides, by M. Maurice d'Ocagne. — On surfaces of lines of spherical curvature, by M. E. Blutel.—On a generalisation of the formula for the area of a spherical triangle, by M. X. Stouff.—Note on the resistance of beams, by M. Paul Toulon.—Method of measuring double refraction in monochromatic light, by M. R. Dongier.—Influence of the chemical nature of substances on their transparency to the Röntgen rays, by M. Maurice Meslans. Compounds of carbon, hydrogen, oxygen, and nitrogen are very nearly transparent for these rays, but the introduction of phosphorus, sulphur, or the halogens (especially iodine) largely increases their opacity.—Application of the method of M. Röntgen, by M. A. Londe. The dark and light parts of a photographic negative are equally transparent to the rays.—Increase of the photographic effect of the Röntgen rays by phosphorescent zinc sulphide, by M. C. Henry. It was found that by coating coins opaque to the rays with phosphorescent sulphide of zinc, photographic impressions of substances beneath the coins could be obtained, metals coated in this manner appearing to lose their opacity to the Röntgen rays.—Photographs obtained by means of the X-rays, by M. C. V. Zenger.—On a mechanical action proceeding from a Crookes' tube, analogous to the photogenic action discovered by Röntgen, by MM. Gossart and Chevallier. In attempting to show the heating effect of a Crookes' tube by means of a radiometer, it was found that the latter, instead of rotating, took up a fixed position under the control of the tube. If the radiometer arms were set in motion by heat, oscillations about this fixed direction ensued, which were the more rapid the smaller the distance between the tube and the radiometer. This force was stopped by the same media as the X-rays.—On the silicide of copper, by M. Vigouroux. Silicon and copper, heated in the electric furnace, give homogeneous products which may contain silicon up to 15 per cent. Prolonged heating at a temperature sufficiently high to drive off excess of copper, leaves the definite compound $SiCu_2$.—On the bromide and chlorobromide of thionyl, by M. A. Besson. Dry HBr, acting on $SOCl_2$ at its boiling-point, gives rise to a mixture from which SOClBr, $SOBr_2$, and S_2Br_2, which can be separated by fractional distillation under reduced pressure. Thionyl bromide is not formed by the action of sulphur dioxide upon phosphorus pentabromide.—On a crystallised sulpho-phosphide of tin, by M. A. Granger. Tin sulphide, acted upon by phosphorus vapour, gives the compound SnP. 2SnS.—Oxyiodides of zinc, by M. Tassily.—Method for determining the purity of butter by means of the density, by M. R. Brullé.—Retineal stroboscopy, by M. Aug. Charpentier.—The expulsion of blood as a means of defence in some Sauterelles, by M. E. Cuénot.—On the frontal expansion of some insects of the family of the Muscides, by M. J. K. d'Herbulais. A criticism of a note on a recent communication on the same subject by M. A. Labboulbène.—On the signification of the fertilisation in the Uredineæ, by M. Sappin-Trouffy.—On the sugars produced in leaves, by M. G. Bonnier. It is shown that in many cases these sweet liquids are directly exuded from the stomata of the leaf, and are not always of animal origin. The rate of production of this vegetable honey is at a maximum during the night.—*Mucor* and *Trichoderma*, by M. J. Ray. Reply to a criticism of M. Paul Vuillemin.—The Hippurite bearing layers in the Valley of the Rhône, by M. H. Douville.—On the existence of numerous Radiolaria in the Ardèche, by M. L. Cayeux.—On the mode of formation of the auriferous minerals of the Witwatersrand in the Transvaal, by M. L. de Launay. The hypothesis of a chemical precipitation of the gold and pyrites during the actual sedimentation is shown to be the most probable.—On a hypothetical mode of formation of the auriferous conglomerates of the Transvaal, by M. E. Cumenge.—On some new and rare forms of calcite at Couzon (Rhône), by M. F. Gonnard.—On the high atmospheric pressures during the month of January 1896, by M. P. Dechevrens.

BERLIN.

Physical Society, January 17.—Prof. du Bois Reymond, President, in the chair.—Dr. Frölich spoke on the protection of physical laboratories from the effects due to electric tram-lines, and described the arrangement used by Siemens and Halske. This consists of two coils of wire-netting at right angles to each other, which being stretched round a wooden frame, and surrounding the instrument it is desired to protect, are put into metallic contact by a cable with the conducting rail of the tram-line. The disturbance due to the passage of a car is thus compensated, and the effect on a magnetised needle is reduced to a small percentage.

January 31.—Prof. du Bois Reymond, President, in the chair.—Dr. Kaufmann gave an elaborate demonstration of Röntgen's X-rays. He also exhibited a very striking photograph of a mouse, which showed in detail the separate vertebræ of the tail, the ribs, and other bones.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Chemistry for Engineers and Manufacturers: B. Blount and A. G. Bloxam, Vol. 1 (Griffin).—A New Natural Theology based upon the Doctrine of Evolution: Rev. J. Morris (Rivington).—Universal Electrical Directory (Alabaster).—Geology: C. L. Barnes (Rivington).—Life and Exploits of Alexander the Great: Dr. E. A. W. Budge (Clay).—Grundriss der Krystallographie für Studirende und zum Selbstunterricht: Dr. G. Linck (Jena, Fischer).—Traité des Matières Colorantes: L. Lefèvre, 2 Vols. (Paris, Masson).—*Electrician* Electrical Trades' Directory and Handbook for 1896 (*Electrician* Company).

PAMPHLETS.—Report of S. P. Langley, Secretary of the Smithsonian Institution, for the Year ending June 30, 1895 (Washington).—Classification Chart of the Commoner British Orders of Flowering Plants: W. P. Winter (Cheltenham).—Über Germinal-Selection eine quelle Bestimmt Gerichteter Variation: A. Weismann (Jena, Fischer).

SERIALS.—Journal of the Franklin Institute, February (Philadelphia).—American Naturalist, February (Philadelphia).—Journal of the Chemical Society, February (Gurney).—The Asclepiad, Vol. 44, Vol. xi. (Longmans).—Proceedings of the Physical Society of London, Vol. 14, Part 2 (Taylor).—Journal of the Institution of Electrical Engineers, No. 119, Vol. xxiv. (Spon).—Internationales Archiv für Ethnographie. Band ix. Heft 1 (Leiden, Brill).—Astrophysical Journal, February (Wesley).—Strand Magazine, February (Newnes).

THURSDAY, FEBRUARY 27, 1896.

THE CATALOGUE OF SCIENTIFIC PAPERS.

Catalogue of Scientific Papers (1874-1883). Compiled by the Royal Society of London. Vol. xi. [Pet—Zyb]. Pp. 902. (London: Clay and Sons, 1896.)

THIS volume marks the completion of the third series of the Royal Society's contribution to the bibliography of science. With it the "Index Auctorum" for the ten years 1874-83 is completed, as originally planned, but in order to make the list of papers as exhaustive as possible, the Society are, as is known, actively preparing a supplementary volume to contain additional titles and references, taken from serials published not only during that decennium, but also of earlier date, which from one cause or another are not included among those at present indexed. When this supplement is issued, as we hope it may be within the next two or three years, we shall be in possession of a practically complete author-index to the whole vast mass of the serial literature of science, back from the year 1883 to the beginning of the nineteenth century.

Such a register, simple and straightforward, but accurately and systematically compiled, must always form an invaluable and indispensable basis on which to elaborate any further schemes of indexing which may attempt to furnish a guide to the contributions to each of the special departments of science. The whole problem, how best to grapple with the task of recording and indexing the ever-increasing mass of scientific literature, is one of the burning questions of the time for all cultivators of science. This problem the Royal Society have been steadily attacking since the middle of the century, when (in 1858) they commenced work upon their great Catalogue.

In our notice of vol. ix., the first of the present series (NATURE, vol. xlv. p. 338, February 1892), we gave a brief summary of the origin and progress of the Royal Society's bibliographical undertaking, and in the same article we referred to the long-canvassed and still unsettled question of a parallel subject-index. To this we will recur further on. Meantime, a short analysis of the contents of the series now completed may furnish some particulars at once instructive and interesting.

The total number of individual papers entered in the 2900 odd pages of these three volumes we estimate to be between 89,000 and 90,000. The number contained in the two volumes for the preceding decennium (1864-73) we make, by a similar estimate, about 70,000. This shows an increase of about 25 per cent., and such may probably be taken as fairly representing the actual amount of increase in scientific activity during the second ten-year period, on the assumption that the two series comprise a like proportion of the total literature of science. The original series, covering the long period 1800-1863, indexed the remarkably high total of 1500 publications. The exact number indexed for the second series (1864-73) is not quite apparent. The number for the present series is 570, a rather unaccountable decrease when compared with the large number just quoted, and undoubtedly too small to furnish a sufficiently exhaustive record of the scientific work of the world. The Society themselves recognise this, and, as we have said, are making provision for the amplification of the Catalogue by indexing some hundreds of additional serials. The greater part of these must doubtless be of minor importance, but there are also a considerable minority of publications of a high order of merit which, as we pointed out in our notice of vol. x. of the Catalogue (NATURE, vol. l. p. 241, July 1894), were unhappily not included in the list the Society originally worked from.

Of those indexed in this third series we count 192 publications bearing English titles, equal to about 33 per cent. of the whole; 116 French, or about 20 per cent.; and 165, or about 29 per cent., German. These numbers may possibly give a fair idea of the actual proportion obtaining between the contributions to the total literature of science as divided among these three languages; but we need not go further, and attempt to draw conclusions from them as to the relative scientific activity of the peoples speaking them.

The proportions in which the various branches of science contribute to the aggregate of serial literature is not very easy to determine. So far as a somewhat rough estimate may suffice, we should say that nearly 40 per cent. of the entries in the list of publications are devoted to general science, about 35 per cent. to biological, and 25 per cent. to physical and mathematical science. The distinction, however, is not always easy, but there seems a decided preponderance of biological over physical literature.

The printing of the three volumes of this series has occupied some six years, and the supplementary volume will, we imagine, not be issued before another two years at least, making a total interval of fifteen years between the date to which the work extends and the date of complete publication. It is easier to deplore these long intervals than to avoid them, especially while one Society endeavours to cope single-handed with the vast and ever-increasing mass of material. In his address at their last anniversary, Lord Kelvin said that "the continuation of such a work was almost beyond the resources of the Royal Society," and referred to the efforts that were being made to secure effectual international co-operation. As a step towards this, the Society have issued invitations to an International Conference to be held in London during the coming summer, at which the whole question of cataloguing and indexing the literature of science may be discussed from an international point of view, and at which it may be hoped the outlines of a scheme may be agreed upon, the details of which could be filled in later on. As a result co-operative work on a comprehensive and well-considered system might be definitively commenced, say, with the turn of the century, starting as from January 1, 1901.

If the same research work is often needlessly done twice or thrice over, it is equally certain the same cataloguing and indexing work is done needlessly many times over when once might have sufficed. To save this waste of time and labour, organised collaboration on a large scale seems the one thing needful, and we see no reason to fear that this cannot be successfully arranged. The desideratum of comprehensive and accurate subject-indexes makes itself more acutely felt with every year

that passes, and one of the questions of method which calls loudest for settlement is what particular plan should be adopted for the preparation of such indexes. The feeling of bibliographers now leans strongly towards the general adoption of the ingenious system of decimal notation devised by Mr. Melvil Dewey, the director of the New York State library—a numerical system of indicating and distinguishing the divisional sections and sub-sections of a classification to any desired degree of subdivision, the number affixed to an entry distinguishing not only the particular ultimate subdivision of the general subject, but at the same time indicating all the superior divisions to which the work in question also belongs. The merits of this principle of notation are independent of those of the elaborate classification of all literature which Mr. Dewey has laboriously prepared for use with it. The latter may be open to criticism, but it must be remembered that no classification is likely to satisfy every one. Some sacrifices are inevitable, and we believe that, even as it stands, Mr. Dewey's classification is a workable scheme adequate for most practical purposes. Indeed, American experience has tested this point for some years now. Accordingly, the International Conference of Bibliography, which met at Brussels last autumn, recommended the entire adoption of Mr. Dewey's system, which has also been approved and adopted, among others, and not to mention its American supporters, by the Association Française, the International Congress of Zoology, the recently-founded Institut International de Bibliographie (Brussels), and our Paris contemporaries, the *Revue Scientifique* and the *Revue Générale des Sciences.*

Other questions which remain to be settled by general agreement are the mode of preparing the material, the extent to which cognisance should be taken of the contents of papers as well as of their titles, the degree of subdivision to which classification should be carried, the terminology, and the language or languages to be employed. These and other associated questions are all ripe for settlement, and it cannot be said that any of them are beyond the reach of general agreement when all are convinced of the urgent need for their practical solution. Meanwhile schemes are formulating and maturing. M. Otlet, of Brussels, and his collaborators of the Institut de Bibliographie have developed and are applying a comprehensive system. The Faculty of Medicine of Harvard University have appointed a special committee to report on the question of a general bibliography of science. The French Ministry of Public Instruction is publishing a "Bibliographie des Travaux Scientifiques publiés par les Sociétés Savantes de la France."

About the last-mentioned work, an undertaking presenting, on a smaller scale, many points of similarity to that of the Royal Society, we may say a word or two. The idea originated with M. Milne-Edwards, and the work is being carried out by Dr. Deniker, the librarian of the Muséum d'Histoire Naturelle. It covers the long period from 1700 to 1888, and is to be divided into three sections. The first section, which is now going through the press, is an enumeration, volume by volume, of all the scientific articles contained in every serial, the serials being taken in alphabetical order of departments, and of the towns in each department, in which the societies are domiciled. The second section is to be the general "Index Auctorum," each title bearing as reference the *numéro d'ordre* prefixed to it in the first section; and the third section is to be the "Index Rerum," each entry again bearing its reference number as before. This plan may be open to criticism, but the bibliography will be a fine piece of work when completed, and, as we said, to some extent parallel to the Royal Society's Catalogue, and indeed duplicating a large fraction of its contents. While admiring the industry and enthusiasm of its compiler, we are bound to feel some degree of regret when skill, labour and time are thus expended upon isolated sporadic and unco-ordinated undertakings, while they might be far more efficiently employed in co-operating upon one well-considered and carefully organised international scheme. This is the direction which future indexing work must inevitably take, and we look forward with impatience to the realisation of this crowning development of the Royal Society's long-sustained labours.

NATURAL SELECTION AND ITS CRITICS.

Nature v. Natural Selection. An Essay on Organic Evolution. By Charles Clement Coe. Pp. 591. (London: Swan Sonnenschein and Co., 1895.)

THE author at the outset of this work tells us he "believes that the process of organic evolution has taken place, but he does not believe that natural selection has been the means by which that result has been brought about." The object of his work is the attempt to support the latter contention. He does not profess to speak as an expert, or to bring forward any new observations, but chiefly occupies himself with the quotation and criticism of isolated passages from previous writers. He evidently feels a very sincere disbelief in the adequacy of natural selection, and regards himself as compelled by some sort of inspiration to communicate this disbelief to the world.

It is evident that the criticisms are intended to be fair, and they are conceived in no unfriendly spirit, and expressed with no want of respect to the great writers on the subject; but the method of minute verbal criticism of single sentences and short passages is one which almost invariably leads to unfairness, however unintentional, and the work before us has certainly not escaped from this very natural tendency.

A few instances, upon all of which comment is superfluous, will sufficiently indicate the competence of the author to deal with his subject, and the spirit in which he approaches it.

In speaking (p. 23) of the two phrases (he unaccountably calls them "two contradictory theories"), "Natural Selection" and "Survival of the Fittest," he says: "It seems almost incredible that a great writer should have rejected the more accurate in favour of the sometimes more convenient phrase." He seems to forget that it was too late to withdraw a phrase which was already world-wide, and, furthermore, that convenience in such matters is of very high importance. As the author inquires why natural selection is more convenient, he may be referred to Darwin's "Life and Letters," in which the subject is

discussed in detail. His own remarks on this point afford a clear example of the means by which the unnecessary size of the volume has been attained.

In Book i., Chapter v., numerous examples of co-operation in nature are quoted from various writers, and it seems to the author "to be quite impossible to harmonise the demands of the theory of natural selection . . . with the co-operation which is constantly found in nature."

In attempting to account for the extermination of the black rat by the brown, on other grounds than those of natural selection pure and simple, we meet with the suggestion (pp. 107, 108) that the proportion of brown females was increased in consequence of the proteid diet of black rats!

Upon the destruction of the watercress in the New Zealand streams by means of the willow, he remarks—"There is no abstract survival of the fittest: both are equally fit apart from one another."

The work is divided into three books, each of which contains seven chapters. The first book discusses the possibility, the third the evidences of natural selection, while the second compares it with other attempts to explain evolution.

It would have been far better if the author could have found "peace"—to use his own phraseology—by performing a task of less herculean proportions. In these days of hurry and hard work the world will find it difficult, if not impossible, to absorb a message which requires 591 pages to deliver.

E. B. P.

OUR BOOK SHELF.

Minerals, and how to Study them: a Book for Beginners in Mineralogy. By Edward Salisbury Dana. 8vo, 380 pp.; 319 figs. (New York: Wiley and Sons. London: Chapman and Hall, 1895.)

A GLANCE at this volume is sufficient to show that we have here a book of the sort which is wanted for quite elementary students. A sentence chosen at random from the introductory chapter will indicate at once how it differs from the ordinary text-books, both in style and method. Speaking of the trial of hardness, the author says: "It is necessary to be sure and distinguish between a real scratch on a smooth surface and the crushing of a rough surface by the knife-edge; a very hard mineral may often be scratched in this way. The danger of making a mistake of this kind is made less if, besides the useful knife-point, the mineral be rubbed on a piece of glass; better have a piece at hand (not disfigure a window-pane). Only do not make the opposite mistake and call a white ridge left by a soft mineral on the glass, which can be easily rubbed off, a scratch." Here is a real attempt to guide the beginner through the pitfalls which beset an unwary student; how different from the usual bald statement of facts, in which the possibility of any difficulty which may occur is not even mentioned. The same is true of the excellent chapter on blowpipe-testing; thus: "Another trial may be made with sphalerite or zinc blende, but to succeed now the mineral should be pulverised first, since it is infusible before the blowpipe, and the compound is only with difficulty decomposed on charcoal," &c.

It is of course difficult to maintain this style of writing when the author comes to the description of the various mineral species, but in that portion of the book also he has contrived to present the facts in attractive language and make them interesting to an elementary student, and he is content to describe only the most important minerals; the smaller text-books at present available, excellent though they may be in other respects, are usually condensed epitomes of the larger treatises; they contain too much, and are not written in simple language calculated to engage the attention of beginners.

The book closes with an excellent chapter on the determination of minerals, full of useful and suggestive hints.

As might be expected from the author, or joint-author, of the best and most exhaustive treatise on minerals which exists, Prof. Dana's book, though elementary, maintains throughout a high standard of scientific method.

From the educational point of view, we note some striking defects due to the use of language which, though picturesque, may be misunderstood by a beginner. For example, the statement that "the reflecting goniometer demands polished faces if good results are to be obtained," will inevitably suggest the need of artificial polish to the student who takes all things literally; a similar misunderstanding will be produced by the description of Chalcotrichite as a variety of Cuprite, in which "the cubes are spun out into long threads."

The illustrations are mostly new, and among them are many good pictures of typical minerals; it is only unfortunate that the figures of the simple forms and combinations in the third chapter are so shaded that the faces appear concave. These defects can be easily corrected in a second edition, and do not detract from the merits of the book as a really useful and attractive introduction to mineralogy, which can be safely recommended to beginners.

H. A. M.

Heating and Ventilating Buildings. By Rolla C. Carpenter, Professor of Experimental Engineering, Cornell University. Pp. 400. (New York: John Wiley and Sons. London: Chapman and Hall, Limited, 1895.)

THE subject of heating and ventilating buildings has of late years been more and more considered by engineers in this country. In the United States, on the other hand, the question has received satisfactory treatment, and we have therefore much to learn from the systems in vogue there. The object of this volume is to present to the reader a general idea of the principles which apply, and of the methods of construction usually adopted in various systems of heating and ventilating. The author deals with the subject in a clear and concise manner, the information given being the result of extensive practice in designing and operating heating apparatus. Taken as a whole, the volume is of much value; it is well printed and nicely bound.

The author divides the matter into sixteen chapters, commencing with a description of the "nature and properties of heat"; he very fully enumerates the many laws pertaining thereto. On the general principles of ventilation we find much useful information. Some experiments made by Mr. Warren R. Briggs, of Bridgeport, Conn., on the subject of the proper method of introducing pure air into rooms, and the best location for the inlet and outlet, are described. The illustrations showing graphically the results are highly interesting, the best being obtained by placing the air inlet on the side of the room near the top, and the outlet in the bottom and near the centre of the room. The outlet, of course, must be connected with a flue of ample size, and maintained at a temperature higher than that of the surrounding air. Many authorities are quoted, and extracts from technical papers are given. The loss of heat through walls of various thicknesses is pointed out, and Mr. Alfred R. Wolff's lecture before the Franklin

Institute on this subject is referred to. As the majority of systems make use of heat supplied by radiating surfaces, the author, in chapter iv., very fully explains what is meant by the various terms, and then proceeds to describe the methods of testing radiators at Sibley College to measure the heat discharged. The results obtained are brought together in a table; further tests being given from radiators with extended surface so as to form air-flues.

The remaining portion of the book deals with the practical details and metallic parts of design, and architectural considerations. Much sensible advice is imparted as to the care of steam-heating boilers, and how to avoid boiler explosions, of which statistics are given. We notice many useful rules and formulæ for various purposes when designing a hot-water or steam-heating system. The volume lifts the subject out of the hands of the "plumber," and leaves it in the hands of the "engineer." Prof. Carpenter is to be congratulated on producing a really good book on a subject seldom treated scientifically.

Lessons in Elementary Botany for Secondary Schools. By Thomas H. Macbride. Pp. 233. (Boston: Allyn and Bacon, 1896.)

IN his far-reaching essay on "Education," Mr. Herbert Spencer remarks: "In education the process of self-development should be encouraged to the uttermost. Children should be led to make their own investigations, and to draw their own inferences. They should be *told* as little as possible, and induced to *discover* as much as possible." It is satisfactory to all who are concerned in the progress of science, to know that these sound principles of scientific instruction are being brought more within the region of practical education every day. The present volume is an addition to the steadily growing literature in which the principles referred to are applied. The young students, for whom the book is intended, are led to make their own observations; they are induced to study plants, rather than printed books, and thus to derive their knowledge at first hand from nature. The opening lesson in the book is typical of the fifty-three which follow it. The pupils are told to collect the twigs of various trees or shrubs and to compare them, noting various peculiarities. A single twig is then examined, and attention is directed to the arrangement of the buds and leaf-scars upon it. In the second lesson, twigs are compared with particular reference to buds and their relations to branches, and are grouped according to bud-arrangement. The structure of stems afterwards forms the subject of several lessons, and then the root, leaf, flower, fruit and seed are studied in succession, after which come lessons having for their object the elucidation of the structure and history of individual plants and trees. Much more attention is given to trees than is usual in books on botany. The book is hardly suitable for class use on this side of the Atlantic, but an English edition of it would be welcomed by many teachers of botany.

Vegetable Culture. By Alexander Dean, F.R.H.S. Pp. 136. (London: Macmillan and Co., 1896.)

METHODS and results are what amateur gardeners, cottagers, and allotment-holders want, and this is the book to supply their need in regard to the culture of vegetables. Theirs not the ambition to ask the reason why, but merely to know exactly what to do in order to reap rich fruits of their industry. Very admirably does the author impart this kind of information. In concise language he describes the best methods to be followed in the preparation and after-treatment of the soil, the best varieties of the various classes of vegetables, and the best systems of cultivation. Both the text and the illustrations are instructive, and together they make up a sound and serviceable primer for gardeners.

The Röntgen Rays.

IT may interest your readers to hear that, with the assistance of Mr. J. C. M. Stanton, I have succeeded by means of the Röntgen rays in actually seeing the coins inside a leather purse, the metal instruments inside a closed wood and leather case, a coin through a piece of wood half an inch in thickness, and also through a sheet of aluminium.

Photography was not employed, but the shadows of the enclosed objects were made directly visible to the eye by means of a fluorescent screen.

The precise arrangement was similar to that recently described by Prof. Salvioni, of Perugia, whose results, though in accordance with certain experiments of Prof. Röntgen, confirmed, I understand, by Mr. Porter, of University College, have so far been received in this country with a certain amount of scepticism.

The apparatus consisted of a tube of opaque paste-board with a simple aperture at one end, to which the eye was applied. The other end was provided with an opaque diaphragm of double black paper, upon which, on the inner side, was laid a piece of blotting-paper impregnated with platino-cyanide of barium in a crystalline state.

The purse or other object was held against the diaphragm with the Crookes' tube beyond it, so that the rays from the latter cast a shadow of the coins through the leather and black paper upon the inner impregnated screen. The platino-cyanide fluoresced brightly under the stimulus of the rays on those portions of the blotting-paper where no shadow was cast, and consequently the form of the metallic objects was made clearly visible. Non-metallic objects were also clearly seen, though more faintly, owing to their greater transparency to the rays.

Besides being exceedingly interesting in itself, and possibly capable of sufficient improvement to render it of service in medicine and surgery, the appliance will be very useful for the purpose of ascertaining, without the tedious process of exposing and developing a plate, whether any given Crookes' tube is suitable as regards exhaustion and form for photographic purposes.

It can be seen at once whether the tube is working to the best advantage, and is giving clearly defined shadows.

The place on the glass of the tube from which the maximum radiation is proceeding, can also be easily determined, and I may mention as confirming a point previously noticed by myself—*i.e.* that a tube with a well-marked fatigue spot on the glass will not answer satisfactorily for photography—that with the above-described instrument the fatigue spot is visible to the eye through the black paper, thus showing that the glass when fatigued does not transmit the Röntgen rays. A. A. C. SWINTON.

66 Victoria-street, Westminster, February 25.

P.S.—Since writing the above, I have been able to see distinctly the bones in the thick portion of my own hand.

AS the hand appears to feel a cold sensation when exposed to the X-rays, an experiment was made with the thermopile to put the matter to the test. This showed that heat was being radiated from the phosphorescent patch in the Crookes' tube; if the current be reversed so as to make the opposite pole the anode, then heat was again radiated, but in a very much smaller amount. The phosphorescent patch becomes very markedly warmed in some tubes. On replacing the thermopile by a lighted candle, the flame exhibited a flickering motion, and was slightly drawn towards the phosphorescent patch; this could be observed at a distance of six inches. The phenomenon was also observed when the candle was placed on the side of the tube opposite the anode, but less markedly. A flame is almost transparent to the X-rays; on taking a shadowgraph of a lighted candle or gas jet, the shadow of the flame is just visible as an exceedingly faint impression, the internal core in the case of the gas flame being slightly more marked than the external.

Edinburgh. DAWSON TURNER.

The Cause of an Ice Age.

THOUGH I have no wish to prolong this discussion, yet I will ask you to spare me space for a few lines.

In his last letter, Sir Henry Howorth expresses his belief that, as a consequence of the recent correspondence, I have been led to change the opinions I previously held as to the cause of an Ice Age. May I assure Sir Henry Howorth that he must have quite mistaken the purport of my letter.

With all due courtesy to Sir Henry Howorth, as well as to any others who may have differed from me, I may say that I have seen no reason to swerve from the belief that the position taken in my book on "The Cause of an Ice Age" is the sound position. My opinions are, therefore, unchanged.

I would like to take this opportunity to thank Dr. A. R. Wallace for his letter on this subject in your columns, and to express the satisfaction with which I found that he had been led to the same conclusion, with respect to Mr. Culverwell's argument, as that at which I had myself arrived by an independent method. I note that Mr. Culverwell dissents: but, even at the risk of being thought very obstinate, I must say that I still believe Dr. Wallace and I are right. ROBERT S. BALL.

So far as I know, it has not been suggested that a comparatively small elevation of the crust of the earth would cause a glacial state in the elevated part. The roughness of an ordinary terrestrial globe, representing an elevation that might be compared with the thickness of letter-paper, would correspond with an elevation of the crust of the earth that even in the tropics would cause perpetual snow. A few thousand years would be sufficient to cause a sufficient elevation without any catastrophic hypothesis. THEODORE RYLAND.

The Measurement of High Temperatures.

IN a valuable paper on the "Determination of High Temperatures" (*Wied. Ann.* 1895, No. 10), Messrs. Holborn and Wien give the results of their observations on the changes in the resistance of platinum wire over a range of 0° to 1600° C. The authors come to the conclusion that the relation between temperature and resistance "cannot be accurately represented by the Callendar and Griffiths formula"; although, on the other hand, they admit that by means of that formula Heycock and Neville have determined a number of melting points which are in good agreement ("die sich in guter Uebereinstimmung mit unsern Werthen befinden") with the values found by Holborn and Wien when using a thermo-couple standardised by direct comparison with the air-thermometer.

Platinum thermometers are now so generally used for high temperature measurements that an adverse conclusion of this kind is a matter of importance, especially when associated with the names of accurate observers such as Holborn and Wien.

I trust, therefore, that a brief criticism will not be regarded as out of place.

I would first remark that my delay in commenting on this paper is not due to any want of respect for the authors, but from a sense of the importance of the matter. Before attempting any reply, I wished to ascertain the views of Prof. Callendar, and I accordingly wrote to Montreal calling his attention to the paper, but I have not as yet received his answer. I feel, however, that further delay is undesirable.

Neither Prof. Callendar nor I have at any time claimed that the relation between t and pt, as given by the empirical formula, has been *rigorously* verified at temperatures exceeding 600° C.

In NATURE, November 1895, p. 40, I wrote as follows:— "Results of this kind prove that even if the reduction does not express the temperature accurately in the air-scale, it at all events gives us a *constant* scale in which all high temperatures can be expressed, and it is further evident that this constant scale differs but little (even at these high temperatures) from the true air-scale."

The context shows that the "high temperatures" referred to were those in the neighbourhood of 1100° C.

The above quotation defines my own position with sufficient accuracy, and I will therefore pass on to consider the work of Messrs. Holborn and Wien.

(1). The authors state that the platinum wires (in experiments up to 1200° C.) were placed in an externally glazed porcelain tube, and isolated from each other by means of special porcelain capillaries ("die Drähte wurden durch besondere Porzellan Capillaren von einander isolirt"); and at higher temperatures "in externally glazed tubes of a very infusible substance, and isolated from each other by capillaries of the same material."

From this description it appears evident that the wire was in contact with the porcelain, or the other material, probably throughout the greater portion of its length; otherwise it must have been subjected to some strain. Now, contact with porcelain or any similar substance has been found by us to be absolutely fatal: if by any chance the wire has come into contact with the walls of the surrounding tube at high temperatures, the coil has had to be replaced by a new one. This is probably caused by the action of the silica: but whatever the reason may be, the effect has long been known, and care has been taken to avoid this source of error.

It is true that in the present form of the platinum thermometer the wire comes into contact with mica, and I have little doubt that some similar action (although in a lesser degree) takes place between the platinum and the mica. The method of constructing the framework and coil, however, causes the length of platinum in actual contact with the mica to be but an exceedingly small fraction of the length of the wire (probably less than $\frac{1}{100}$th), and thus any such effect is diminished. I think it possible that the small changes at high temperatures to which I have called attention in NATURE, (November 1895, p. 40), are in some measure due to action at the points of contact.

Unless Holborn and Wien took greater precautions in regard to this matter of contact between case and wire than they indicate in their paper, there is no need to seek for further explanation of the somewhat erratic behaviour of the two platinum wires examined by them; in fact, other experiments by the same observers show how materially the resistance of platinum is affected by exposure to the action of silica or hydrogen.

(2). No adverse conclusion should be drawn from the changes in their Wire No. I., for the authors state that "at the termination of the observations the protecting tube was found to have broken in the oven, and the wire had been exposed to the gases of the oven."

The necessity of complete protection from the furnace gases has from the first been insisted upon by those accustomed to the use of platinum thermometers. It was want of attention to this essential matter which led the B. A. Committee of 1874 to a false conclusion. The behaviour of Holborn and Wien's Wire I. has no significance or value, except in so far as it emphasises the importance of complete protection. It appears doubtful if sufficient precautions were taken in this matter with regard to their series of experiments with the platinum Wire II. The infusible tubes which they used for the air-thermometer bulbs at high temperatures were covered externally with a glaze. The authors say: "As the glaze in this case and also in the porcelain becomes liquid much sooner than the softening point of the material, we made use of our method by which there must always be a smaller pressure inside the vessel than outside. Under these conditions the glaze is pressed into the pores of the tubes, otherwise it would immediately come off."

Now I do not find any mention of a similar precaution when heating the platinum wire in what appear to have been similar tubes; it is possible, therefore, that the changes observed in Wire II. were also in some degree due to contamination by furnace gases.

(3). The authors speak of Wire II. as formed from "pure platinum" ("*Aus reinem Platin*"). They give the value of its temperature coefficient as—

Before heating	·003801
After ,, ...	·003783

As a general rule, the purer the platinum the higher its coefficient. The samples used by us (as, for example, in the Kew Observatory thermometers) have coefficients which vary from ·003860 to ·003880. It would hardly appear, therefore, that the wire used by Holborn and Wien merits the term "pure." The purity is, however, not of great consequence, as (see NATURE, November 1895, p. 40) we have found that although the coefficient depends on the purity, the deduced temperatures are unaffected provided that the coefficient is not reduced by the impurities to lower than about ·0032. The fall in the coefficient (above indicated) is, however, of great significance, and in itself is evidence that the wire had become contaminated during the experiments. Assuming (as was doubtless the case) that the wire had been previously annealed, the above change sufficiently establishes inadequate protection of the wire.

I have carefully investigated the numbers in Table II., where the authors give the results of their observations on this second specimen of "pure platinum." I am unable to draw any con-

clusion from the figures there given, except that this wire, either from its quality or its situation, behaved in a different manner from any one of the many specimens I have examined during the past five years. The value of $\delta R/\delta t$ decreases with increase of temperature in a most phenomenal manner.[1] In cases in which I have observed this phenomenon in a lesser degree it has indicated a breaking down in the insulation, consequent on rise in temperature. I am unable to find any evidence that the insulation was tested at high temperature during these experiments.

(4). Any expression of opinion by Messrs. Holborn and Wien necessarily carries weight; nevertheless, I would venture to suggest that (considering the amount of experimental work previously performed by those who advocate the methods of platinum thermometry) the examination of only two wires, one of which was admittedly exposed to the action of furnace gases, affords insufficient grounds for the adverse conclusions arrived at by the authors.

(5). Heycock and Neville's determinations of the freezing points of copper, gold, and silver are admitted by Holborn and Wien to be in "good agreement" with their own. The nature of this agreement is shown in the following table.

	Heycock and Neville.	Holborn and Wien.
Copper	1080·5	1082
Gold	1061·7	1072
Silver	960·7	971

It is worthy of notice that copper is the only metal of which Holborn and Wien used large quantities, comparable with the masses experimented on by Heycock and Neville. Also in this case Holborn and Wein determined both melting and freezing points. Their results (using practically the same thermometer throughout) range from 1076° to 1093°, whereas Heycock and Neville's values, when using six distinct platinum coils possessing very dissimilar constants, range from 1079°·0 to 1081°·7, a very different order of agreement.

In the case of gold and silver, Holborn and Wien used small quantities, determining their results by observations of the *melting* points, and thus the method of experiment adopted renders it probable that the temperatures observed would err on the side of excess. The close agreement in the case of copper, and the higher values found by Holborn and Wien in the experiments on gold and silver, are therefore significant.

Thus, when the conditions are similar (as in the case of copper), we may regard the results obtained by the different observers as practically identical. Such agreement would be impossible if platinum resistance thermometers ordinarily underwent, at high temperatures, changes of the nature of those observed in the wires studied by Holborn and Wien. The differences would then be measurable not by units, but by tens and hundreds! and these discrepancies would be found not only when different methods were used, but also when the same observations were repeated with different platinum thermometers.

If Tables XI., XII., and XIII. of Heycock and Neville's paper[2] are examined, it will be found that although in each case from 6 to 8 different platinum thermometers were used in which, for example, the value of δ varied from 1·495 to 2·04, the extreme resulting temperatures differ by a smaller quantity than the differences obtained by Holborn and Wien when repeating an observation without change in the conditions, by means of the same thermo-couple.

Finally, I assert that Holborn and Wien have produced no evidence sufficient to support the somewhat sweeping conclusions given by them on p. 394 of their paper. I have shown that in their experiments on only two samples of wire, they have neglected the precautions insisted upon by those who have devoted years of study and experiment to the investigation of the platinum thermometer, and this portion of their work is only useful in so far as it emphasises the validity of the conclusions arrived at by those who preceded them.

I fully appreciate the great value of Holborn and Wien's direct determinations of high temperatures by means of the thermo-couple and the air thermometer, and I admit it is probable that for temperatures exceeding 1400° C. or so, the thermo-couple is the more convenient, and possibly the more accurate instrument. Below such temperatures, however, I consider that the weight of evidence is in favour of the accuracy of the platinum thermometer. In any case, such evidence is in no way weakened by the experiments of Holborn and Wien.

E. H. GRIFFITHS.

[1] This extraordinary behaviour of Holborn and Wien's Sample II. (for reasons previously given the behaviour of Sample I. is of no significance) is noticeable in the numbers attained by them at *low*, as well as at high, temperatures.

Earth Tremors.

IN Prof. Milne's article in NATURE of December 26, he states that earth tremors are more frequent during the winter than during the summer, that they are frequent with a low barometer, and still more frequent when the locality of observation is crossed by steep barometrical gradients. In the North-West Himalayas, throughout the winter months, slight earth tremors are exceedingly frequent, and occur, so far as can be judged without instrumental records, more frequently by night than by day. This may be in part due to the fact that during the day most people would be moving about in downstairs rooms, while at night the same people would be in upstairs rooms, and both they and their surroundings perfectly quiet; but, whatever may be the day and night relation, there can be no doubt that during the winter months in Simla peculiar little earth tremors are remarkably frequent. My experience has been that these tremors are not so much connected with areas of low barometer as with the *commencement* of a sudden and large change in atmospheric pressure from a high to a low, a reduction of pressure which need not necessarily be accompanied with steep barometric gradients or high winds at or near the earth's surface. In the case of earthquakes, also, I have noticed subsequent large changes in atmospheric pressure. Thus at about midnight on January 15-16, 1896, a (for these regions) rather severe earthquake occurred, which lasted from 1m. 20s. to 4m. in different localities. On the plains the most severe shocks were felt at midnight, 15th, at Simla, at 0h. 30s. a.m. on the 16th, and at Srinagar at 1 a.m. on the 16th. Times for other places in the Punjab were published in the newspapers, but I have omitted to keep them. The above, however, show that the shock was felt at Lahore at midnight, at Simla half an hour later, and at Srinagar an hour later. The barometric records show that for the forty-eight hours from 8 a.m. on the 16th to 8 a.m. on the 18th, pressure changed as follows:—

	"
Srinagar (Kashmir)	−0·187
Astor ,,	−0·062
Murree	−0·165
Lahore	−0·144
Simla	−0·140
Quetta	+0·022

From the above figures, it appears that a considerable decrease of barometric pressure occurred between the morning of the 16th and the morning of the 18th, and that this fall was central over Srinagar; while the times of occurrence of the earthquake show that the movement of terrestrial disturbance was directed towards this central area of diminishing pressure. It has always appeared that the atmospheric changes which ordinarily occur in tropical and subtropical countries would be a wholly inadequate cause to account for the considerable earthquakes which at times occur; but I have undoubtedly noticed that very slight earth tremors constantly take place when a sudden and large decrease in atmospheric pressure *commences* after a considerable period of high pressure.

W. L. DALLAS.

Simla, January 29.

"Roches moutonnées."

SOME ten years ago, I came across in an old memoir a rational explanation of the term *roches moutonnées*; but I made no note at the time, and have been unable to trace the reference. However, my scepticism was fortified, and I proceeded to search French dictionaries, which made it clear that *moutonné* meant "frizzled like sheep's wool," and not "sheep-like." Yet M de Lapparent tells us ("Traité de Géologie," 3me ed., p. 281) that these glaciated rocks "produisent une impression analogue à celle d'un troupeau de moutons endormis, d'où le nom de *roches moutonnées*"; and who shall question this precise statement of a French author interpreting his own language? It is the explanation that has been taught to all of us, though I know of only one field-geologist who seriously maintains that *roches moutonnées* might be taken for a flock of sheep. Agassiz states

that De Saussure is the author of the term; but I have long been foiled by its omission from the index of the famous "Voyages dans les Alpes." In "Open-Air Studies," however, I ventured to compare the mammillations of a glaciated surface to those upon an antique wig; but all the time, it seems, Mr. Whymper held the key of the matter for us, in a passage which has escaped the memory even of Prof. Bonney (see "Ice-Work," 1896, p. 10). Mr. Whymper, in fact ("Scrambles amongst the Alps," fourth edition, 1893, p. 133), supplies the reference to De Saussure; and in the "Voyages dans les Alpes," 1804, tome ii. p. 435, par. 1061, we may read of what are styled in the margin "montagnes moutonnées." De Saussure states that behind Envionne (the modern Envionnaz), in the upper valley of the Rhône, "ces rondeurs contiguës et répetées forment en grand l'effet d'une toison bien fournie, ou de ces perruques que l'on nomme aussi *moutonnées*." In face of this, there is no longer any need to tax the credulity of our pupils with a fanciful explanation, which we seem to have forced even upon French-speaking peoples.

Royal College of Science for Ireland,
Dublin, February 17.

The Age of the Present Canadian Flora.

PROF. D. P. PENHALLOW has recently identified some fragments of wood found in the Leda clays of Montreal, as *Picea nigra*, the common black spruce. This is another addition to the group of plants which represent our present knowledge of the flora of Canada in Pleistocene times. This Pleistocene flora may now be taken to include not merely the plants found in these Leda clays and in the clays believed to be equivalent to them in age in Ontario, but also the ancestors of the present inland maritime flora found on the shores of the Great Lakes, hundreds of miles from the sea-coast, and of the plants which are common to Europe and America, and which include so many arctic and sub-arctic, as well as northern temperate species. The inland maritime plants, and probably also the sub-arctic species now found so far south as the headlands of Lake Superior, made their way to their present localities during the deposit of the Leda clays when a considerable part of Eastern Canada was submerged. Six of the species which occur in the Leda clays at Ottawa and Montreal, and thirteen of the inland maritime plants, as well as several of the Lake Superior sub-arctic species, are also European, showing that at that period the intermingling of the American and European floras was well established, but leaving open the possibility of these plants common to the two continents being even older than the period of the Leda clays.

The intermingling of the Asiatic and American floras appears to have taken place at a still earlier period. The oldest known representatives of the existing Canadian flora are those few identical species found by Mr. Lester F. Ward in the Laramie rocks of the Western United States—rocks which Sir William Dawson refers to the Lower Eocene. Two of those identified now occur in both Japan and Canada; and one, still living in Japan, has, if correctly identified, become extinct on the American continent. Again, among the Leda clay and inland maritime plants there are several species which are likewise common to the two countries. The intermingling of Asiatic and American plants evidently took place prior to the upheaval of the Rocky Mountain chain, as the extensive flora peculiar to British Columbia, Oregon, and southward, is almost without a representative in Japan. This British Columbia flora, so well represented by various species of Claytonia, Lupinus, Trifolium, Astragalus, Saxifraga, &c., as well as Coniferæ, is of more recent birth—probably Later Tertiary and Post-Tertiary.

The most recent creations in Canada would appear to be the plants which—well represented by Compositæ, an order of no great antiquity—are now so marked a feature of the prairies of Manitoba and the surrounding country—prairies which in some places are still in process of formation.

A. T. DRUMMOND.

Children's Drawings.

WITH regard to young children drawing upside down, I have for some time past collected observations. It is certainly true, that a great many children do draw in this way; on the other hand, many from the first draw the right way up. I have seen a boy of four, when asked to draw a rook on a haystack, begin at the bottom of the paper with the rook's back, and gradually work his way up to the haystack; he then turned it round, and handed it to me to look at, evidently realising that it was inverted.

I do not think the explanation depends in any way on the inversion of the retinal image. If a child, who draws upside down when drawing on a horizontal table, is asked to draw on a blackboard placed vertically, he will draw everything the right way upwards. It seems to me, that the explanation simply is that the child has to draw an object, which he has seen in a vertical plane, on paper placed in a horizontal plane—an extremely difficult task to him—and it is a mere question of convenience to him at which end he begins, both being equally wrong from his point of view. This will also explain why children sometimes look at picture-books upside down, and also why small children are much more ready to draw objects, which they have been accustomed to see in a horizontal plane, such as a plate with oranges on it, than an erect object.

The Old Palace, Richmond. RINA SCOTT.

THE RÖNTGEN RAYS.

THE discovery by Prof. Röntgen of the rays which bear his name has aroused an interest perhaps unparalleled in the history of physical science. Reports of experiments on these rays come daily from laboratories in almost every part of the civilised world. A large part of these relate to the methods of producing Röntgen photographs, and the application of the "new photography" to medical and other purposes. A considerable amount of work has, however, been done on the physical properties of these rays; this has entirely confirmed the results stated by Röntgen in the paper in which he announced his discovery. The freedom of refraction of these waves, in which they are different from ordinary light, has been the subject of direct experiments made by M. Perrin and by Dr. Joly, while Dr. Lodge and others have confirmed the absence of any deflection in the magnetic field which differentiates these rays from the ordinary kathode rays.

Up to the present, however, no phenomena have been observed which enable us to say whether these waves are or are not transverse vibrations of very small wave-length, longitudinal vibrations, or even vibrations at all. Nothing of the nature of polarisation or of interference has been described. The absence of polarisation can at the present stage of the investigation hardly be pressed as an argument against these rays being transverse vibrations. For, of the three methods of producing polarisation in light —reflection, refraction, and absorption—only the latter is available for these rays. Now the number of substances which produce sensible polarisation in ordinary light by absorption is very small, and unless a much larger number possess this property for the Röntgen rays, it is hardly likely that, even if there are such substances, they would have been discovered in the three months which have elapsed since the publication of Röntgen's discovery. I may remark that I have made a large number of experiments on the opacity to these rays of plates of tourmaline (1) with their axes crossed, (2) with their axes parallel, testing the intensity of the rays which came through in some cases by their action on a photographic plate, in others by the discharge they produced in an electrified plate on which they were incident. The result of these experiments was entirely negative, for although the tourmaline plates produced very considerable absorption of the rays, no difference was detected between the absorption when the axes were crossed and when they were parallel. It is very desirable that a large number of substances should be tested in this way.

M. C. Henri has made the very interesting observation that an opaque coin coated with the phosphorescent sulphide of zinc will allow these rays to pass through it; the details of this experiment will be received with much

interest. I have found that when the Röntgen rays pass through any substance, they make it for the time being a conductor of electricity, even although the substance is in its normal state a perfect insulator. Thus solid paraffin, paraffin oil, solid sulphur, ebonite, mica, air—all conduct electricity when the Röntgen rays pass through them. This explains the fact observed by Righi, Bergman, and myself, that an electrified plate in air loses its charge when exposed to these rays, whether it be electrified positively or negatively. The air is converted into a conductor by these rays, and the charge escapes through it. It is not necessary that a gas should surround the plate, as I have found that the leakage takes place whatever the medium surrounding the plate may be. That this leakage is due to the condition of the insulator, rather than to that of the plate, is shown by the fact that it occurs when the plane of the electrified discs is parallel to the rays, as well as when it is at right angles to them. The air through which these rays have passed retains traces of conductivity for some little time after the rays have ceased to pass through it; this can be shown by blowing the air, from a place where the rays are plentiful, against a charged disc placed where there are only a few rays; the rate of leak from this disc is much increased by the blast.

With the assistance of Mr. J. A. McClelland, of Trinity College, Cambridge, I have made a large number of measurements of the rate of leak from positively and negatively electrified discs surrounded by air, and have found that the rate of leak in the two cases is almost identical. We have also made a series of measurements of the rate of leak through air at different pressures; the rate of leak is greater at a high pressure than at a low one, and is over a wide range of pressures approximately proportional to the square root of the pressure. The rate of leak is also greater in air than in hydrogen, being at atmospheric pressure about twice as great in air as it is in hydrogen, while the leakage through carbonic acid gas is faster than that through air.

The leakage of electricity through non-conductors is, I think, due to a kind of electrolysis, the molecule of the non-conductor being split up, or nearly split up, by the Röntgen rays, which act the part played by the solvent in ordinary electrolytic solutions. If the air through which the rays are passing is ionised, the number of ions would, according to the well-known law of dissociation, be proportional to the square root of the pressure, provided the amount of ionisation is small. Thus the result we obtained for the rate of leak through air at different pressures, indicates that the rate of leak is proportional to the number of ions.

The view that the air is turned by these rays into an electrolyte, is supported by some experiments made in the Cavendish Laboratory, by Mr. Erskine Murray, on the contact difference of potential between metal plates in air. He finds that when the Röntgen rays are passing through the air in the neighbourhood of the plates, the plates (as far as their potential differences are concerned) behave as if they were connected by an electrolyte.

Mr. C. J. R. Wilson has investigated, in the Cavendish Laboratory, the effects produced by Röntgen rays on the condensation of clouds caused by the expansion of air, and has found that when the rays pass through the vessel in which the cloud is formed, the cloud is very much denser than when the rays are absent, showing that these rays increase the number of nuclei which act as centres of cloud condensation. The ions with their electrical charges would act as such nuclei, so that this, again, is in favour of the view that these rays turn the air into an electrolyte. These experiments seem to show that these rays exert a powerful disintegrating effect on the molecules of substances through which they pass, and suggest that their use may throw light on some questions of molecular structure. It would be interesting, for example, to find the rate of leak through gases which are reputed to be monatomic, such as mercury vapour, argon, and helium. Again, if air and other gases can be made to act as electrolytes, we could use a mercury dropping arrangement, similar to that employed by Ostwald to measure the potential difference between metals and liquid electrolytes, to measure, by means of it, the potential difference between metals and various gases through which the Röntgen rays are passing.

By measuring the rate of leak from a disc charged to a fixed potential, we can compare the efficiency, as producers of Röntgen rays, of different tubes or of the same tube at different periods. The conclusion I have arrived at, by means of such measurements, is that bulbs generally improve for some time after they are sealed off from the pump, and attain a maximum efficiency, after which they begin to deteriorate.

Some measurements of the absorption of Röntgen rays by various thicknesses of metal, have led me to the conclusion that the Röntgen rays are not all of the same kind. The experiments were made by measuring the change of the rate of leak from an electrified disc, produced by changing the number of sheets of tinfoil interposed between the disc and the phosphorescent tube. When a small number of sheets of tinfoil were interposed, the addition of another sheet of tinfoil produced a very considerable diminution in the rate of leak; when, however, the phosphorescent bulb was a very good one, a considerable leakage remained when the number of sheets of tinfoil was considerable, and this "residual leakage" diminished but slowly as the number of sheets of tinfoil was increased. This seems to indicate that while there are some rays which are rapidly absorbed by the tinfoil, there are others which can pass through it with comparative facility. It is only when using one or two of the most efficient bulbs that I have remarked this "residual leakage," but with these bulbs when in their most efficient state it was very marked.

J. J. THOMSON.

THE DEEPEST SOUNDING YET KNOWN.

IN NATURE (vol. lii. p. 550, October 3, 1895), I mentioned that H.M.S. *Penguin*, Commander A. F. Balfour, R.N., had found in the Pacific Ocean deeper water than any yet known in lat. 23·40 S., long. 175·10 W., but had failed to reach the bottom owing to breakage of the wire at 4900 fathoms.

Captain Balfour has been enabled to try again, and I have just received the announcement of his obtaining three satisfactory soundings of over 5000 fathoms.

The deepest trustworthy sounding heretofore known is 4655 fathoms near Japan, obtained by U.S. S. *Tuscarora* in 1874.

The deepest of the *Penguin's* casts is 5155 fathoms, or 500 fathoms (3000 feet) deeper; but it is especially remarkable that the three casts now obtained are not in the same hollow, but are separated by areas of considerably less water, the two extreme soundings being 450 miles apart.

The usual abysmal red clay was brought up by the sounding-tube on two occasions; on the third the wire broke.

Mr. V. Thorpe, surgeon of the *Penguin*, reports that a microscopic examination of the specimen from 5147 fms. shows that the remains of siliceous organisms are almost, if not entirely, absent. The mineral particles are in a minute state of disintegration, and consist of exceedingly fine flocculent matter, mixed with pumice and other glossy volcanic products, green crystals of augite and reddish crystals of pelagonite.

These deep hollows furnish fresh evidence to the observed fact that all the extreme depths in the ocean

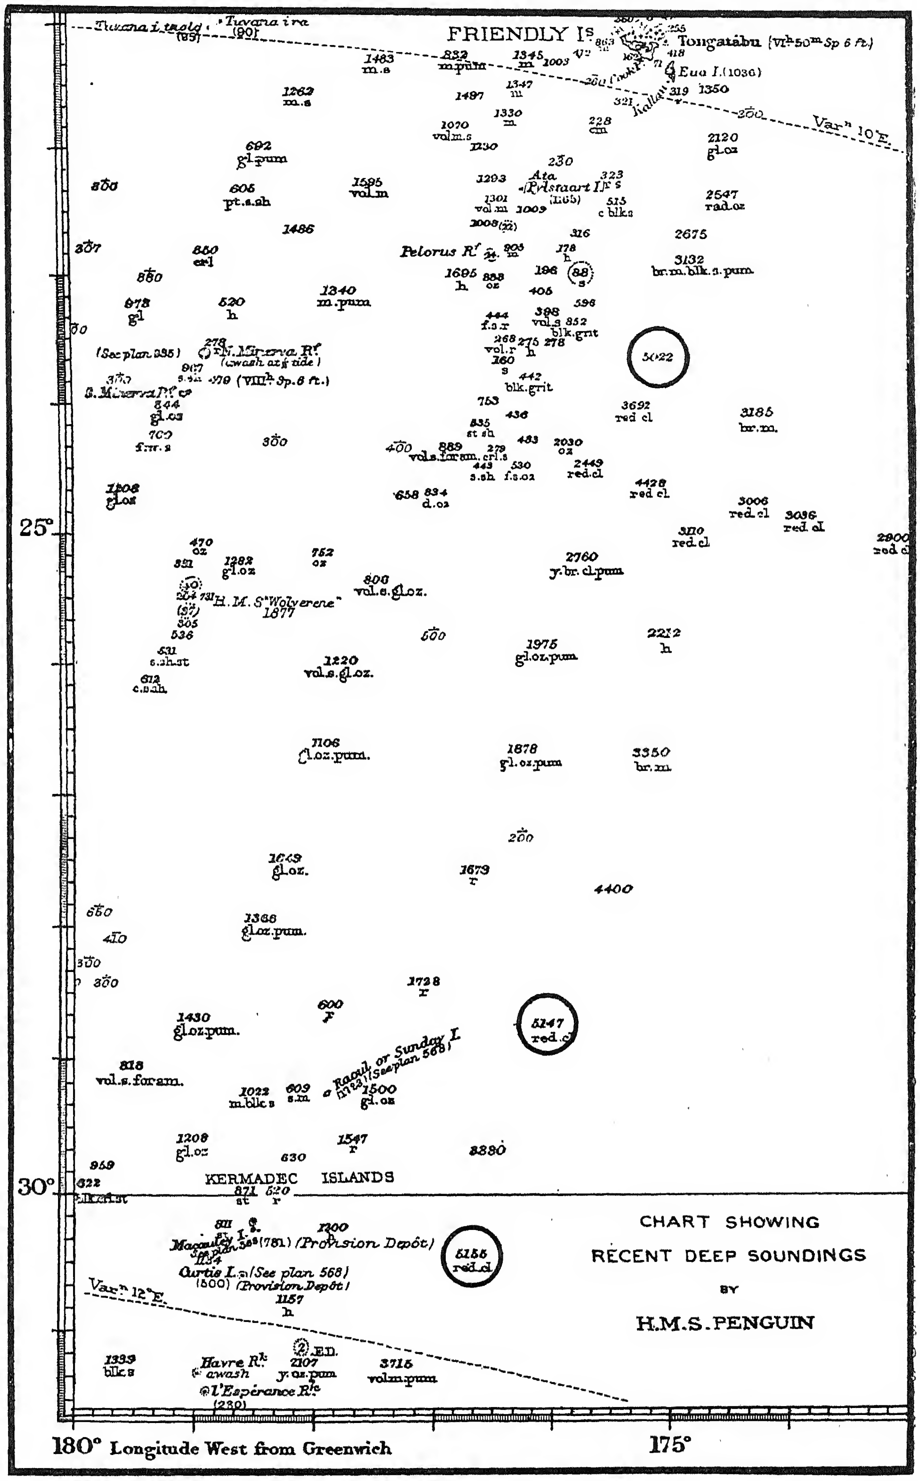
are near land or shallow water, and apparently follow the trend of such upheaved parts of the earth's crust.

The positions of the soundings are:—

Lat. S.	Long. W.	Depth. Fms.	Feet.	Nature of bottom.
23° 39′	175·04	5022	30,132	(Wire broke.)
28° 44′	176·04	5147	30,882	Red clay.
30° 28′	176·39	5155	30,930	Red clay.

The attached chart shows their general position, the Kermadec Islands being 500 miles north-east of Auckland in New Zealand.

W. J. L. WHARTON.



THE DESTRUCTION OF TREES BY LIGHTNING.

IN an article[1] by Dr. Carl Müller, on the probable causes which induce lightning to strike certain kinds of trees and not others, the writer brings together some very interesting information, which has from time to time been gleaned from experiments and observations. In Germany, where the study of forestry is considerable, and where any experiments for procuring the welfare and preservation of trees are treated with great importance, the investigations on the point now under consideration have a very practical object, for great damage must be yearly done by the storms which occur there during the summer months. The work to which reference is here chiefly made is that of Dimitrie Jonescu,[2] and his observations are based on close observation in the field and experiments in the laboratory. The knowledge that we thus obtain contrasts strikingly with that previously attained, which was founded, for the most part, on conjecture and hearsay.

It has long been known that lightning seemed to have a special fascination for certain kinds of trees, and therefore preferred to strike these rather than others. We have been informed, for instance, that the laurel was seldom if ever struck; while the oak, on the other hand, was the tree which, above all others, was signalled out for this purpose. We do not mean to say, however, that other trees are never damaged in this way, for all are to a more or less extent: but it seems that, in consequence of an unknown reason, preference is given to some more than to others.

A study of this question therefore, if it is to be

[1] *Himmel und Erde* for Jan. 1896.

[2] "Uber die Ursachen der Blitzschläge in Bäume" in "Jahresheft des Vereins für Vaterländ. Naturkunde in Württemberg," 1893, S. 32-62.

thoroughly well undertaken, must not be restricted simply to the species of tree, but should include the conditions of their position and surroundings, such as soil, moisture, &c., as these may play an important part.

The only operations, as far as we know, that seem to have been systematically carried out on these lines, are those which since the year 1874 have been made by the fürstlich Lippe-Detmoldschen Forstdirektion.

The statistics show that from 1879 to 1890 lightning had struck 56 oaks, 3 or 4 pines, 20 or 21 firs, but not a single instance of a beech tree was recorded. These facts will be seen to be of importance when it is stated that the relations between the numbers of different kinds of trees in the region under observation were such that, out of 100 trees, about 70 were beech, 11 oaks, 13 pines, and 6 were firs. The numbers show at a glance that beech trees seemed to have been entirely free from attack, although they were twice as numerous as all the other trees put together. A practical hint can at once be deduced from this; for protection against lightning, when one is in, perhaps, a wood, can be apparently secured, provided of course there are beech trees there!

In the investigation of the underlying causes, it was considered unnecessary to take into account the nature of the soil, for observation showed that trees situated on wet ground were very often struck, thus contradicting the generally conceded idea that this only occurred when they were on soil which contained a very small amount of water. Further, it was also difficult to trace any connection between the different depths to which the roots of trees extended, since this is a subject about which very little is known, and no statistics are at hand for trees that have been thus damaged.

The next step was to consider the species of tree, and investigate whether any facts here might be brought to light. With this point well in mind it was necessary, first, to determine the degree of conductivity of the different kinds of wood. Experiments in this direction have previously been made by Du Moncel, but his observations, for many reasons, gave very variable values, so variable in fact that he himself could not lay any weight on them.

One fact known, with regard to the conductivity of different species of wood by the help of the electric spark, is that electricity is conducted better in the direction of the grain than in the direction perpendicular to it. Further, Caspary has shown, in the case of lime- and dry pine-wood, that conductivity varies according as the direction is longitudinal, radial, or tangential.

Notwithstanding the results just mentioned, Jonescu[1] undertook the work afresh, and made independent observations, employing the electric spark throughout, and taking into consideration the anatomical, chemical, and physiological properties of the different kinds of wood.

It will be sufficient for us to deal simply with the results of these investigations, without entering into the method of experiment adopted.

The first experiments with oak and beech indicated that the former was a very much better conductor than the latter, just as appeared to be the case from the statistics given above, if conductivity be assumed to play the most prominent part. Similar experiments were made with black-poplar and willow. With living wood—that is, wood just cut, and therefore containing moisture—the percentage of the latter being, according to Schübler and R. Hartig, for black-poplar 51·8, beech 39·7, oak 35·4, and willow 26·0, experiments led to the result that conductivity of wood in this state is independent of the amount of moisture inside.

[1] Berichten der Deutschen Botanischen Gesellschaft. Bd. xii., 1894, S. 129-136.

Extending the observations over a far wider range, and employing numerous different kinds of woods containing varying quantities of fatty materials, such as oil and resin, it was discovered that the wood cut from living trees was in every case a worse conductor of electricity the more oil or resin they contained. The fresh wood of trees, on the other hand, which are rich in starch but poor with regard to fatty matter, conducted electricity very well, although no large difference for the various kinds of wood was noticed.

It will thus be seen that the question under consideration seems to reduce itself to the finding out the qualities of the juicy matters in the wood of the trees, as these seem to play an important, if not the whole, *rôle* in the proceedings.

As regards the distribution of the fatty materials and the starch in the wood of trees, we have to apply to Fisher and Suroz, who, from their investigations on these points, have shown that the quantity of oil and starch varies with the time of year; they have, further, classified trees according to their richness in these materials.

According to these facts then, assuming in the case of Germany that it is during the summer months that thunderstorms are most frequent, those trees rich in fatty materials (Fettbäume), and which during the summer contain much of them, are to a great extent protected against lightning. Those, on the other hand, that are poor in oil during the period of thunder-storms, and especially such trees which contain much starch (Stärkbäume), are more liable to be struck.

One very interesting example to which reference is made is the wood-pine. This tree, during the summer months in Germany, is, comparatively speaking, very often damaged, while in countries where the thunderstorms occur in the winter months (Ireland and Norway) it is usually untouched. To explain this according to the deductions of Jonescu's observations, it must be shown that in winter the tree is richer in oil than in summer. A microscopic examination of samples at both these periods of the year has proved conclusively that this is really the case, the oil disappearing in April, to have its place taken by glucose and starch. Employing the apparatus previously referred to, Jonescu found that for the winter wood of this tree double the amount of potential energy was required for sparking purposes than was required when operating with the summer wood.

As a check on his own results, Jonescu took the wood of typical trees rich in fatty materials (Fettbäume), beech and walnut, and found that when deprived of their oil by means of ether, their degrees of conductivity were increased and became practically the same as those of the wood of typical trees rich in starch (Stärkebäume).

The above explanation of the causes which render some trees more than others liable to the destructive power of a lightning flash, helps certainly to explain other points of less importance. Experiment showed that for both kinds of trees, namely, those rich in fatty materials and starch respectively, the wood in the living state is a far worse conductor than when dead. This leads to the deduction that trees with dead branches on them are more likely to be struck than those without any, so that they should be avoided if possible. Jonescu's hypothesis also explains why it is that lightning does not as a rule strike the highest part of a tree, but generally the trunk, either inside or underneath the crown.

In conclusion, it is to be hoped that these investigations of Jonescu, to which only brief reference here has been made, will be followed by observations and statistics from other sources, for this question is one that is of very general interest. It is sad to think, however, that the oak, a tree which we cherish so much, is such a friend to flashes of lightning in the way of conduction, that it in this way brings on its own destruction. D.

THE GREAT MADRID METEOR.

ON Monday, February 10, at 9h. 29m. 30s., there was observed an instantaneous bluish-white illumination in the atmosphere, so strong and vivid as to be visible in the inner rooms and in the open air.

The day was a magnificent one: blue sky, no wind, and a radiant sun.

Soon after there was plainly visible near the zenith, and some few degrees to the south-east, a white spot, like smoke, bearing north-east to south-west, of about 6° length and 1° wide; its form was semicircular, with the convexity turned to the east. In the centre, and near the apex of the curve, it presented a condensation of a reddish colour, similar to those of clouds at sunset. The general appearance of the spot was that of a light cirro-cumulus.

At 9h. 30m. 40s. there was heard a deep and very strong detonation, accompanied by many others not so intense, similar to the noise produced by a large cannon-ball running along the upper storey of a house. This noise was very prolonged; it was found to last two minutes.

Meanwhile the vibration of windows and partitions (not the thick walls) was extraordinary, and the rattling of panes of glass alarming. In some houses all the window-glasses were broken.

Judging from the time which elapsed between the light and the sound of the first detonation, the meteor exploded in the air at a distance not inferior to 24 kilometres; and this number is evidently too low.

Considering the aspect of the spot of smoke, it seems probable that the meteor proceeded from the south-east towards the north-west, and that near the zenith of Madrid it exploded.

Changed into smoke and dust, totally or partially, this smoke was carried away by the superior currents of the atmosphere to the east. We find here a splendid confirmation of the theory which supposes that, at the upper limits of the air, the wind moves from west to east.

In the accompanying rough sketch, one part corresponds to the trajectory of the celestial body; and the other, which forms an angle with the first, to the action of the aerial current.

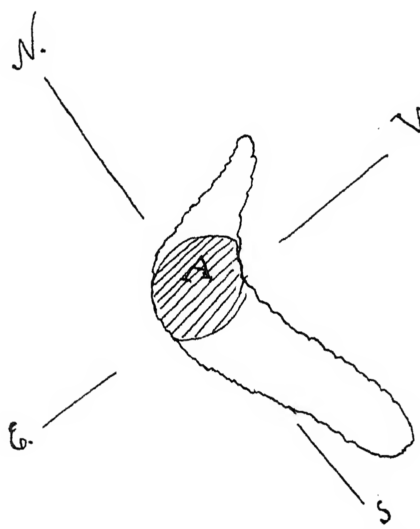


FIG. 1.—Aspect and position of the cloud some minutes after the explosion. A, Condensation of a reddish colour.

The accompanying photograph of the phenomenon was taken by an amateur some few minutes after the explosion.

The cloud continued its course to the E.N.E., or E. ¼ N.E., dissolving gradually away, and at 3h. p.m. it was still perfectly visible like a light cirrus in the east at some 20° above the horizon.

The compression of the atmosphere in the instant of the conflagration was indicated by the registering barometers. In the aneroids the trace is small; but in the mercurial one the column rose 1·6 m.m., and lowered 0·7 m.m., the amplitude of the total oscillation being 2·3 m.m.

In the neighbourhood of Madrid some fragments of the meteor fell, and I have obtained one of them.

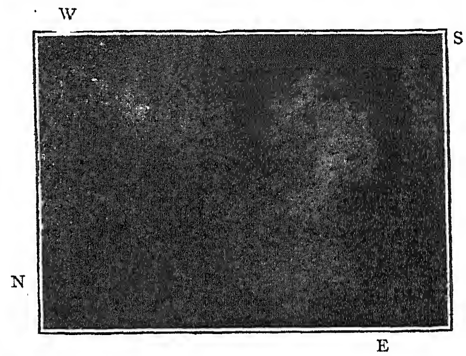

FIG. 2.—Photograph of the cloud immediately after the explosion.

Externally the fragment is of a black metallic aspect; inside it is of white stony appearance, with some brilliant points like nickel; it weighs 6·3 grams.

From information received later, it appears that the phenomenon was visible in a large part of the Peninsula, from Sierra de Estrella (Portugal) to Denia in the Mediterranean coast, and from Segovia to Aguilas, or a distance of 700 kilometres from east to west, and 400 from north to south. These are inferior limits.

AUGUSTO ARCIMIS.

THE FRILLED LIZARD: "CHLAMYDOSAURUS KINGI."

THE above-named lizard inhabits the northern or tropical territories of the Australian continent, and is tolerably abundant in both North Queensland and the Kimberley district of Western Australia. Its earliest record is that given by Captain Philip P. King, in his "Narrative of a Survey of the Intertropical Coasts of Australia" (1826), and wherein it is named, figured, and described in a Natural History Appendix by Dr. J. E. Grey.

The habitat of the frilled lizard is essentially sylvan, its resort being the thickly-wooded scrublands, and its favourite abiding-place the trunks and lower limbs of the larger trees. The length of the finest examples rarely exceeds three feet, and of this the long, rough, though slender tail monopolises the greater moiety. Living specimens exhibit a considerable individual colour variation. The predominant hue of the body is pale brown with reticulated markings; while the frill, in the males more especially, is usually decorated with interblending tints of yellow, scarlet, and steel-blue.

No living example of this singular lizard had, up to the present year, been brought alive to Europe, a circumstance which will account, to a large measure, for the fact of certain abnormal phenomena connected with its life-habits having hitherto attracted little or no scientific attention. Through the possession of living specimens of *Chlamydosaurus* in both Queensland and Western Australia, several interesting data concerning the species have fallen within my notice. Having, furthermore, succeeded in bringing one out of several examples embarked safely to England, my presentation of the animal to the

Zoological Society's Gardens, where it was on view for some weeks, has afforded many fellow-naturalists the opportunity of verifying the phenomena here recorded.

The most conspicuous structural feature of *Chlamydosaurus kingi* is the extraordinary development of the cuticle of the neck, that gives to it its popular title. This takes the form of a voluminous frill or collar, which, while the animal is at rest or undisturbed, is neatly folded in symmetrical pleats around the creature's neck and shoulders. No sooner, however, is the lizard excited to hostility by the approach of a threatening assailant, than, coincident with the opening of the mouth, the frill is suddenly erected, much after the manner of the unfurling of an umbrella, and stands out at right angles to the longer axis of the body, measuring under such conditions some seven or eight inches in diameter.

The mechanism by which the erection and depression of the frill of *Chlamydosaurus* is accomplished is intimately connected with a slender process of the hyoid bone, which traverses the substance of the frill on each side, and is so adjusted that the opening of the creature's mouth and the erection of the frill are synchronous operations. A characteristic photograph from life of this lizard in a condition of excitement, and standing at bay, with mouth open and frill erect, is afforded by Fig. 1, representing one of many I was fortunate in securing from the specimen I brought to England.

The function of the frill in *Chlamydosaurus* is, as apparently indicated by the circumstances and conditions under which alone it is displayed to view, purely that of a "scare-organ," wherewith by its sudden expansion many of its would-be assailants are frightened and deterred from attacking it. Instances have, in fact, been recorded to me of dogs, which will readily rush upon and kill other and larger lizards, such as *Varani*, refusing to come to close quarters with so formidable-looking an object as *Chlamydosaurus*, when it turns upon them with gaping mouth and suddenly erected frill.

Chlamydosaurus displays, however, additional defensive tactics. When approached these lizards will often spring aggressively at the intruder, and in addition to using their not very formidable teeth, will lash sideways with their long rough tails with such vigour as to smartly sting the hand which may fall within range of the unexpected impact.

The natural food of the frilled lizard consists almost exclusively of Coleoptera and other bark-frequenting insects; a fact which emphasises the difficulty of keeping them long in a state of captivity. The several specimens in my possession became fairly accustomed to dieting on raw meat, though they would not take to this artificially substituted pabulum voluntarily. On the slightest excitement, however, they would open their mouths and erect their frills, and on which occasions it was a simple matter to administer pieces of meat, which were then readily assimilated.

The most remarkable feature placed *en evidence* by the specimens I kept in captivity, was their peculiar method of perambulation. The statement that the frilled lizard was in the habit of running erect on its hind legs only, was made to me in Queensland some years ago. I failed, however, to verify this assertion through the single living specimen I there had in captivity for a short interval; and neither was a friend in the northern district of the colony more fortunate, who, at my request, made experiments with several specimens. I was, on these grounds, inclined to suspect that the rumour, that had previously reached me, was the outcome of an optical illusion; many lizards, such as *Grammitophoræ*, running so erect on their haunches that it might be imagined their fore-limbs were raised from the ground.[1]

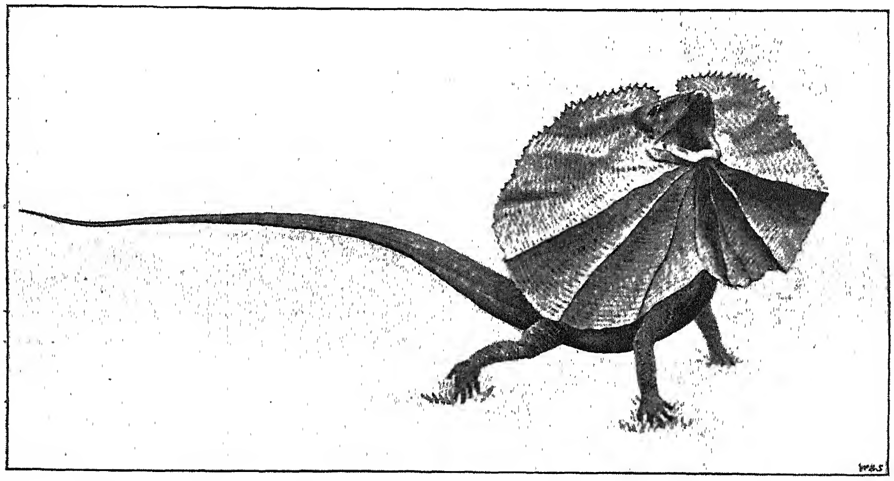

FIG. 1.—*Chlamydosaurus Kingi*, standing at bay with erected frill. (Reproduced from an instantanous photograph by W. Saville-Kent.)

It was consequently to my no small gratification and delight, on becoming the owner of several specimens, including the one brought to England, obtained for me with the assistance of the aborigines of Roebuck Bay, Western Australia, that I found myself in a position to fully establish the truth of the report concerning the erect gait of *Chlamydosaurus* that had been communicated to me in Queensland. Possibly the specimens previously experimented with had been slightly injured during capture, and lacked the stamina to walk upright. At all events the Roebuck Bay examples, brought in straight from the bush, were in vigorous health, and at the first trial when left at liberty, save for a light retaining cord, ran along the ground almost perfectly erect, with both

[1] It has quite recently come to my knowledge that a report of the bipedal comportment of *Chlamydosaurus* was communicated some years since to Dr. Henry Woodward, F.R.S., who referred to the circumstance in a paper on "Forms Intermediate between Birds and Reptiles" in the *Quart. Journ. Geological Society*, vol. xxx. 1874, The concluding paragraph of that paper, wherein Dr. Woodward favours the interpretation that "the bipedal habit of the secondary reptiles is a peculiarity still maintained by the Australian *Chlamydosaurus*," is of special interest with relation to the latter portion of this article. The assertion made by Dr. Woodward's informant in the journal quoted, that *Chlamydosaurus* is common near Sydney, is a mistake due, probably. to the circumstance that another lizard, *Amphibolurus barbatus*, having a less developed neck-membrane, inhabits that district, and is sometimes also known locally as the Frilled Lizard. The structure of this type, however, would not permit of its bipedal progression.

their fore-limbs and long tails elevated clear of the ground.

The attempt was made on the spot to permanently register, with the aid of the Kodak camera, the absurdly grotesque appearances these lizards presented when progressing in this bipedal fashion. Such, however, was the speed at which the animals ran, that the shutter of that instrument did not work fast enough to secure anything better than a blur at close quarters, and it was only by bringing an Anschutz camera with its most rapid roller-blind shutter to bear on the specimen, after its arrival in London, that the Figs. 2 and 3, here reproduced, were secured. While even these partake much of the nature of silhouettes, they will serve to indicate the more characteristic running attitudes which this lizard may assume.

Fig. 2 in this series carries with it so essentially human an aspect that one is sorely tempted, at the risk even of incurring scientific contumely, to place a cricket-bat in its right hand. The distance *Chlamydosaurus* will traverse in this remarkable erect position may average as much

FIG. 2.—*Chlamydosaurus* running erect. Posterior view, taken with Anschutz hand camera

as thirty or forty feet at a stretch, and when, after resting momentarily on its haunches, it will resume its running course. When, however, a short space of a few yards only have to be covered, the animal runs on all-fours, sitting somewhat high on its haunches after the manner of many ordinary lizards, such as the *Grammitophoræ*, previously referred to.

The profile outline of *Chlamydosaurus*, presented by Fig. 3, is peculiarly interesting, since it possesses so much in common with that of a running long-tailed bird, such as a pheasant. This bird-like aspect of the frilled lizard, as exhibited when it crosses the observer's path in bipedal fashion, has been the recent subject of remark to me by a friend familiar with the species in the Kimberley district of Western Australia.

Special interest is attachable to this avian-like ambulatory deportment of *Chlamydosaurus* by reason of the generally accepted interpretation that the birds are modified descendants of a reptilian archetype. The temptation is naturally also very great to institute comparisons between, and to suggest possible affinities with, this peculiar lizard and the extinct group of the Dinosauria, and among whose representatives a bipedal locomotive formula was apparently a characteristic feature. A reference, however, to the skeleton of *Chlamydosaurus* does not encourage any sanguine anticipations that may have been previously entertained in this direction. It yields no indication of that peculiar avian modification of the pelvic elements, adapted for bipedal locomotion, that are so essentially diagnostic of the more typical Dinosauria, while in all general points it is indistinguishable from that of the ordinary Agamidæ.

Though, as a consequence, no serious attempt would be justified to correlate the erectly progressional *Chlamydosaurus* with such ponderous specialised Dinosaurs as, say, *Iguanodon* or *Brontosaurus*, there are some few species at the lacertilian end of the chain, that probably presented when living, a by no means remote likeness to this existing type in both aspect and gait. The *Compsognathus longipes* of A. Wagner, from the lithographic stones of Solenhofen, is more especially worthy of mention in this connection. In size, some three feet long only, and in the proportions of the limbs and other points, it must have been almost a counterpart of *Chlamydosaurus kingi*. It is particularly noteworthy of it, moreover, that, as pointed out by the late Prof. Huxley

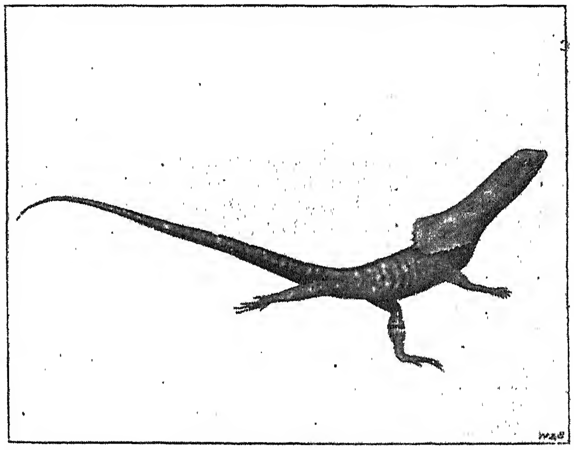

FIG. 3.—*Chlamydosaurus* running erect. Profile view.

("Anatomy of Vertebrata," p. 262, ed. 1871), the pelvic elements of *Compsognathus* correspond more essentially with those of the ordinary lizards than with those of the aviform Dinosauria, the pubes in particular being apparently directed forwards and downwards, like those of lizards. This type, as likewise *Stenopelyx*, is also referred to by the same authority (p. 263) as indicating that the more typical modification of the pelvis, and in which the pubes are directed backwards parallel with the ischia, as in birds and Iguanodon, "was by no means universal" among the Dinosauria or Ornithoscelida, as Prof. Huxley preferentially named them.

Notwithstanding the distinctly recognised lacertilian character of the pelvis of *Compsognathus*, Prof. Huxley had no hesitation in assigning to this type an erect bipedal method of locomotion. Writing of it in the *Popular Science Review*, 1866, that illustrious biologist remarks: "It is impossible to look at the conformation of this strange reptile, and to doubt that it hopped or walked in an erect or semi-erect position after the manner of a bird, to which its long neck, slight head, and small anterior limbs must have given it an extraordinary resemblance."

The silhouette presentment of *Chlamydosaurus* afforded by Fig. 3, forms a not inapt embodiment of the flesh-clad

skeleton that must have suggested itself, ghost-like, to the learned Professor's mind. And it is among my keen personal regrets for the loss the world has sustained through the decease of Prof. Huxley, that I should have been deprived by so short an interval of gladdening my former teacher's eyes with the sight of a living organism which, if only in the direction of superficial analogy, so nearly realised one, among the many, of his most sagacious interpretations of the fossil past. One remaining point in the erect running gait of *Chlamydosaurus* invites brief attention. Such is the conformation of the hind foot and its component digits, that when thus running the three central digits only rest upon the ground. As a consequence of this structural peculiarity, the tract made by this lizard when passing erect over damp sand or other impressible soil, would be tridactyle like that of a bird, and would also correspond with such as are left in Mesozoic strata by various typical Dinosauria. This tridigitigrade formula of the gradation of *Chlamydosaurus*, induced by the great relative shortness of the first and fifth digits, is distinctly indicated in the second of the accompanying figures.

Whether or not the bipedal locomotive comportment of *Chlamydosaurus* has been transmitted by heredity from a lizard-like Dinosaurian such as *Compsognathus*, or has been re-developed independently among its allocated family group of the Agamidæ, is a question concerning which, I humbly recognise, it would be unbecoming temerity on my part to pronounce a verdict. The phenomenon, while dominant among the Reptilia of bygone ages, is, with the exceptional instance afforded by *Chlamydosaurus*, extinct among living types, and is, on that account alone, of unique interest.

Without overstepping the bounds of prudence, it may be finally suggested that the occurrence within the Australian region, embracing New Zealand, of such a wealth of archaic types such as the mesozoically related lizard *Hatteria* and the fresh-water fish *Ceratodus*, as also a dominant mammalian fauna that pre-existed, but is now extinct, in other continents, would justify the anticipation that a reptile inheriting the phenomenal habits of a Mesozoic race might be sought for with the greatest prospects of success upon Australasian territory.

W. SAVILLE-KENT.

NOTES.

THE list of Presidents for the ten Sections of the British Association, for the Liverpool meeting in September next, has been published. All the Sectional Presidents having accepted the nominations, the list may be regarded as definitive. President of the Association—Sir Joseph Lister, Bart., P.R.S. Section A—Mathematics and Physics, Prof. J. J. Thomson, F.R.S. Section B—Chemistry, Dr. Ludwig Mond, F.R.S. Section C—Geology, Mr. John Edward Marr, F.R.S. Section D—Zoology, Prof. E. B. Poulton, F.R.S. Section E—Geography, Major Leonard Darwin. Section F—Economics, Right Hon. Leonard Courtney, M.P. Section G—Mechanical Science, Sir Charles Douglas Fox. Section H—Anthropology, Mr. Arthur Evans (Keeper of the Ashmolean Museum, Oxford). Section I—Physiology and Pathology—Dr. Walter Holbrook Gaskell, F.R.S. Section K—Botany, Dr. D. H. Scott, F.R.S. Evening discourses will be given by Prof. Flinders Petrie and, probably, by Sir Andrew Noble. The lecture to working men will be given by Prof. Fleming, F.R.S.

THE Toronto Local Committee are assiduously engaged in preliminary work for the meeting of the British Association for the Advancement of Science in 1897. Meetings of the executive committee are held every fortnight. Besides the executive committee, a number of sub-committees are at work, including those on finance, conveyances, publication and printing, rooms for offices, meetings of the association and committees, hotel and lodgings, press, hospitality, reception, and for securing co-operation of other institutes, associations, and corporations, postal, telegraph and telephone facilities. The attention of the committee on conveyance has already been called to the desirability of securing from the Canadian Pacific Railroad transportation for such members of the Association as may desire to extend their travels to the Pacific coast, with special reference to the suggestion that a meeting of the American Association for the Advancement of Science may follow the Toronto meeting, if adequate facilities for transportation are assured. This suggestion is based upon the fact that the American Association have already once voted in favour of such a meeting if satisfactory rates could be obtained; and the hope is still entertained that delegates from both British and Australasian Associations might find San Francisco a convenient point at which to meet the American Association. Mr. Griffith, the general secretary of the British Association, is expected to be in Toronto about May 22, to make arrangements for the meeting, and set out the proper lines of work.

FROM McGill University, Montreal, comes the information that Röntgen's experiments were not only repeated there with considerable success immediately on the announcement of his results in America, but have been applied to two important medical cases within the first week of their demonstration. Before any full description of Röntgen's method had crossed the ocean, Prof. Cox was enabled by a lucky guess, and with the aid of the fine McDonald apparatus, to reach success at the first attempt. Four days later a photograph was obtained, clearly showing the bones of the leg from the knee downwards, with the image of a bullet (which had been there for seven weeks and was causing trouble) clearly defined between the two bones, and resting against the inner angle of the tibia. The same photograph showed a copper wire which had been bound round the leg as a fiducial mark from which to measure. The bullet was six centimetres below the wire. On the following day the bullet was reached at a depth of two inches, and was extracted successfully. The exposure required for this photograph was forty minutes. The Pulüj tube (Geissler Catalogue 3080) has been found by Prof. Cox to be superior to any others tried. Its fluorescing screen seems to protect the glass, and is far brighter than that of the other tubes. It gave continuous exposures of 65 minutes without injury, and has since been used to detect a fracture of the ulna, and to produce a photograph of the hand, with perfect definition.

OUR U.S. correspondent writes under date February 14:—"The new photography continues to be the absorbing topic in scientific circles, and innumerable experiments and results are reported. Dr. Henry W. Cattell, of the University of Pennsylvania, has taken pictures of anatomical preparations with such success, that he infers it will be easy to obtain pictures of acromegaly, osteitis deformans, rheumatoid arthritis, &c. Prof. W. F. Magie, of Princeton, has invented a new instrument for use in diagnosis. A sheet of black paper, coated on one side with barium platino-cyanide, is placed with the coated side inward across the end of a tube or box, into which the observer looks, and which is so fitted to the face, or so shielded by cloths, that the phosphorescent substance and the eyes are protected from all extraneous light. If the tube be then directed towards the excited Crookes' tube giving the Röntgen rays, the phosphorescent paper in the tube glows, and the shadows of objects interposed between it and the Crookes' tube appear upon it. The first successful experiments in Brooklyn are by Prof. William C. Peckham, at the Adelphi Institute, using more direct methods than have heretofore been used, with a current of $3\frac{1}{2}$ amperes and an electrical pressure of six volts. Dr. A. Mau succeeded in

obtaining a photograph of a key, covered by a board, by five hours' exposure to direct sunlight. Elaborate experiments are in progress at Columbia, under the direction of Profs. Rood, Papin, and Hallock, with a prospect of important results."

WITH reference to the report that Prof. Salvioni had discovered how to make directly visible the bones of the hand by means of Röntgen rays, the Rome correspondent of the *British Medical Journal* says:—"At a meeting of the Perugia Medico-Chirurgical Society, held on February 5, Prof. Salvioni, teacher of physics at the University, made a most important communication on the new results obtained by him in Röntgen's rays. In studying the question, his aim was to invent an apparatus which would enable one to see direct and without the intervention of photography certain bodies enclosed in wood, flesh, cardboard, &c. He therefore studied the possibility of rendering the retina sensitive to Röntgen's rays. In this he has succeeded by inventing an apparatus which he has called a cryptoscope, which he exhibited at the meeting, and by means of which one can clearly see the contours of the bones of one's own hand, objects enclosed in cardboard boxes, leather purses, &c. This apparatus is very simple, and consists of a black cardboard tube enclosed at one end with a disc of black cardboard coated internally with a fluorescent substance (barium platino-cyanide, sulphate of calcium, &c.); in the other end is placed a lens which permits one to clearly see the fluorescent surface. The object to be observed is placed before the luminous source given by a Crookes' tube, and then one looks at it through the cryptoscope placed at a suitable distance. As in the fluorescent cardboard the parts of the object impermeable to Röntgen's rays are drawn in shadow, thus one clearly sees the contours of the bones of the hand, &c. A model of the instrument was made under the direction of Prof. Blasema at the Physical Cabinet of the Roman University on February 11, and with it one could clearly see the bones of one's own hand, coins in a purse or the clenched hand, &c. It is evident from these results that the apparatus, when perfected, will be of great use in medicine and surgery."

THE current number of the *Comptes rendus* contains no less than seven papers bearing on the Röntgen rays. In following up the analogy of certain properties of these rays with some properties of the ultra-violet rays, M. R. Swyngedauw has found that the X-rays cause a lowering of the explosive potential according to the same general laws as the electrically active ultra-violet rays. Whilst the influence of the latter, however, is entirely suppressed by interposing a screen of wood, glass, or blackened paper, these materials do not affect this property of the Röntgen rays. It was also noticed that these rays lowered the dynamic explosive potentials to a greater extent than the static potentials. As a result of the study of the property of the Röntgen rays of discharging an electrified body, M. A. Righi concludes that the time necessary for a given fall of potential is practically the same, whether the original charge be positive or negative. With an initial positive charge the discharge is not complete; but if negative initially, not only is the discharge complete, but the disc becomes positive. The results obtained by MM. J. J. Borgman and A. L. Gerchun, however, are precisely contrary to these, a positively charged disc losing its charge nearly instantaneously, and becoming negative on prolonged exposure to a Crookes' tube. MM. L. Benoist and D. Hurmuzescu contribute further researches on the same subject of a quantitative character. By measuring the time required for a given reduction of angle between the leaves of an electroscope, and the distance of the leaves from the Crookes' tube, they prove that the ratio of the times are as the ratio of the squares of the distances. From the coefficient of transmission (0·85) of an aluminium plate, 0·1 mm. thick, it is shown that a plate of aluminium 15 mm. thick, such as was used by Röntgen in his original experiments, must be practically opaque to the rays *unless the rays are heterogeneous*. In an extract from a letter by M. de Heen, an ingenious experiment is described which proves conclusively that the X-rays proceed from the anode, and not the kathode. A leaden plate perforated with holes is placed between the Crookes' tube and the photographic plates, and the direction of the bundles of rays thus obtained shows clearly that these rays are anodic.

DR. M. ARMAND RUFFER has resigned the post of Director of the British Institute of Preventive Medicine, and has been appointed Professor of Bacteriology at the Medical School of Cairo, vice Dr. Kaufmann, resigned.

COLONEL C. F. CROCKER, a member of the Regents' Committee of the Lick Observatory, has undertaken to pay the expenses of an expedition which will be sent from the Observatory to Japan to observe the forthcoming solar eclipse. The expedition will be under the direction of Prof. Schaeberle, and its programme will be wholly photographic.

CHARLES WACHSMUTH, well known as a palæontologist in the line of Crinoids, died suddenly at Burlington, Iowa, February 17, aged sixty-six years. He was a native of Germany, and had spent forty years in scientific research among the Crinoids of the Mississippi Valley and the Tennessee Mountains.

THE deaths are announced of Prof. J. Graindorge, Professor of Mathematical Physics and Kinematics at Lüttich; M. Abel Hovelacque, the distinguished Anthropologist and Orientalist, at Paris; Dr. K. Stölzel, Professor of Technical Chemistry and Metallurgy in the Technical High School at Munich; Dr. P. Hedenius, Professor of Pathology and Pathological Anatomy at Upsala.

THE progress in electric propulsion appears in many ways. Electric motors have been tried and will be substituted for steam on the New York and Brooklyn Bridge as a means of switching trains at the termini, thus practically doubling the capacity of the bridge. A Westinghouse system railroad locomotive, the first one constructed, has just been completed at Philadelphia, and sent to Pittsburgh for its electric equipment. A speed of 200 miles an hour is claimed. Experiments indicate that electricity will soon supplant steam as a motor on the entire New York elevated railroad system.

. THE following prizes have recently been awarded by the Académie Royale de Belgique: M. J. Verschaffelt, 600 francs for his work on the determination of molecular weights of bodies in solution; M. E. Haerens, 1420 francs (Prix Charles Lemaire) for the best treatise on public works. The following have been elected Foreign Associates of the Academy: Profs. Sylvester (Oxford), Cannizzaro (Rome), Strasburger (Bonn), Cope (Philadelphia), M. Marey (Paris), and Sir Archibald Geikie (London). M. Fraipont (Liège) has been elected Correspondant in the Natural Science Section.

ALL who are working for the reform of our system of weights and measures will be interested to know that the Swiss Government have recently invited the countries parties to the Berne Convention—in other words, all the leading countries of the continent of Europe—to a conference to discuss *inter alia* the introduction of a uniform gauge of screws based on the metric system. Mr. W. M. Acworth remarks in the *Times* that, according to the official document, this gauge is intended to take the place of the "so-called Whitworth system, based on English measures, which is at present in use under various forms." It is pointed out that there is an immense advantage in having the material for the repair of rolling-stock, which often travels

thousands of miles from home, interchangeable. It is added, moreover, that, if the way to this reform be once opened under the lead of railways, private manufacturers may be confidently expected to promptly follow suit.

THE spring meeting of the Iron and Steel Institute will be held in London, at the Institution of Civil Engineers, on May 7 and 8; and the autumn meeting will be held at Bilbao at the beginning of September, under the presidency of Sir David Dale. Special arrangements are being made for the autumn meeting, the programme for which will include visits to the important Spanish mines, from which so large a proportion of the iron ore used in Great Britain is obtained. Owing to the limited hotel accommodation at Bilbao, arrangements are being made to secure one of the Orient Company's steamers to convey the members to Bilbao and back, and to serve as a floating hotel. It is proposed that the cruise should last a fortnight, and that calls should be made at some of the Spanish and French watering-places.

IN a letter to the *Times*, Admiral Richards briefly reviews Dr. Nansen's expedition and the report of its having reached the North Pole. It will be remembered that Nansen's intention was to place his ship in the solid ice off the coast of Siberia and to drift with it across the Pole into the Greenland Sea, believing it would be carried there by a current. Admiral Richards points out, however, that in the Polar basin proper it is doubtful if the ice ever finds an exit. The ships which entered on its confines in Wellington Channel found it blocked there; M'Clure also found it blocked between Banksland and Melville Island. Nares could not get a mile north from the top of Smith Sound for very heavy ice, and the only channel it could escape by is the Greenland Sea, of which there is no evidence, while by Davis Strait great numbers of bergs and enormous quantities of ice are constantly passing down in the months of July and August, but none of it from the Arctic basin proper. These facts, remarks Admiral Richards, tell strongly against Nansen's succeeding in his original project, but they need not have been an obstacle in his reaching a certain distance north from the coast of Siberia.

THE anniversary meeting of the Geological Society of London was held on Friday, when Dr. Henry Hicks, F.R.S., was elected President for the ensuing year. The retiring President (Dr. Edward Woodward) delivered his anniversary address, which dealt with the life-history of the Crustacea in later Palæozoic and in Neozoic times. The following awards of medals and funds were made: The Wollaston medal to Prof. E. Suess; the Murchison medal, and part of the proceeds of the Murchison fund, to Mr. T. Mellard Reade; the Lyell medal, and part of the proceeds of the Lyell fund, to Mr. A. Smith Woodward; balance of the Wollaston fund, and part of the proceeds of the Barlow-Jameson fund, to Mr. Alfred Harker; balance of the proceeds of the Murchison fund to Mr. Philip Lake; moiety of balance of proceeds of Lyell fund to Dr. W. F. Hume; moiety of balance of proceeds of Lyell fund to Mr. C. W. Andrews; moiety of balance of proceeds of Barlow-Jameson fund to Mr. Joseph Wright; moiety of balance of proceeds of Barlow-Jameson fund to Mr. John Storrie.

WE understand from the *Lancet* that the arrangements for the next International Congress, which will be held in Moscow in August 1897, are now being worked out by the special Committee appointed for the purpose. There will be twelve sections, as follows: (1) anatomy, (2) physiology, (3) general pathology and pathological anatomy, (4) general therapeutics, (5) internal diseases, (6) children's diseases, (7) nervous and mental diseases, (8) dermatology, (9) surgery and diseases of the eye, (10) midwifery and gynæcology, (11) hygiene, and (12) legal medicine. The Government has assigned 35,000 roubles for the expenses of the congress. The official language of the congress will be the French language, but in the general meetings, of which there will be three, communications may be made in any European tongue. In the sectional meetings only three languages will be admitted—namely, French, German, and Russian. Englishmen must regret that they will be debarred from making communications in their own tongue to the sectional meetings, and that their only opportunity of reading papers in the English language will be in the three general meetings.

THE scientific study of the mental and physical condition of children, carried out by Dr. Francis Warner in connection with a Committee of the Congress of Hygiene, has led to results which claim full consideration. Dr. Warner gave an account of his investigations before the Royal Statistical Society last week. It appears that defective development is more frequent in boys than in girls, and more associated with nervous disorder in the former and with delicacy and dulness in girls. Mental dulness is found much associated with irregular movement and action, especially among boys, showing that physical exercises should form a part of brain culture in school. Dealing with the question of mental dulness, Dr. Warner showed that the want of physical training of the brain appears to be a more frequent cause than defective development of the body. Defective physiognomy and proportioning of the features and parts of the body is often associated with mental dulness, but the occurrence of brain disorderliness, indicated by observable signs, is a more general and direct cause. Both defect in development and nerve disorderliness, either alone or in combination with low nutrition, are much associated with mental dulness. From the facts collected, Dr. Warner has been able to deduce the indications of some of the physical causes of defect of body, defect of brain, and mental dulness. It is to be hoped that it will be possible to continue such research beyond the metropolitan area, and that a commission might be appointed by the Government to consider the many important recommendations on national education resulting from the investigation thus far completed.

THE ancient and familiar process used in the manufacture of linen, and known as the "retting" of flax, has long eluded all endeavours to place it upon a sound scientific basis. Prof. Winogradsky, of St. Petersburg, has, however, recently shown that it is directly dependent upon the action of particular bacteria. Considerable difficulty was experienced in discovering the special microbes responsible for the process, and several different varieties were isolated by means of gelatine plate culture from the retted or fermented flax; but in no case, when inoculated on to sterilised flax, did retting ensue. When, however, portions of retted flax were added to the sterilised flax, vigorous fermentation was set up in from twelve to fifteen hours. In the next series of experiments pieces of sterilised flax were inoculated, placed in tubes containing water, the surface of which was sealed from the air by means of a film of oil. In this manner, after a long series of successive inoculations, a somewhat large, spore-forming bacillus was discovered, which subsequent experiments proved to be the specific microbe responsible for the retting of flax. It was obtained in a condition of undoubted purity by anaërobic cultivation on slices of potato which were rubbed over with chalk, and from these cultures the retting of sterilised flax was accomplished with the greatest ease. Prof. Winogradsky is of opinion that the so-called pectic fermentation, by which is understood the transformation during retting of insoluble pectic substances into soluble, must now be regarded as a fermentation process in the strict bacteriological sense of the word.

IN the *Meteorologische Zeitschrift* for December 1895, Prof. G. Hellmann discusses the yearly period of storms in Europe, with

especial reference to the so-called equinoctial gales. In order not to entirely omit large districts, observations both at stations with and without anemographs have been utilised, and he has deduced the yearly period at some fifty stations; but, partly not to complicate the discussion, and partly from want of necessary details, no account has been taken of the duration, force and direction of the storms. The position of the station has a great influence upon the yearly period; a place with a good western exposure will have more westerly storms than a station with an easterly exposure, and *vice versâ*. The author finds that in the extreme south-west of Europe March is the most stormy month; this is very marked at San Fernando, near Cadiz, where 45 per cent. of all storms occur in that month. Further northwards, on the Atlantic coast, the March maximum gradually recedes; and on the coasts of France, the British Isles, and Norway, there is a decided maximum in January, and at some inland places this also holds good. This agrees with the results obtained by Mr. R. H. Scott for the British Isles (*Quarterly Journal* of the Roy. Meteor. Society, 1884), who showed that mid-winter was the stormiest season. The stations of South Norway and part of North Germany show a considerable increase of storms in October, but there is a great variation in the yearly period in relatively small districts. The author considers that although storms do not preponderate exactly at the times of the equinoxes, the popular theory holds good to a certain extent, that they frequently occur near those seasons; and that if the year be divided into two parts—one of stormy, and one of relatively calm weather—the months of March and October must be taken as the limiting periods, at all events over a great part of Europe.

WE have received an atlas of the "isanomales" and of the lines of secular change of the earth's magnetism, by Lieut.-General Alexis de Tillo. The atlas contains sixteen maps, which give the isanomales and the lines of equal secular change of the declination, dip, horizontal force, vertical force, and total force for the epoch 1859. In addition there are two maps showing the agonic lines for the epochs 1700, 1800, and 1859, and the lines of maximum secular change in declination for the epochs 1745, 1810, and 1859. The author, from an examination of these maps, concludes that with reference to each of the magnetic elements the globe can be divided into two hemispheres by a great circle approximately parallel to the meridians. In one of these hemispheres the values of the magnetic element are greater than in the other hemisphere, and there is a similarity between the general lie of the isanomales (*i.e.* of the lines of equal departure of each element from the mean value of the element along a parallel of latitude) of the several elements. The agonic lines are reproduced on the maps of the isanomales of dip, vertical force, and of magnetic potential. In particular the places at which the declination is zero coincide with the points of maximum or minimum value of these elements along the parallels of latitude. The isanomales of the horizontal force show that in general in those parts of the surface of the earth at which the declination is westerly the horizontal force is less than in the parts of the surface of the earth at which the declination is easterly. An indication of the Siberian oval appears on the vertical force and dip charts, while on the horizontal force and total force charts there is an indication of a similar oval near the Sandwich Islands.

THE belief in the vampire—that is, a spirit which leaves its dead body in the grave to visit and torment the living—is a very ancient and widely-spread superstition. It is startling to find, according to Mr. G. R. Stetson (*The American Anthropologist*, ix. p. 1), that this ghastly belief still persists in Rhode Island, U.S.A. Persons now living claim to have had their life saved from death by consumption by the exhumation, mutilation, and generally the cremation of some member of their families who had died a short time previously. In the same journal, Dr. J. W. Fewkes has a preliminary article on Tusayan Ethno-botany. This is a subject which has not received the attention it deserves, and it would be well if residents in our colonies and dependencies, who have a taste for botany, would preserve the transient plant-lore of our native races.

WHILE the old-fashioned view of igneous rocks as merely accidental and irregular intruders into the regular sedimentary series has been greatly modified by the results of petrological researches, it is not often that it is found possible, from an investigation of rock-structures, to obtain so complete an account of a series of events in a district as Messrs. Holland and Saise have recently done in the Giridih coalfield in Bengal. They show how a liquid rock-magma of highly basic composition was injected as a series of dykes through the rocks of this area at a temperature so high that near the dykes the coal was coked and columnar structure developed in it, while sandstones were so far fused that they came to closely resemble siliceous lavas. This magma was rich in chlorine, as the abundance of apatite in it shows, and from it thermal waters conveyed chlorides in solution to permeate the rocks around. This permeation by chlorides produced marked changes in certain more ancient igneous rocks, so that when at a later stage earth-movements crushing them led to their metamorphism and re-crystallisation, the results of that metamorphism were quite different in the areas where the chloride-permeation had and had not been effected. Where there were no dykes to supply the chlorides, hornblende-schists were produced; in the neighbourhood of the dykes, scapolite rocks were formed. These and other interesting facts are worked out in convincing manner in a paper contributed to the *Records* of the Indian Geological Survey (vol. xxviii. pt. 4).

MR. CHARLES J. JOLY, Fellow of Trinity College, Dublin, is editing an annotated edition of Sir W. Rowan Hamilton's "Elements of Quaternions." The work is now passing through the press.

AN important article on "Venezuela: her Government, People, and Boundary," by Mr. W. E. Curtis, appears in the February number of the *National Geographic Magazine*, illustrated by pictures of La Guayra, and the Valley of Caracas, east and west of the capital.

WE have received the second volume of meteorological data, published by the U.S. Weather Bureau, containing the results of observations made during 1893, and, as a special contribution, the records in detail of temperature, pressure, and wind at Pike's Peak and Colorado Springs.

A SET of thirteen "Laboratory Tables for Qualitative Analysis," drawn up by the Demonstrators in Chemistry of the Owens College, has been published by Mr. J. E. Cornish, Manchester. The tables are printed upon cards apparently intended for use in chemical laboratories, so that students can be drilled in the mechanical operations of analysis.

THE second "Psychological Index," published annually as part of the *Psychological Review*, has just been issued. The index is a bibliography of the literature of psychology and cognate subjects for 1895, compiled by Dr. L. Farrand and Mr. H. C. Warren. To psychologists, this well-arranged and complete list of published books and papers must be invaluable.

A SECOND edition of "The Methods of Microscopical Research," by Mr. Arthur C. Cole, has been published by Messrs. Baillière, Tindall, and Cox. The book is a practical guide to microscopical manipulation, embodying descriptions of many original processes and methods of work. The first edition was

well received, and the second, much enlarged and in great part re-written, will assuredly be just as successful.

A VOLUME has been received containing the results of rain, river, and evaporation observations made in New South Wales during 1894, under the direction of Mr. H. C. Russell, C.M.G., F.R.S. Two new maps of the colony have been introduced into the report, one showing the average monthly temperature in each square degree, and the other showing the temperatures of spring, summer autumn and winter, also the mean temperature for the year, and the highest and lowest temperatures ever recorded in each square degree.

MESSRS. G. BELL AND SONS have published a dainty brochure on the Koh-i-Nur diamond and the celebrated Pitt diamond, reprinted from Mr. E. W. Streeter's "Great Diamonds of the World." Mr. Streeter prints a letter received from Mr. J. Ball in 1882, containing an opinion against the identity of the Great Mogul and Koh-i-Nur diamonds; but he does not seem to have made much use of the detailed history of the Koh-i Nur in relation to the Great Mogul, as told by Prof. Story-Maskelyne in these columns in 1890 (vol. xliv., p. 555).

THE Library Bureau has sent us the first number of this year's "New Book List"—a catalogue of British literature published during January—compiled and arranged by Mr. Cedric Chivers. We have also received a specimen of a card catalogue which has been inaugurated with the list. It is proposed to publish at monthly intervals, and at a low price, a catalogue of new publications, printed on cards. Every book published will be catalogued under the author's name, and full particulars of the book will be printed upon the card. The card catalogue thus constructed should be of great service in libraries and other institutions.

A CATALOGUE of the "Students' Geological Collection" of the Bristol Museum has just been issued by Mr. E. Wilson, the Curator. This is a special collection of the commonest fossils of British formations, and of typical rocks and minerals, which is available, under proper conditions, for actual handling by elementary students. Such a collection must both be a boon to those who use it, and save the general collections from possibility of misuse. As the specimens are carefully selected, and the localities of almost all are given, the list may prove useful as a suggestion for the formation of similar ones elsewhere. From the same source comes the sixth edition of the popular penny guide to the Bristol Museum.

THE Magnetical and Meteorological Observatory of the Royal College of Belen, Havana, has published a pamphlet on the circulation and cyclonic translation of West India hurricanes, which was originally prepared by the late Father B. Viñes for the Chicago Congress. The paper is one of considerable importance upon the subject in question, as the author spent twenty-three years of his life in constant study of the storms in that part of the world. The first section deals with the general laws of cyclonic circulation and the relations of the movements of cirrus and other clouds to the locality of the centre of disturbance. The second part explains at considerable length the laws of the translation of the disturbance in different months, and its rate of travel in various parts of its path. It is well known that the West India hurricanes first advance towards the west, then turn northwards and recurve towards east-north-east or north-east. The rate of progress is found to differ in various parts of the path, and according to different seasons and latitudes. On these important points and their practical application to navigation Father Viñes' long and attentive studies have led to very valuable results. The work is written in the Spanish language.

THE Society for the Protection of Birds reports progress. The total number of members is now 13,134, no less than 1673 names being enrolled during the year 1895. Various are the reasons which result in an increase of membership of the Society. Naturalists join because they desire to prevent the extermination of rare species, many people become members from æsthetic considerations, and others because they have regard for the feelings of birds. The Society mourns a "deplorable outbreak of savagery in female adornment"—to wit, a recrudescence of the feather-wearing fashion, especially a rage for aigrettes. But, apart from this, the Committee reports the existence of a growing desire in the country to preserve its wild bird life. It is certain that in 1895, such signs have been more frequent and unmistakable than in former years. A greater and ever-increasing impatience is felt against the annual massacre, in August and September, of gulls, terns, guillemots, razorbills, puffins, and other sea-birds on our coasts; the shooting of every rare bird, in the interests of private collectors; the wholesale trapping of songsters, 70 per cent. of which perish within a week of capture, by unlicensed bird-catchers; and the use of the pole-trap. We give our support to the remark that last year was astonishingly prolific in ornithological literature, scientific and popular: it is certain that so large a number of books on the bird-life of the British Islands has not appeared in any previous year. These works should have a beneficial influence upon the Society.

THE preparation of metallic carbides in the electric furnace has, as is now well known, led to an easy method for the direct synthesis of pure acetylene, this gas being produced by the action of water upon the carbides obtained from the alkaline earths. But all metallic carbides do not behave similarly towards water; some (chromium, molybdenum, titanium) being unacted upon at ordinary temperatures, others (aluminium, beryllium) giving methane. In a recent number of the *Comptes rendus* (February 10), M. H. Moissan gives a detailed account of the preparation and properties of uranium carbide. This substance, which has the composition $C_3.Ur_2$, does not differ to any marked extent in its general chemical and physical properties from other substances of the same class, except in its reaction with water. This gives rise to a complex series of solid, liquid, and gaseous hydrocarbons. Of these, only the last have been completely examined, the analysis of the gaseous mixture showing hydrogen (13 per cent. to 15 per cent.), methane (78 per cent. to 80 per cent.), and ethylene (5 per cent. to 7 per cent.), together with a trace of acetylene. M. Moissan, remarking on the presence of the hydrogen, points out that this is probably produced by a secondary reaction, the lower oxide of uranium being able to decompose water. The acetylene also is stated to be probably due to the presence of a little calcium carbide as an impurity.

THE researches of M. Guntz, on the preparation of metallic lithium and its nitride, have led to the discovery of a hydride of this metal possessing some remarkable properties. Wishing to heat some lithium in a current of an inert gas, and nitrogen being obviously excluded, some lithium was raised to a bright red heat in a current of hydrogen, when, much to the astonishment of M. Guntz, the whole caught fire and burnt with flame in the tube, depositing a white powder, and leaving no trace of unburnt lithium. On analysis this proved to have the composition LiH, and is noteworthy as giving the maximum weight of hydrogen on treatment with water for minimum weight of substance, one kilogram giving 250 grams, or 2780 litres of hydrogen. It is not deliquescent, and alters very slowly in air, and is stable at a full red heat, thereby differing from the previously known hydrides of the alkali metals. Heated in a current of nitrogen converts LiH into Li_3N.

THE additions to the Zoological Society's Gardens during the past week include a Lion (*Felis leo*, ♂) from Africa, presented by Mr. Rowland Ward; a Common Squirrel (*Sciurus vulgaris*), British, presented by Mrs. Herbert Morris; a Woodlark (*Alauda arborea*); a Whinchat (*Pratincola rubetra*), British, presented by Mr. J. Young; a Black Tanager (*Tachyphonus melaleucus*) from South America, presented by Madame Caté; a Rhinoceros Hornbill (*Buceros rhinoceros*, ♂) from the Malay Peninsula, deposited; two Black-necked Stilt-Plovers (*Himantopus nigricollis*) from South America, a Long-eared Owl (*Asio otus*), two Common Pheasants (*Phasianus colchicus*, ♀ ♀), British, purchased.

OUR ASTRONOMICAL COLUMN.

CASSEGRAIN AND GREGORIAN REFLECTORS.—For some time past, Prof. Schaeberle, of the Lick Observatory, has been experimenting on the applications of these rather neglected forms of reflecting telescopes with the special view of applying them for celestial photography. The field of view in such instruments is darker than in refracting telescopes, and if the mirrors are good, there is every reason to expect that in planetary photography the results obtained by a telescope twelve or fifteen feet in length will be at least equal to those obtained with the most powerful refractors. There is so little published on the theory of the instruments that Prof. Schaeberle has re-investigated the fundamental formulæ, which may be useful to many observers (*Astronomical Journal*, No. 364). In the case of the Cassegrain it is easily shown that the secondary mirror must theoretically be the convex side of an hyperboloid of revolution, while in the Gregorian it must be the concave side of an ellipsoid of revolution; in both cases the axis and focus of the secondary reflector must coincide with those of the primary. If F denote the focal length of the parabolic reflector, H the distance between the centre of the mirror and the secondary focus (being negative when it falls between the two reflectors); the axial radius of curvature of the secondary reflector; L the equivalent focal length of the combination; then, for both forms

$$L = \frac{F}{r}\left\{(F + H) \pm \sqrt{r^2 + (F + H)^2}\right\} \quad . \quad . \quad . \quad (1)$$

$$r = \frac{2LF(F + H)}{L^2 - F^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

$$H = \frac{r(L^2 - F^2)}{2LF} - F \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

These formulæ refer to the theoretical conditions for perfect definition; in practice, the secondary mirror is so small that for the same value of r, a spherical surface, or a paraboloid, hyperboloid, or ellipsoid, of any eccentricity, gives tolerable images, the size of which may be varied by simply moving the secondary along the optic axis. There will, however, always be a point of best definition; and if this does not give a convenient position for the secondary focus, the eccentricity of the small reflector must be altered by local polishing. The figuring of the secondary mirror is too delicate for direct measurements, and can only be tested in the telescope itself.

WELLS' ALGOL VARIABLE.—Further particulars of the new variable of the Algol type in the constellation Delphinus (NATURE, vol. liii. p. 206) are given in *Harvard Observatory Circular*, No. 5. The observations so far obtained show that its time of minimum, uncorrected for the velocity of light, can be closely represented by the formula J.D. 2412002·5 + 4·8064 E. For nearly two hours before and after the minimum it is fainter than the twelfth magnitude, but it is not yet possible to say how faint it really becomes. The increase of brightness takes place at first very rapidly, but afterwards more slowly, and the full brightness, magnitude 9·5, is reached in about five hours. Numerous photographs indicate that during the four days between the minima, the brightness is sensibly constant. The changes can be explained on the assumption that the star revolves about a relatively dark body, and that it is totally eclipsed at the minimum, the light then, if any, being that of the companion. The conditions are accordingly somewhat similar to those of U Cephei. The new variable is BD + 17° 4367, its R.A. and decl. for 1900 being respectively 20° 33′·1 and + 17° 56′.

THE NEW COMET.—From observations of the new comet, Perrine-Lamp, made on February 15, 16, and 17, the following elements and ephemeris for Berlin midnight have been computed by Dr. Lamp:

T = 1896 January 31·999 Berlin mean time.

$$\left.\begin{aligned} \omega &= 358^\circ\ 38'\ 16'' \\ \Omega &= 208\ \ 36\ \ 29 \\ i &= 155\ \ 30\ \ 15 \end{aligned}\right\} 1896{\cdot}0$$

$$\log q = 9{\cdot}77022$$

	R.A. h. m. s.	Decl. ° ′	Brightness.
Feb. 27 ..	22 59 40 ...	+ 46 8·7	
,, 29 ...	23 54 31 ...	+ 49 49·2 ...	0·9

M. Bigourdan, who observed the comet at Paris on February 16, states that the comet was not then visible to the naked eye, though bright enough to be easily seen in a telescope of 50 mm. aperture. It was observed to be round, about 2′ in diameter, with a diffuse central condensation about 20″ in extent. At the centre of this condensation a small stellar nucleus was occasionally suspected. No tail was visible.

PERRINE'S COMET (1895).—Dr. E. Lamp has drawn our attention to a misprint in the ephemeris of Perrine's comet, given in NATURE on January 23; the declinations throughout should be placed a line lower. Hence our statement last week, that on re-discovery the declination of the comet was a degree in error was unfounded; as a matter of fact, the corrections to the ephemeris were only + 4s. and + 0′·5. The following is a corrected and extended ephemeris:—

	R.A. h. m. s.	Decl. ° ′	Brightness.
Feb. 29 ...	19 46 48 ...	+ 1 55·1 ...	0·12
Mar. 4 ...	46 41 ...	3 0·7 ...	0·11
,, 8 ...	19 46 16 ...	+ 4 6·7 ...	0·10

M. Bigourdan describes the comet as being round, with a diameter of about 50″, and showing a somewhat diffuse nucleus. It is seen with about the same facility as a star of the twelfth magnitude.

MAGNETIC SURVEYS.[1]

ON looking through these two volumes, the first thought that strikes one is that magnetical observations require a great deal of time for reduction and preparation for publication. In the Russian work, this great consumption of time is perhaps to some extent explained by the distance that separates the place of observation from any centre of civilisation, whence the results could be published, and the inevitable difficulties of communication. Perhaps still more is it to be explained by the fact, that several authors have to compile their separate portions under editorial supervision. Still, eleven years does seem a long interval to elapse between the completion of the observations and the distribution of the results to the public. In the Italian work; carried out in the cultured and accessible cities of Italy, six years have sufficed for the reduction and the printing.

This remark must not be construed as expressing any wish to minimise the difficulties that a scientific expedition to the wilds of North-East Siberia must of necessity encounter, or to make light of the dangers that these enterprising officers experienced in their expatriation, cheerfully endured for scientific ends. One disaster that these scientific experts had to undergo may be mentioned, as it illustrates not only the severities under which they were placed, but the readiness of resource with which they remedied the mishaps, far away from trained workmen and mechanical apparatus. On August 6, 1882 (about the time of the Fort Rae Expedition, it may be remarked), when nearing their destination, they experienced a north-east storm of more than an unpleasant character, which carried their craft on to the rocks, and tumbled their apparatus into the water. The chest containing the instruments for observing the magnetic variation at Ssagastyr (Long. E. 8h. 26m.; Lat. 73° 23′ N.) remained some hours at the bottom, before it could be successfully landed,

[1] "Beobachtungen der Russischen Polarstation an der Lenamündung." I. Theil Astronomische und Magnetische Beobachtungen 1882–1884." Bearbeitet von V. Fuss, F. Müller und N. Jürgens. Herausgegeben von Dr. A. v. Tillo, 1895.

"Misure Assolute degli Elementi del Magnetismo Terrestre, eseguite in Italia negli anni 1888 e 1889 dal Dott. Luigi Palazzo." (Roma, 1895.)

and when opened, on September 6, it presented a gruesome spectacle. The magnets were covered with rust, the wood-work was swollen and would not fit the joints for which it was intended, the wires in the eyepieces missing, silvered mirrors spoilt, and other horrors which it can be imagined scientific apparatus would present after such treatment. All the damages had to be remedied on the spot by their own ingenuity, while, to add to their distress, they lost by the upset much of their petroleum, and had to reduce their light. Nevertheless, in the early days of November, all repairs were effected and the instruments ready for work.

The results of the expedition are practically divided into three parts. In the first, which is more especially under the superintendence of M. V. Fuss, are given the description of the method and the results of the observations at numerous stations for the determination of geographical position. These observations have not been made with that rigorous accuracy to which we are accustomed in inquiries that have for their aim the discussion of the variations of latitude. They are rather field observations, made with the sextant, and instruments possessing similar accuracy, and are no doubt very useful in constructing maps of a practically unknown country. In the same way with the longitude determinations, there is no electrical communication between these places, of which Jakutsk is possibly the only one that would be recognised by the ordinary English reader. A few box chronometers were carried from station to station to determine the difference of local time. Moon culminations and occultations were also employed, and, strange to say, eclipses of Jupiter's satellites. Nothing is said about the errors of the tables or the corrections that have been applied to remove those errors, but the results agree fairly well with other methods. Possibly those observations only have been used, which coincided with others made in a known longitude; but since the whole chain is made to depend for absolute longitude on that of a station at Jakutsk, determined on the occasion of the eighteenth century transits of Venus, and now unrecognisable, they do not probably interfere much with the final accuracy. The outcome of the inquiry is to give us more or less trustworthy positions of some twenty-four stations ranging between 8h.-9h. east longitude from Greenwich, and from 60°-74°, north latitude.

In the next section, under the superintendence of MM. N. Jürgens and F. Müller, are presented the results of the magnetical observations. M. Müller's part is more particularly confined to deriving the elements of the earth's magnetism at a considerable number of stations, all in North-East Siberia, by a few observations of the declination, dip, and horizontal force at each. M. Jürgens took charge of the Ssagastyr station, where, in greater detail, he sought not only the absolute force, but the hourly variation of the magnetic elements. M. Müller, as his share, is able to present a table in which, for seventeen stations, the three elements have been fairly well determined, while in twenty-eight more or less complete observations have been made. From November 1882 to June 1884, M. Jürgens' department made hourly observations of the declination, and of the horizontal and vertical force, and on selected days observations at every five minutes. The instruments appear to have been critically examined, and the results of an inquiry conducted so far away from beaten tracks possesses a special interest.

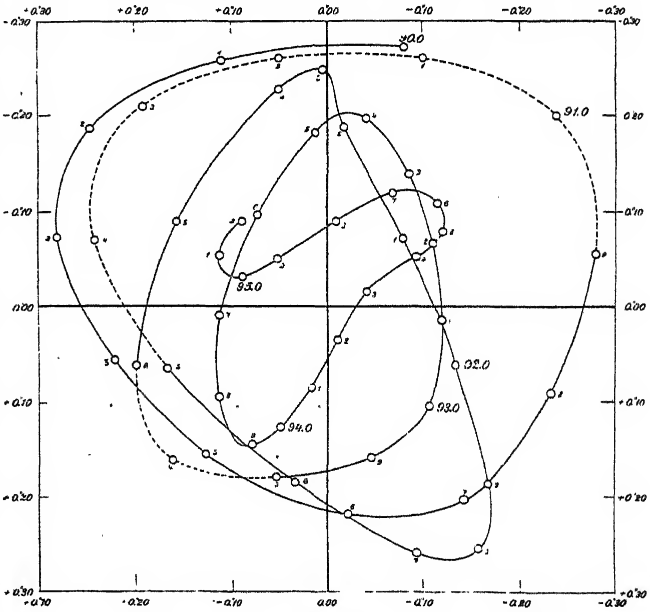
Advantage was taken of the peculiar position to make some observations on the aurora as to its form, colour, direction, and altitude. These will be found in what may be called the third section, together with the history of the expedition written by Dr. A. Bunge, wherein will be found many interesting remarks on a country but little known. The climate, the native inhabitants, the flora and fauna of the district, all come more or less under his observant notice, and are treated easily and pleasantly.

In the second work the element of adventure is, of course, wanting, and, with greater ease, Dr. Palazzo has been able to collect his data from various points on the Italian Peninsula, in such a way as to present a tolerably complete magnetic survey of the whole country. A chain of stations has been selected, starting from Rome and proceeding south-east past Naples towards Brindisi. Other positions have been occupied on the Adriatic coast, including one in the Tremiti Isles; while another group occupies the north-east, and includes Venice, Ravenna, and other well-known places. The entire series includes twenty-two stations. Dr. Palazzo has devoted great attention to the form of his instruments, and has been alive to the importance of deriving the instrumental constants with accuracy. His method of procedure is set out at length in the first part of his paper. In the second part, the details of his observations are given. On the average, these do not extend over more than two or three days at each station, which have sufficed for the determination of the declination by observing azimuths of the sun. The horizontal force has been obtained by the method of counting the number of oscillations made by the magnet in a given time. These in connection with the dip, also derived at each of the stations, have permitted him, in the usual method, to derive the vertical force and total intensity. The whole operation and deductions are conveniently exhibited in symmetrically arranged tables.

THE MOVEMENTS OF THE TERRESTRIAL POLE DURING THE YEARS 1890-95.

TOWARDS the latter end of last year Prof. Albrech gave a preliminary account of the, then, known movements of the terrestrial pole at the eleventh general conference of the "International Erdmessung." Since that date he has made a more definite investigation, the results of which will be published in the *Verhandlungen der Berliner Conferenz*; but as this will not just yet appear, he gives in the current number of the *Astr. Nach.* (No. 3333) a brief summary of the results.

The observations have been made at several observatories, namely, Kasan, Pulkowa, Prag, Berlin, Bamberg, Kiel, Karlsruhe, Strassburg, New York (Columbia College), and Bethlehem, also at the Military Geographical Institute in Vienna, the



Curve showing the relation between the *mean* and *apparent* positions of the pole during the years 1890-95.

Geodetic Institute in Potsdam, and at the American Coast and Geodetic Survey.

Prof. Albrech has not, however, used all the observations in the discussion, but enough "um den Versuch einer Ableitung der Bahn des Pols für den ganzen fünfjährigen Zeitraum mit Aussicht auf Erfolg durchführen zu konnen."

The method of computation adopted was somewhat analogous to that employed by Kostinsky in 1893. Commencing with the monthly observed mean from each station, the deviations $(\phi - \phi_0)$ of the instantaneous pole elevations from a very accurate mean value were graphically formed for every tenth part of the year; a system of coordinates was also arranged in which the positive-axis of x pointed towards Greenwich, that of y 90° to the westward, the origin coinciding with the mean position of the pole.

In this way Prof. Albrech obtained a series of points, which, when plotted out and connected together by means of a curve, would show the relation of the position of the terrestrial pole, at any moment during the interval covered by the observations, to its mean position.

The accompanying curve is a reproduction of that given by Prof. Albrech.

It will be seen that the curve commences moving round the origin of coordinates, gradually closing up, and becoming more elongated in form, the difference between its instantaneous and mean positions decreasing up to 1895 very perceptibly. The dotted path is traced through points which have been interpolated, and which could not be directly obtained owing to insufficiency of observations.

The general trend of the plotted points indicates an unmistakable decrease in the amplitude during the five years of observation, and, as Prof. Albrech points out, the movement is by no means simple, but necessitates the presence of more terms in the expression for representing this motion.

The communication concludes with a table giving the values for every 30° of longitude of the terms

$$x \cos \lambda + y \sin \lambda$$
$$\text{and } y \cos \lambda - x \sin \lambda$$

for the different epochs in connection with the three equations for calculating the variations in the altitude, azimuth, and longitude, namely,

$$\phi - \phi_0 = + x \cos \lambda + y \sin \lambda$$
$$a - a_0 = + (y \cos \lambda - x \sin \lambda) \sec \phi$$
$$\lambda \quad \lambda_0 = - (y \cos \lambda - x \sin \lambda) \tan \phi$$

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Prof. J. J. Thomson, F.R.S., has been appointed Rede Lecturer for the present year.

The Natural Sciences Tripos will begin on May 27, and the various practical and oral examinations will not be concluded until June 16.

Prof. Ramsay, F.R.S., has been appointed an Elector to the Jacksonian Professorship of Natural Philosophy, now held by Prof. Dewar, F.R.S.

A meeting of members of the Senate, presided over by the Provost of King's, was held on Saturday last, at which resolutions were passed unanimously in favour of granting a titular recognition (such as an honorary B.A.) to qualified women, and against conceding anything that might lead to the transformation of Cambridge into a "mixed" University.

SIR HENRY ROSCOE has been elected Vice-Chancellor of the University of London, in the place of the late Sir Julian Goldsmid. Mr. F. V. Dickins, the Assistant-Registrar, has been elected Registrar, in the place of Mr. A. Milman, retired.

WE have received a combined Calendar, History, and General Summary of Regulations of the Department of Science and Art (1896). From the statistics therein given it appears that there are 2889 Science and Art Schools in the United Kingdom, and that they contain among them 167,822 students in science classes, and 132,256 students in art classes.

THE fourth annual Report of the Technical Instruction Sub-Committee of the City of Liverpool, which deals with the work accomplished by them during 1895, is eminently satisfactory. Abundant evidence is furnished that great things have been accomplished in Liverpool during the past year. Preliminary steps have been taken towards the erection of a central institution for the accommodation of evening science and technological classes. Three organised day science schools have been established; and a school of applied arts has been called into existence. An electro-technical department, evening courses of advanced work in the engineering laboratories, a special department dealing with the science and art of education, have all grown up at the University College of the city as a result of the assistance given by the Technical Instruction Sub-Committee. But the difficulty arising from insufficient previous education, which is hampering the work of similar Committees in all parts of the country, is very much felt in Liverpool. The Chairman reports: "Institutions which were founded to give a strictly technical education have had, in many cases, to enlarge their borders, and provide preparatory departments or classes, in which to prepare students, by a general preliminary training, to take proper advantage of the special technical teaching." We cordially commend the following decision of the Liverpool Committee to all whom it may concern: "Partly on this ground, but still more from a conviction that the best preparation for commercial pursuits—the staple 'industry' of Liverpool—is to be found in a thoroughly good modern general education, the Committee have sought to encourage and assist the public secondary schools of the city to adapt themselves to give such an education."

The variegated nature of the technical education which has been developed throughout the country as a result of the Acts dealing with the question, is strikingly apparent to us each time we receive a new report. Though that of Liverpool is so satisfactory as a whole, its list of "technical" subjects emphasises this point yet again. On p. 49 of the Technical Instruction Committee's report, we find they encourage the teaching (amongst a large number of other subjects) of singing and musical notation, instrumental music, type-writing, tailors' work, cabinet-making, ship carpentry and joinery, and so on. The extraordinary thing is, in view of the express clause of the Technical Instruction Act, 1889, "that technical instruction shall not include teaching the practice of any trade or industry, or employment," that the Science and Art Department should sanction such subjects as these.

SCIENTIFIC SERIALS.

Bulletin de la Société des Naturalistes de Moscou, 1895, No. 1.—The vascular cryptogams of the Middle Urals and the surrounding territory, by P. W. Ssüsew (in German). The ferns which freely grow in the shadow of the pine forests of the Urals, make a substantial and most picturesque part of the flora of the country. The most common species are:—*Polypodium dryopteris*, *Phegopteris polypodiodides*, *Athyrium filix femina*, *Asplenium crenatum*, *Aspidium spinulosum*, &c. In the stony parts of the highlands one finds the elegant species of *Allosurus*, *Woodsia*, *Asplenium ruta muraria*, *A. viride*, *A. septentrionale*, and many others, which disappear already at a short distance from the Ural range, although the conditions for their growth seem to be the same. Latest research has shown that only three species, characteristic of the Northern Urals, do not appear in the middle and southern parts of these mountains. Forty-seven different species are described.—On adhesion between metals, glass, and different other substances, by J. Weinberg (German). The observations of M. Charles Margot are discussed, and the author shows that the different degrees of adhesion between different substances agree with his molecular formula.—From the shores of the Mediterranean, by H. Trautschold (in German). The structure of the conglomerates and other deposits on the shores of the Mediterranean Sea at Nizza is discussed in order to show that the phenomena are best explained by a retreat of the sea, but do not agree with an upheaval of the coast.—*Lanius eleagni*, a new species, akin to *Otomela Bogdanowii*, Bianchi, by P. Suschkin.—The tail-organ of the *Raja*, by N. Iwanzoff (in German), with three plates. Detailed anatomical work, in which the difficulties that the pseudo-electrical organs of fishes are supposed to offer to Darwin's theory are discussed and explained.—On the *Libellulideæ* of Poltava and Kharkov, by V. N. Roozianko (in Russian). Fourteen species are described.—Catalogue of the fungi of Smolensk, by A. A. Jaczewski (in Russian). Two hundred and fifty-four species are enumerated. The author makes the remark that the forests are extremely rich in species of *Russula*, and that all the species of this genus, without exception, are used for food by the peasants, but that cases of poisoning are never heard of. He makes the suggestion that perhaps the poisonous species, *Russula emetica* and *R. rubra*, are very rare (each was found only once); but altogether it must be supposed that the manner of cooking destroys their poisonous properties, if they exist—a question which well deserves scientific investigation.—List of members.

Bollettino della Società Sismologica Italiana, vol. i., 1896, No. 8.—The Cecchi microseismograph, by G. Giovannozzi. The first description of the instrument published in a scientific journal.—Hydrothermal observations at Fiumecaldo (Catania) in May and June 1895, by C. Guzzanti.—Notices of Italian earthquakes (June–July 1895), the more important being the Venetian and Lubiano earthquakes of June 10, and the disastrous earthquake which occurred on the east coast of the Caspian Sea during the night of July 8–9. Copies of two of the microseismographic records of the latter earthquake obtained at Rome are given.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 12, 1895.—"Impact with a Liquid Surface, studied by means of Instantaneous Photography." By Prof. A. M. Worthington, F.R.S., and Mr. R. S. Cole.

This communication was the first instalment of a review by the aid of instantaneous photography of the ground covered by three previous papers (*Roy. Soc. Proc.*, vol. xxv. pp. 261 and 498, 1877, and *ibid.*, vol. xxxiv. p. 217, 1882), in which the phenomena that accompany various kinds of splashes are described. The advance made lies in the unquestionable accuracy and fullness of detail of the information now afforded.

Chemical Society, February 6.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read:—The molecular weight and formula of phosphoric anhydride and of metaphosphoric acid, by W. A. Tilden and R. E. Barnet. Vapour density determinations of phosphoric anhydride show that it has the molecular composition P_4O_{10}; metaphosphoric acid, which partially dissociates into water and the anhydride on heating, is similarly shown to have the formula $H_2P_2O_6$.—Lead tetracetate and the plumbic salts, by A. Hutchinson and W. Pollard. Lead tetracetate, prepared by dissolving red lead in acetic acid, crystallises in monosymmetric needles. Lead tetraphosphate and tetrapropionate have also been prepared.—An improved method of determining urea by the hypobromite process, by A. H. Allen. The incomplete evolution of nitrogen occurring when hypobromite is added to urea may be avoided by mixing potassium cyanate with the urea solution; it is also preferable to run the urea and cyanate solution into the hypobromite instead of *vice versâ*.—Preliminary note on the absorption of moisture by deliquescent salts, by H. W. Hake. The author has determined the amount of water absorbed by exposing deliquescent salts to the air, and finds that in many cases the amount of water taken up points to the formation of a definite hydrate.—Some derivatives of γ-phenoxyethylmalonic acid and of γ-phenoxyethylacetic acid, by W. H. Bentley, E. Haworth, and W. H. Perkin, jun.—Note on the preparation of glycol, by E. Haworth and W. H. Perkin, jun.—Luteolin, by A. G. Perkin. Luteolin, the yellow colouring matter of Weld (*Reseda luteola*), has the composition $C_{15}H_{10}O_6$, combines with mineral acids, and yields tetracidic derivatives; it seems to be allied to its isomeride fisetin.—An examination of the products obtained by the dry distillation of bran with lime, by W. F. Laycock. On distilling bran with quicklime an aqueous and oily distillate is obtained, which contains ammonia, ketones, ethylic alcohol, pyridines, pyrrolines, furfuranes, hydrocarbons, and an indole.—Constitution of glycocine, by Jōji Sakurai.

Entomological Society, February 5.—Prof. Raphael Meldola, F.R.S., President, in the chair.—The President announced that he had nominated Dr. D. Sharp, F.R.S., Mr. Roland Trimen, F.R.S., and Mr. Walter F. H. Blandford, Vice-Presidents for the Session 1896-97.—Mr. Waterhouse exhibited pupæ and portions of pupæ of a silk moth, *Antheræa mylitta*, selected from some scores of specimens, which he had opened to see if they showed stages of development agreeing with the examples given by Dr. Spuler. The results appeared to confirm Dr. Spuler's researches: some specimens showed the tracheæ, the median vein having two branches, very rarely emitting a third branch in the direction of the radial. Other specimens had faint indications of the veins and of the discoidal spot of the imago. Even at this very early stage the vein branching from the subcostal vein to unite with the upper radial, and the short branch uniting the second median vein with the third median were distinctly traceable, no tracheæ being yet visible in these branches. Mr. Merrifield, Mr. Hampson, and Dr. Sharp took part in the discussion which ensued.—Mr. E. E. Green remarked that in the *Trans. Ent. Soc.*, 1881, p. 601, there was a short paper by the late Prof. J. O. Westwood, describing a curious little insect from Ceylon under the name of *Dyscritina longisetosa*. Prof. Westwood believed his typical specimens to be immature. Mr. Green exhibited what he supposed to be a later stage of the same species. He said his example differed in some particulars from Westwood's description and figure—notably in the proportions of the caudal appendages. Prof. Westwood pointed out the affinities of *Dyscritina* to the Forficulidæ. This was very apparent in the specimen under consideration. Putting aside the nature of the caudal appendages the insect was in all particulars an earwig. The present specimen was taken in the Punduloya district of Ceylon, at an elevation of about 4000 feet. Mr. Green said he had more than once seen this insect under loose pieces of bark and in crevices of rocks, and had always been struck by its likeness to an earwig both in appearance and habits. Mr. McLachlan, F.R.S., Dr. Sharp, Mr. Gahan, Mr. Blandford, and Mr. Hampson made some remarks on the subject.—Mr. O. E. Janson exhibited a Goliath beetle, from the Upper Congo, which he believed to be the male of *Goliathus rusus*, Kolbe, described from a unique female example in the Berlin Museum.—Mr. Blandford called attention to the case of the eye of a boy affected with inflammation caused by the hairs of the larvæ of *Lasiocampa rubi*. The attack recurred after an interval of nineteen weeks, and in several continental cases this recurrence of the attack had been found to take place, and in some cases permanent injury to the eye had followed. Mr. Blandford discussed the various kinds of hairs on several caterpillars, certain species having hairs of two kinds, one kind being barbed, and thus having the power to work into the skin. He said that the urticating property of the hairs appeared to be mechanical: there was no evidence of any poison glands. Mr. Lawford said he had had some difficulty in discovering hairs in the lid, and he thought that the symptoms in the case in question were not to be explained by mechanical irritation due to the presence of hairs in the tissues. The subject was a new one to him, and he had looked up all the medical literature bearing on it. Lord Walsingham, F.R.S., Mr. Tutt, Prof. Poulton, F.R.S., Canon Fowler, and Mr. Jacoby made some remarks on the subject.—Dr. F. A. Dixey read a paper entitled "On the Relation of Mimetic Patterns to the Original Form." The paper was illustrated by a number of coloured diagrams. Prof. Poulton expressed his gratification with the paper, and that the Hope Collection under his charge had afforded material for the work. He thought the result of the paper was to give support to the theories of Fritz Müller rather than to those of Bates. Mr. Blandford, Mr. Tutt, and Prof. Meldola continued the discussion.—Dr. Sharp contributed a paper entitled "The Rhynchophorous Coleoptera of Japan. Part iv."

Linnean Society, February 6.—Mr. C. B. Clarke, F.R.S., President, in the chair.—Sir W. H. Flower, K.C.B., F.R.S., presented to the Society, on behalf of the subscribers, a portrait of Mr. William Carruthers, F.R.S., a former President of the Linnean Society, painted by Mr. J. Hay. At the motion of Mr. J. G. Baker, F.R.S., it was resolved that the portrait be accepted, and that a cordial vote of thanks to the donors be recorded.—Prof. C. Stewart exhibited a series of dissections of skulls, illustrating the development of air cavities. The skull of a herring, carefully dissected to show the relations of the ampullæ of the pneumatocyst to the cranial bones; of a crocodile, to show those of the extra tympanic cavity and siphonium; of a rook, to show the limitations and relationships of the vesicular and other strata of the cranial roof; and of a chinchilla and a *Phascolarctus*, to illustrate the variations and development of the "bulla" and of its associated structures, were the chief objects shown. Prof. Stewart expressed himself favourable to the belief that the parts mentioned in the herring are functional for acoustic purposes. In this he was supported by Prof. Howes, who referred in detail to the arrangements occurring in *Hyodon* and *Myonomyrus* as substantiating this conclusion.—On behalf of Mr. B. G. Cormack, Dr. D. H. Scott gave the substance of a paper on polystelic roots of certain palms. He remarked that with scarcely any exception roots show one normal vascular bundle or stele. The author, utilising material from Ceylon, found that in *Areca Catechu*, Linn., *Cocos nucifera*, Linn., and a species of *Verschaffeltia*, the young roots agree with this condition, but on examining older and thicker portions of the same roots, he found many steles present. After discussing the origin of this, the author considered the change to be primary, not secondary, and suggested that these roots might serve as props to the stem. The paper was criticised by Mr. George Murray and Prof. Trail, Dr. Scott replying to objections. Mr. R. Morton Middleton then read a paper on a remarkable use of ants in Asia Minor, communicated by Mr. Miltiades Issigonis, of Smyrna. It was stated that the Greek barber-surgeons of the Levant employed a large species of ant for the purpose of holding together the edges of an incised wound. The ant, held with a forceps, opens its mandibles wide, and being then permitted to seize the edges of the cut, which are held together for the purpose, as soon as a firm grip is obtained the head is severed from the body. Mr. Issigonis had seen natives with wounds in

course of healing, with the assistance of seven or eight ants' heads. The species of ant referred to was a large-headed *Camponotus*, not unlike one found in India. Mr. Middleton recalled the fact that a similar observation, concerning a species of ant in Brazil, had been recorded many years ago by Mr. Mocquerys, of Rouen (*Ann. Soc. Entom. France*, 2[me] sér. ii. 67), as quoted by Sir John Lubbock in his work on ants, bees, and wasps; but the observation, strange to say, had not been confirmed either by Bates or Wallace during their travels in South America. Dr. John Lowe pointed out that in this operation apparently no attention was paid to the usual antiseptic precautions which are regarded as indispensable in modern surgery. Sir William Flower considered the observation of much interest from an ethnological point of view, as showing the independent existence of the same custom in countries so far apart as Brazil and Asia Minor.

Mathematical Society, February 13.—Prof. M. J. M. Hill, F.R.S., Vice-President, in the chair.—The Chairman read the opening paragraphs of a paper by Prof. Forsyth, F.R.S., entitled "Geodesics on a Quadric, not of Revolution."—Prof. Elliott, F.R.S., gave an account of a paper by Mr. A. L. Dixon, on the potential of cyclides.—Mr. Love, F.R S. (Hon. Sec.), communicated a paper on solid ellipsoidal vortex, by Mr. R. Hargreaves.—Dr. J. Larmor, F.R.S., and Lieut.-Colonel Cunningham took part in the discussions on the papers.—The Chairman (Mr. M. Jenkins, Vice-President *pro tem.*, in the chair) and Mr. Tucker (Hon. Sec.) made short impromptu communications. The latter was to the effect that if any square PQRS be inscribed in a circle ABC, and the Wallace lines of P, Q, R, S, with regard to the triangle ABC be drawn, they form by their intersection a quadrilateral the mid-points of whose *three* diagonals are the centre and ends of a diameter of the nine-point circle of ABC.

Zoological Society, February 18.—Prof. G. B. Howes in the chair.—A communication was read from Dr. Arthur G. Butler on the butterflies obtained in Arabia and Somaliland by Captain Charles G. Nurse and Colonel J. W. Yerbury in 1894-95.—A communication was read from Lord Walsingham, F.R.S., and Mr. G. F. Hampson, on the moths collected at Aden and Somaliland by the same naturalists and by other collectors.—Mr. F. E. Beddard, F.R.S., communicated (on behalf of Miss Marion Newbigin) a paper dealing with the metallic colours of humming-birds and sun-birds. It had been held that these peculiarly coloured feathers played some special part in the economy of the bird, for they could not be of much use for flight owing to the disconnected barbules. The author combated this view, pointing out in the first place that the statement of fact did not apply to all humming-birds, in the metallic feathers of which the barbules were often connected by cilia. It was urged in the next place that the very perfection of the flight of humming-birds led to correlated variations in feather structure productive of their especially brilliant metallic tints. The difficulty of the plain-coloured swifts—possibly near allies of the humming-birds—was met by the suggestion that the latter have fewer enemies, and had therefore had greater scope of possible colour-variation.—Mr. C. W. Andrews read a note on a skull of *Orycteropus gaudryi*, an extinct species of ant-bear from the Lower Pliocene deposits of Samos, originally discovered and described by Dr. C. J. Forsyth-Major.—Mr. Frank E. Beddard, F.R.S., read a paper upon the anatomy of the Scissor-bill (*Rhynchops*), in which the structure of the viscera and muscles of this bird were described. The muscular anatomy was found to differ greatly from that of the gulls, skuas, and terns, and was held amply to justify its separation as a distinct subfamily *Rhynchopinæ*.

PARIS.

Academy of Sciences, February 17.—M. Cornu in the chair.—Preparation and properties of cerium carbide, by M H. Moissan. This substance, of which the composition is CeC_2, is produced in the electric furnace from charcoal and CeO_2. Its properties and reactions are similar to those of other carbides previously described, water, however, giving a gas containing ethylene (4 per cent.), methane (21 per cent.), and acetylene (75 per cent.), the composition of the gas obtained in different experiments being very constant. A small proportion of the carbon is obtained in the form of liquid and solid hydrocarbons.—On carbide of lithium, by the same. This carbide, LiC_2, forms a transparent crystalline mass, which, on account of its high percentage of carbon (69 per cent.), acts as a powerful reducing agent. It is volatile at the temperature of the electric furnace, with partial decomposition into its elements, and on treatment with water yields pure acetylene.—Observations of the Perrine comets (*a* 1896 and *c* 1895) made at the Observatory of Paris, by M. G. Bigourdan.—Observations on the Perrine comet made with the large equatorial at the Observatory of Bordeaux, by M. L. Picart.—On the integration of some partial differential equations, by M. Le Roy.—On Taylor's theorem, with approximation to the third degree, by M. N. Bougaief.—On groups of substitutions, by M. A. Miller.—On sensitive flames, by M. E. Bouty. A study of the influence of the nature of the gas on the sensibility to sound. The sensitiveness of a pure hydrogen flame is very small, but it can be increased by the addition of a sufficient proportion of an inert gas, such as nitrogen or carbon dioxide. Pure acetylene gives only a moderately sensitive flame, but a mixture of equal volumes of hydrogen and acetylene responds readily to the ticking of a watch.—On the lowering of the statical and dynamical explosive potentials by the X-rays, by M. R. Swyngedauw.—Electric phenomena produced by the Röntgen rays, by M. A. Righi.—Action of the Röntgen rays on the electrostatic charges and the explosive distance, by MM. J. J. Borgman and A. L. Gerchun.—New researches on the X-rays, by MM. Benoist and D. Hurmuzescu.—Photographic researches on the Röntgen rays, by MM. Auguste and Louis Lumière.—An experiment showing that the X-rays proceed from the anode, by M. de Heen.—Photographs obtained with the Röntgen rays, by MM. A. Imbert and H. Bertin-Sans.—On the property possessed by phosphorescent rays of passing through bodies opaque to solar light, by M. G. H. Niewenglowski.—Nature and properties of dark light, by M. Gustave Le Bon.—Photographic prints obtained in the dark, by M. A. Briançon.—On a rapid method for the estimation of arsenic, by MM. R. Engel and J. Bernard. The arsenic is precipitated in hydrochloric acid solution by hypophosphorous acid, and titrated with standard iodine solution in presence of sodium bicarbonate. The results of the test analyses are satisfactory.—Partial synthesis of geranic acid and constitution of lemonol and lemonal, by MM. P. Barbier and L. Bouveault.—On some derivatives of eugenol, by M. Ch. Gassman.—On the composition of fire-damp, by M. T. Schlœsing, jun. A careful examination of the combustible gas in sixteen samples of fire-damp, from various mines, showed that in thirteen cases the hydrocarbon was pure methane; in the other three, besides methane, traces of ethane (from 2–4 per cent.) appeared to be present.—Walking and running *en flexion*, by MM. Comte and Regnault. A study of a new method of walking and running called *en flexion*, on account of a sudden bend of the knee at a particular point of the stride. It is shown that in this method, which has already been proved to be of great practical advantage in the movement of troops, the vertical oscillations of the body are rendered more gradual, besides being reduced in magnitude. A dynamographic study of the variations of the pressure on the feet also brings out the same point, sudden variations of pressure disappearing from the curve—On a new application of photography, by M. G. Guéroult.—Some applications of a mode of production of colour, hitherto unexplained, by M. C. Henry.—Undulatory irradiation of luminous impression, by M. A. Charpentier.—Assimilation and activity, by M. P. Vuillemin.—On an epidemic of pneumonia of the hare, caused by *Strongylus retortæformis*, Zeder, by M. E. Yung.—The lacunar apparatus of the starfish, by M. L. Cuénot.

BERLIN.

Physiological Society, January 10.—Prof. Munk, President, in the chair.—Dr. Joachimsthal spoke on a supposed self-regulative process in muscles as based on the observation that the calf-muscles are long and thin in negroes, but short and thick in whites. This depends on the relative lengths of the calcaneum. In the negro the muscle is inserted on a longer arm of this bone, and this necessitates a more extended contraction of the muscle; in a white man the arm is shorter, but this requires a correspondingly greater force, and hence the muscle is shorter and thicker. An experiment had been made by Marey on rabbits with reference to the above, and the speaker described some recently made by himself on a cat in support of his views. In the subsequent discussion considerable objection was raised against the validity of the experiments, some of the results being attributed to muscular atrophy.—Prof. Zuntz reported on experiments made by Dr. Lewin, of New York, in which, using a dog, the stomach had been connected directly with the intestine so as

to exclude that portion into which the ducts of the liver and pancreas open. He then fed the animal on cream, and found that in no single case was any of the emulsified fat absorbed.—Dr. R. du Bois Reymond exhibited a number of Röntgen photographs.

January 24.—Prof. du Bois Reymond, President, in the chair.—Dr. Apolant spoke on the ciliary ganglion, which has at one time been regarded as a spinal, at another time as a sympathetic structure, these views being based on anatomical, morphological, embryological and physiological researches. Of late years it has been shown by stimulation that this ganglion is in the closest relationship to the oculomotor nerve, and the speaker had made experiments on cats and found that the degeneration set up by section of this nerve progresses only as far as the cells of the ganglion; whereas the latter, as well as the ciliary nerves which spring from them, remain intact. He hence concluded that the ganglion belongs to the sympathetic system.—Dr. Rawitz described how he had, by means of his new method of staining, investigated the attraction-spheres in the testicular cells of salamander maculosa during the first stages of division. He found that the sphere, which is stained dark by alizarin, becomes larger and stains less deeply, after which amœboid processes make their appearance on its surface. These then separate off in a globular form, whereby the sphere becomes divided up into some six or nine small dark spherules. Later on the central zone of the sphere becomes elongated, oval, and spindle-shaped, the spherules arranging themselves longitudinally in the axis of the spindle. After this the central spherules disappear, leaving only the two polar end particles, which then undergo the ordinary well-known later changes. These observations were made on salamanders caught in June; later in the year, the above phases were no longer to be seen.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, FEBRUARY 27.

ROYAL SOCIETY, at 4.30.—On the Spinal-Root Connections and Ganglion-cell Connections of the Nerve Fibres which produce Contraction of the Spleen: Prof. Schäfer, F.R.S., and B. Moore.—A Method for rapidly producing Diphtheria Antitoxines. Preliminary Note: Dr. C. Wood.
ROYAL INSTITUTION, at 3.—Some Aspects of Modern Botany: Prof. H. Marshall Ward, F.R.S.
INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Electric Wiring Question: F. Bathurst.—Concentric Wiring: Sam. Mavor.—High-Voltage Lamps and their Influence on Central Station Practice: G. L. Addenbrooke.
SOCIETY OF ANTIQUARIES, at 8.30.

FRIDAY, FEBRUARY 28.

ROYAL INSTITUTION, at 9.—Marine Organisms and their Conditions of Environment: Dr. John Murray.
PHYSICAL SOCIETY, at 5.—Experiments with Incandescent Lamps: Sir D. Salomons.—The Alternating Current Arc: Messrs. Fleming and Petavel.
INSTITUTION OF CIVIL ENGINEERS, at 8.—Loughborough Sewage-Disposal Works: Arthur S. Butterworth.

SATURDAY, FEBRUARY 29.

ROYAL INSTITUTION, at 3.—Light: Lord Rayleigh, F.R.S.

MONDAY, MARCH 2.

SOCIETY OF ARTS, at 8.—The Chemistry of certain Metals and their Compounds used in Building, and the Changes produced in them by Air, Moisture, and Noxious Gases, &c.: Prof. J. M. Thomson.
SOCIETY OF CHEMICAL INDUSTRY (Burlington House), at 8.—Artificial Silk: Messrs. Cross and Bevan.
VICTORIA INSTITUTE, at 4.30.—Paper by Dr. Guppy.

TUESDAY, MARCH 3.

ROYAL INSTITUTION, at 3.—The External Covering of Plants and Animals: Prof. Charles Stewart.
SOCIETY OF ARTS, at 8.—The Commercial Prospects of English East Africa and British Central Africa: G. Scott Elliot.
ZOOLOGICAL SOCIETY, at 8.—Remarks on the Divergences between the "Rules for Naming Animals" of the German Zoological Society and the Stricklandian Code of Nomenclature (to introduce a discussion on Zoological Nomenclature): P. L. Sclater, F.R.S.—On the Ornithological Researches of M. Jean Kalinowski in Central Peru: Graf Hans v. Berlepsch and J. Stolzmann.—On West Indian Terrestrial Isopod Crustaceans: Adrian Dollfus.
INSTITUTION OF CIVIL ENGINEERS, at 8.—On Littoral Drift in relation to River-Outfalls and to Harbour-Entrances: William Henry Wheeler.
PATHOLOGICAL SOCIETY, at 8.30.
ROYAL VICTORIA HALL, at 8.30.—A Visit to the Orkney Islands: J. Saxon Mills.

WEDNESDAY, MARCH 4.

THEORIES OF EVOLUTION.

Darwin and After Darwin: an Exposition of the Darwinian Theory, and a Discussion of Post-Darwinian Questions. By the late G. J. Romanes, F.R.S. &c. II. Post-Darwinian Questions—Heredity and Utility. Pp. 344. (London: Longmans, Green, and Co., 1895.)

PROF. LLOYD MORGAN tells us, in a prefatory note, that the greater part of this work was in type before the lamented death of the author. The material for chapters v. and vi. existed in the form of "notes and isolated paragraphs," which have been arranged for the press, but otherwise practically untouched. The editor has performed his task with great skill, and has succeeded in attaining the object which he wisely held in view—the production of a work which is in every way characteristic of its author and of no one else.

The frontispiece is an admirable reproduction of a photograph of the author—a most excellent likeness, which will, in itself, invest the book with deep interest for many readers.

Of the ten chapters, the first is introductory, the succeeding five deal with "characters as hereditary and acquired," while the remaining four are devoted to "characters as adaptive and specific."

In the introductory chapter, the views of Darwin and Wallace are contrasted in much detail. In a table on p. 6, "the theory of Natural Selection according to Darwin" is apparently compared with "the theory of Natural Selection according to Wallace": in reality, however, the theories are not compared or contrasted in any way—the only comparison being in the extent to which they were applied by these two naturalists respectively, and in their use or neglect of accessory theories. The high importance which Wallace ascribes to natural selection, and his inability to accept any other existing suggestions as to the origin of species, are, in this table, brought together into a set of dogmatic statements, which, as the present writer thinks, are far from expressing his views.

It is contended that Darwin progressively ascribed less and less importance to natural selection: "The longer he lived, and the more he pondered these points, the less exclusive was the *rôle* which he assigned to natural selection, and the more importance did he attribute to the supplementary factors" (p. 8; see also p. 40). Some of his latest letters, however, do not support this view of an unbroken progressive tendency.

Many of the author's well-known arguments against the use of the term "Darwinism," as opposed to "Lamarckism," are here reproduced and brought forward in a very forcible manner. The contest, however, is entirely due to the fact that the combatants ascribe different meanings to the same word. To the author, "Darwinism" means the whole of the views which Darwin entertained upon the origin of species; to his opponents, "Darwinism" means those views upon this subject which were originated by Darwin (viz. the theory of natural selection). It is no doubt true, as is contended on pp. 10, 11, that the "Lamarckian" principles (of use and disuse, &c.) accepted by Darwin were independently conceived by him, and that he did not owe them to Lamarck; but the fact remains that they were originated by the latter, and not by Darwin.

The latter part of the introductory chapter deals in a brief but very effective manner with the three theories of evolution associated with the names of Cope, Geddes, and Henslow, and in greater detail with Wallace's well-known views upon the insufficiency of natural selection to account for the origin of the human race.

In chapter ii. the relationship between Weismann's views is represented in the diagram on p. 43, and in statements which describe the formation of a "postulate as to the absolute non-inheritance of acquired characters" in order to support the "deduction as to the absolute continuity of germ-plasm," and this again in order to support the further deductions "as to the theory of organic evolution" and "as to the architecture of germ-plasm." From this mode of representation the reader unacquainted with Weismann's writings, at first hand, might readily receive the impression of a flimsy speculative structure unsupported by investigation, which would be doing scant justice to the distinguished German biologist.

Weismann's theory of heredity, based on the continuity of the germ-plasm, grew directly out of his researches upon the sexual cells of Hydrozoa, and was thus founded directly upon the results of investigation. The hereditary transmission of acquired characters was not at first called into question, but, later on, the extreme difficulty of explaining such transmission by means of a theory of heredity, which on other grounds appeared to be sound, suggested an inquiry into the supposed fact of the transmission itself. This subject was then dealt with on its own merits, and it was soon apparent that the evidence had a very different bearing from that which had been generally assumed. The later and frequently changing hypotheses as to the architecture of the germ-plasm were an attempt to explain the results of the unceasing inquiry into the changes undergone by the sexual cells. Newer and more complex phases of change were ever being made out in this most fruitful field of investigation, suggesting modifications in the details of Weismann's hypothesis of the structure of germ-plasm, and not ending here, but suggesting also fresh lines of observation and research. Indeed it may be maintained that the errors which have appeared from time to time in the details of Weismann's hypotheses are due to an attempt to render the hypotheses too much up-to-date, by taking into account all the most recent observations in an exceptionally difficult line of research—observations many of which could not be final, and some of which were bound to be altogether erroneous.

It will be impossible to attempt any adequate discussion of the admirable treatment of the facts and arguments for and against the hereditary transmission of acquired characters. These chapters will require the careful consideration of writers on either side of the controversy. Not only is the discussion itself most valuable, but new facts are submitted. Brown-Séquard's experiments on guinea-pigs have been repeated with great care, but no definite conclusions can be safely drawn from the results. "On the whole, then, as regards

T

Brown-Séquard's experiments, it will be seen that I have not been able to furnish any approach to a full corroboration. But I must repeat that my own experiments have not as yet been sufficiently numerous to justify me in repudiating those of his statements which I have not been ably to verify" (p. 122).

The second section of the work deals with "Utility," and opens with the contention already familiar in the author's earlier writings, that natural selection is not a theory of the origin of species, but of the origin of adaptations. The discussion throughout this section is of great interest, although perhaps somewhat too controversial in tone; but this is a consequence of previous controversies on the same subject. The effect of controversy here, as in other cases, is to emphasise the differences of opinion. The present writer ventures to think that if this question of the utility of specific characters were treated less controversially and more by the discussion of particular examples, very little difference of opinion would be found to exist. The essence of the question is contained in the definition of the term "specific character," and this again depends on the definition of the term "species." But we know that no satisfactory, viz. generally applicable, objective definition of species can be given, inasmuch as the subjective ideas of the species describer have been of pre-eminent importance.

In certain classes of cases the species describer has, and obviously correctly, made adaptive characters his criteria; for instance, in the species of Ranunculus alluded to by Mr. Thiselton-Dyer in his discussion of this question, as President of Section D, at Bath (British Association Reports, p. 692). Of the opposite kind are the various representative races or species which we meet as we trace the distribution of numerous forms of life over the earth's surface, and which are especially well seen in the Heliconine Danainæ from tropical America, in the Godman-Salvin Collection. Following one of these forms in its range we find, in numerous cases, that different areas are characterised by differences in the colours and markings of the wings. The colours and markings themselves are believed by many to be adaptive, and to be of value for the purposes of warning; but the local differences alluded to cannot be explained in this way, except in the cases of mimicry between local forms. Assuming the received explanation to be correct, natural selection would appear to have operated only in preventing the local differences from diminishing the efficiency of the warning character. But these local forms of colouring and marking are made the criteria—and are, indeed, apparently the only criteria—of specific distinction in numberless cases. It may be that, in many of these cases, future investigation will prove a biological continuity of the forms over the whole of the range, so that the names which are now applied to species will have to be used for geographical races. In the interests of biological science it is necessary that the naming of different forms should proceed at a much faster rate than the scientific proof of specific rank: indeed, the latter must, in the majority of cases, be a very slow and arduous process. Much confusion and controversy would be avoided if describers were clearly to state, as regards a large proportion of the forms described every day, that specific rank is only provisionally claimed. There is abundant justification for conferring a name, or a number, or some kind of ticket, upon every clearly marked form, quite apart from the question of its specific rank.

It therefore follows that this controversy must be a barren one as regards a very large proportion of the forms which are now distinguished as species, especially in groups like the Insecta, in which such forms are most numerous. Among the cases in which specific rank is indisputable, it can hardly be maintained that all the superficial differences between two allied species which have resulted from separation on the opposite sides of some geographical barrier, are necessarily adaptive.

This work, like all the writings of its author, is sure to appeal to a wide circle of readers, and will be of high value in bringing before the public the discussion, by an exceptionally acute thinker, of some of the most disputed and difficult points in modern theories of evolution; while biological science cannot fail to gain by the attention directed to the need for further observation and experiment in order that a final decision may be reached.

E. B. P.

COMPLETION OF THE "INDEX-CATALOGUE."

Index-Catalogue of the Library of the Surgeon-General's Office, United States Army. Authors and Subjects. Vol. xvi. W—Zythus. Folio, pp. xiv. + [282] + 822. (Washington: Government Printing Office, 1895.)

THIS sixteenth volume completes the twenty years' labour of Dr. J. S. Billings, and brings the catalogue of the finest medical library in the world to the close of the alphabet. We have in previous articles remarked on its extraordinary fulness, and its value to all engaged in the study of medical literature. For it is not merely a guide to the Washington Library; it is a classified index to something like a moiety of all that has ever been published on medicine and its allied sciences. Ample and distinctive descriptions are given of more than 300,000 books and articles, with over 800,000 cross-references. The volume before us has an additional feature of the greatest usefulness. No less than 282 folio pages are required to contain a list of the abbreviated and the complete titles of the periodicals, transactions, reports, and the like, now or formerly issued in all parts of the world and in every civilised language. The abbreviations are those used in the catalogue; but they are so concise, and at the same time so sufficient, that it would be well if they could be uniformly adopted by all who quote—and give their authority.

The recent international testimonial to Dr. Billings, and the public banquet at which, with his fellow-workers, Dr. Chadwick, of Boston, and Dr. Fletcher, originally of Bristol, he was a few weeks ago honoured in Philadelphia, have furnished some indication of the widespread feeling of grateful admiration his great enterprise has evoked among his medical and scientific brethren. The feeling has found stately expression in the Latin diploma whereby an honorary doctorate was conferred by the University of Munich on the Surgeon-General:

"A man who deserves of his country and of literature the highest praise, not only for his numerous important writings on the relations of physicians, on the proper construction and administration of hospitals, on the public health of the United States according to the precepts of the science and art of hygiene, on the preservation and improvement of the health of the army, but also for the great collections thereto relating which he has established and extended; a man who, in the "Index Medicus" of which he is the editor, includes by indefatigable industry all the branches of medicine that are being advanced throughout the whole world, who also, as author of the book entitled the "Index-Catalogue," which by the remarkable munificence of the Government of the United States has been laid before an immense number of learned men, has entitled himself to the gratitude of physicians and students of history over the entire world, and has fashioned for himself a monument more enduring than brass."

It must be remembered that not only the "Catalogue" but the Library itself is essentially of Dr. Billings' creation, and that about one-sixth of its contents have been presented either by way of direct gift or in exchange. It speaks highly for his personal "magnetism" that he can write: "There are few medical writers now living who have not sent to the Library at least one pamphlet." Thus, while the "Catalogue" has been passing through the press, a multitude of fresh gifts and additions have accumulated, and the completion of the "first series" only makes way for the commencement of a second. The manuscript of this is already prepared, and will be forthwith printed in five volumes as large and full as those already given to the world. Dr. Billings has taken up new duties in a different sphere of activity; but the "labour of love" which he here dedicates to international science will still be carried on under the inspiration of his singular genius. The gratitude of his innumerable debtors will be enhanced by a lively expectation of benefits to come.

OUR BOOK SHELF.

Mesures Électriques. By Eric Gerard. (Paris: Gauthier-Villars et Fils, 1896.)

TO those who are acquainted with M. Gerard's previous work ("Leçons sur l'Électricité"), the publication of the present work will probably be extremely welcome, for in it he has, in his usual clear and satisfactory style, gone more fully into the question of the measurement of electrical quantities.

In an introductory chapter, the author considers the question of the errors of observation, and the effects they have on the final result. In this discussion, that interesting branch of pure mathematics called the method of least squares for determining the probable error, and which, in the hands of many observers, seems to perform much the same function as the ink does in the case of the cuttle-fish, is left comparatively in the background. Such questions as errors of observation—properly so called—and of systematic errors are, however, dealt with, and the importance of exercising judgment in deciding the accuracy with which the different quantities have to be observed, in order that the result may be correct to within a certain amount, is insisted upon. There is one paragraph which ought to be written up as a text in all laboratories and testing-rooms, and is to the effect that in making electrical connections too much care cannot be taken in arranging the wires and in cleaning the contacts, and that connecting wires ought not to consist of long spirals, for these only serve to increase the resistance and self-induction of the circuit. Some very useful instructions as to the best method of recording observations are given, together with some hints as to choice of an algebraic function to represent a given curve.

There is also a chapter on the measurement of lengths, time, angles, forces, velocity and power; and one on photometry, a subject which, since the expiration of the incandescent lamp patent, and the introduction of the incandescent gas-lamp, has become of very great importance to the electrician.

The more purely electrical part of the book consists of chapters on electrical standards, galvanometers (including ammeters), voltmeters, coulomb- and watt-meters, and two very fairly complete chapters on the measurement of self-induction, and the magnetic properties of iron. There are also chapters on the measurements of the characteristics of motors and dynamos (both for continuous and alternating currents), and on transformers. Although the devotee to the slide-rule is probably born and not made, an appendix on this instrument may be of service to those who have not yet been initiated.

The whole book is essentially a practical and readable text-book, though, perhaps, hardly a laboratory manual of the subject; it is remarkably free from useless and uncalled-for mathematical formulæ, and will undoubtedly be found of great use. W. W.

Problems in the Use and Adjustment of Engineering Instruments. By Walter Loring Webb, C.E. (Pp. iv + 64. (New York: John Wiley and Sons. London: Chapman and Hall, Ltd., 1895.)

IN every college or university where field work is a subject in the curriculum, such a book as this is found to be almost indispensable. Its aim is to set out problems for each student or group of students to pursue, in order that no time shall be lost, and so that every one may have complete practice with individual instruments. For such a purpose, this is perhaps one of the most concisely written books on the subject, and it at the same time covers a large amount of ground, from single chain measurement to a preliminary railroad survey.

Besides the instruments usually noted, one is glad to see instruction with the plane table and Amsley's polar planimeter, both such very admirable instruments when used with precision, that it is remarkable their introduction is not more universal. Throughout the book, convenient forms for entering notes are shown, and there is also a short chapter on the use of the formulæ of probable error, the utility of which cannot be over-estimated.

Graphic Arithmetic. By H. D. Ellis. (Philip and Son, 1896.)

THIS contribution to the teaching of arithmetic consists of two charts, each 40 in. by 10 in., which can be mounted, or otherwise adapted to class teaching. Chart i., whole numbers, consists of a series of horizontal lines, divided by dots respectively into ones, twos, threes, &c., twelves. By means of vertical lines the multiples of 2, 3, &c., are shown on the line of ones, which is numbered from 0 to 144. In Chart ii., fractions (vulgar and decimal), the series of horizontal lines are 1 metre in length and 1 cm. apart. These lines are divided by dots into halves, thirds, &c., tenths. There are subdivisions into hundredths (cm.) and thousandths (millim). On Chart i. explanations are given of magnitude, unit, number, multiple, &c.; and on ii., of the multiplication and division of decimals, the expression of a vulgar fraction as a decimal, and several other matters. The charts are well adapted for the purpose of giving a sound grounding in the subject, so far as they go.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Sacred Tree of Kum-Bum.

THE eighth number of the *Bulletin du Muséum d'Histoire Naturelle* for 1895, which has just reached me, contains a paper by M. Édouard Blanc, entitled "L'Arbre à prières de Goumboum." This reminds me of a brief article which I contributed to NATURE in 1883 (vol. xxvii. pp. 223, 224).

M. Blanc begins his account by the remark: "Je veux parler du fameux arbre qui croît dans un monastère buddhiste, au nord du Thibet, et qui produit des lettres, des mots, des prières et autres formules religieuses, le plus souvent tracées sur son écorce et sur ses feuilles." Of the actual fact he adds, "des voyageurs européens, M. Potanine et M. Grenard entre autres, ont apporté le témoignage de leur observation directe."

It is evident, then, that the tree still exists much as Huc and Gabet described it. And M. Blanc brought back with him to Europe a branch and a portion of the trunk. He says: "Le phénomène est véritable: il existe réellement, et j'ai vu des caractères thibétains très nettement tracés sur les branches de l'arbre en question."

M. Blanc discusses the cause. He dismisses the probability of their being either natural markings or the work of insects accidentally resembling alphabetic characters. He has no doubt that they are produced artificially, probably with the aid of heat.

In 1891 Mr. William Woodville Rockhill's book, "The Land of the Lamas," appeared; in it (pp. 67, 68) he gives the following account of the tree:—

"Although I did not see the convent treasure-house and the 'white sandal-wood tree' until later, I will describe them here. In a small yard enclosed within high walls stand three trees about twenty-five to thirty feet high, a low wall keeping the soil about their roots. These are the famous trees of Kum-Bum, or rather tree, for to the central one only is great reverence shown, as on its leaves appear outline images of Tsong-k'apa. The trees are probably, as conjectured by Kreitner,[1] lilacs (*Philadelphus coronarius*); the present ones are a second growth, the old stumps being still visible. There were unfortunately no leaves on the tree when I saw it; and on the bark, which in many places was curled up like birch or cherry bark, I could distinguish no impress of any sort, although Huc says that images (of Tibetan letters, not images of the god) were visible on it. The lamas sell the leaves, but those I bought were so much broken that nothing could be seen on them. I have it, however, from Mohammedans that on the green leaf these outline images are clearly discernible. It is noteworthy that whereas Huc found letters of the Tibetan alphabet on the leaves of this famous tree, there are now seen only images of Tsong-k'apa (or the Buddha ?). It would be interesting to learn the cause of this change."[2]

I was anxious to see what could be ascertained from the leaves brought back by Mr. Rockhill. An application to my friend Prof. Sargent, at Harvard, procured me the following interesting letter:

1914 *N Street, December* 23, 1893.

MY DEAR SARGENT,—As regards the famous Kum-Bum tree, I was not permitted, in any of my visits to it, to touch the tree, but I got a lot of leaves fallen from it, some of which I gave to the British Museum (Department of Ethnology), where Franks or Read would, I doubt not, be pleased to show them to Dyer.

From what the people at Kum-Bum told me, especially in view of their reference to the big bunches of violet flowers, I *thought* the tree might prove to be a lilac.

The bark turns up on the trunk like that of a birch. Kreitner is responsible for the identification of this "white sandal-wood" with the *Philadelphus coronarius*.

The roots from which the trees I saw were growing look very old, how old I cannot say, being ignorant in all such matters, the live stems are certainly not over 15 to 20 feet in height, and 4 to 6 inches diameter at the root, and some of them look very healthy. It may be that when Huc and Gabet visited this place (in 1842, I believe) the original trunk was yet alive.

They say that "three men could not stretch around the trunk," but he adds that it was not over 8 feet high. He must refer to an old dead trunk, out of which shoots were growing. If this is not the case, we cannot have seen the same tree; that is all there is about it.

As to the "odeur exquise et qui approche un peu de celle de la cannelle," this must be hearsay, and refers to the popular belief that the tree is a sandal-wood, or else is a native simile for the odour of lilacs.

The large red flowers Huc also refers to may be violet ones. Mongol is not so precise a language, in fact certain colours which which we would call violet are invariably called red by them.

Huc mentions the curling up of the bark.

On the whole, I am inclined to think that here as throughout his book, Huc's reminiscences of facts and hearsay have misled him. He certainly could not see the image on the leaves or bark, for even the Kum-Bum lamas, to whom I mentioned my inability to detect anything on the leaves they had given me, assured me that *faith was necessary*—"as one's faith is so is the clearness of the image on the leaf."

I hope the leaves will assist in throwing some light on the question. Ever sincerely yours,

(Signed) W. W. ROCKHILL.

Sir Augustus Franks kindly sent me some of the leaves, accompanied with the following memorandum:—

"Leaves from the tsandan karpo ('white sandal-wood tree') of Kŭmbŭm, said to have sprung up on the spot where Toongkâpe's mother threw his hair when, having shaved his head, she consecrated him to the house.

"Used when ground as medicine—also carried in charm boxes.

"Collected by W. W. Rockhill at Kŭmbŭm in 1891."

They were carefully examined by Mr. W. B. Hemsley, F.R.S., Principal Assistant in the Kew Herbarium, who has long been engaged on a critical study of the Chinese Flora. He arrived at the conclusion that they belonged to *Syringa villosa*, a Chinese species. He published his determination in *Journ. Linn. Soc.* (vol. xxx. p. 133), and I am disposed to regard it as correct. It confirms the statement of Kreitner (NATURE, xxvii. p. 171).

Rockhill's identification with *Philadelphus* is a mistake easy of explanation. He has confused the popular and the scientific use of the name Syringa. Lilac is botanically *Syringa*: Syringa is botanically *Philadelphus*.

It will be seen from the accounts given above that the phenomenon is not consistent with itself at different times. This confirms the opinion of M. Blanc that it is an elaborate fraud.

W. T. THISELTON-DYER.

P.S.—I have omitted to add that Blanc says (*l.c.* p. 323): "L'arbre paraît appartenir à la famille des Phytolaccacées ou à une famille analogue."—W. T. T. D.

[1] Kreitner, "Im Fernen Osten," p. 708. I was told that in spring these trees have large clusters of violet flowers, but if they are lilacs I am astonished that the Chinese do not speak of them as such, for that shrub is well known in Kan-su and throughout Northern China (see Prjevalsky. "Mongolia," ii. 79). Tibetans call all sweet-smelling wood *tsandan* (*i.e.* sandal-wood). Sir Joseph Hooker (*Himalayan Journals*, i. 298) says that the Lepshahs and Bhoteas call the funereal cypress *tsandan*. The Kum-Bum tsandan karpo is certainly not a cypress, however.

[2] When Lieutenant Kreitner visited this place (1879), the images on the leaves were as at the present time. See "Im Fernen Osten," p 707. The Arab traveller, Ibn Batuta, saw in the fourteenth century, at Deh Fattan, on the Malabar coast, in the courtyard of a mosque, a tree called the "tree of testimony." Every year there was a leaf on it, on which was written "by the pen of divine power," the formula, "There is no God but God; and Mohammed is the envoy of God." The inhabitants used it to cure disease (see Ibn Batutah, Defrémery's Transl., iv. 85).

The Röntgen Rays.

REFERRING to two letters in your last issue, p. 388, it is somewhat disconcerting to have Prof. Röntgen's original experiment—viz. the observation of shadows thrown on a barium-platino-cyanide screen—treated as a novelty. No one at all informed can have had the least scepticism concerning the probable observation of such shadows by Prof. Salvioni, though the sensational announcement made by some daily papers, that the eye had been made "actually to see" objects inside enclosures, was received, and is still received, with complete incredulity. A protected barium-platino-cyanide screen is extremely useful as a tester of the condition of an exhausted tube, and I have constantly used it as such, in imitation of Prof. Röntgen.

That a Crookes' tube gets hot when in action is perfectly patent to the touch; so also is the electrostatic attraction of the tube for pieces of paper and the like.

The term "anode rays" for the rays discovered with so much *éclat* by Prof. Röntgen, whether they be the same as those previously discovered by Dr. Lenard or not, is suggested by remarks from Mr. A. W. Porter at a recent meeting of the Royal Society. They certainly do not start from the kathode, but from some opposed surface, a surface which may be an actual anode, and which always has some anodic properties. From each point of such a surface rays start in all directions; this is proved by the shadows they cast of slits, holes, and wires.

OLIVER J. LODGE.

I MAY state that in a lecture which I gave here on the evening of Tuesday last, the 25th ult., I showed to a large audience, by means of a sheet of barium platino-cyanide, rendered fluorescent by the Röntgen rays from a Crookes' tube, all the things referred to by Mr. Campbell Swinton in his letter in the last number of NATURE. The shadows of coins in a purse, and of a hand, were distinctly visible to the audience when placed behind screens perfectly opaque to ordinary light, and, though more dimly, even through a book of eight or nine hundred pages.

I must confess that I cannot see why, after Prof. Röntgen's account of his own work, the success of such experiments as those made by Mr. Swinton or myself should be regarded as surprising, or accounts of them received with incredulity. They seem to me to be merely a variation of Prof. Röntgen's own experiments, or at most to be a matter of the most obvious inference from these experiments.

The statements that have appeared to the effect that Signor Salvioni has devised a method of rendering the retina of the human eye sensitive to Röntgen rays, and that by his method objects are directly *seen* through planks of wood, sheets of aluminium, &c., are simply absurd. The fluorescent light produced is entirely distinct from the Röntgen rays, and affects the retina like ordinary light; and of course parts of the sheet which do not fluoresce, because they are shielded by the opaque objects behind from the Röntgen rays, appear dark. Seeing such shadows can no more be said to be *seeing the objects themselves* by means of the Röntgen rays, than a man can be said to see himself when he looks at his shadow thrown by an ordinary gas-lamp on the street.

Prof. Röntgen discovered the fluorescence of the barium platino-cyanide under the rays now called by his name, and the transparency of ordinarily opaque matter to these rays, and the discoveries of Signor Salvioni and others, so far, at any rate, as they have been described in NATURE[1] and other journals I have seen, amount to nothing more. It is only just that in accounts of verifications of Röntgen's discoveries an attempt should be made to show clearly that such observations are only verifications, so as to prevent the credit of discovery which is Prof. Röntgen's due from any appearance, however unintentional, of indirect diminution.

Scientific accounts of verifications, as far as I have seen them in NATURE or elsewhere, are in themselves unexceptionable; but extra precaution seems necessary in order that the public should not be led by newspaper paragraphists, retailing such accounts at second-hand, to regard as extensions of Röntgen's work what are only direct and obvious consequences, perceived by himself, of the facts which he has observed.

ANDREW GRAY.

University College of North Wales, Bangor, March 1.

IN your last issue (p. 399), in the account of the work appearing in the *Comptes rendus*, you state that M. de Heen "proves conclusively that the X-rays proceed from the anode and not the kathode." May I point out (as I did at the Royal Society, in the course of the discussion on Prof. J. J. Thomson's paper, February 13), that I have proved that this is undoubtedly true for the bulb that I have been using *throughout* my experiments on the X-radiation. The bulb is one in which the negative electrode is concave, and the negative stream is thereby focussed to a point on the anode, which is a platinum disc placed near the centre of the bulb. By measuring the positions of different parts of a radiograph of a series of concentric zones of tinfoil placed in a measured position, I have shown that the actinic rays diverge from the anode disc.

I am of opinion, however, that in this respect this bulb differs from those which have been employed by others. In these latter, judging from the published accounts, the negative stream impinges directly on the glass; and for bulbs of this kind, it has been shown conclusively by Prof. J. J. Thomson that the seat of the origin of the rays is the glass itself. The proof is that a sensitive plate placed inside the bulb in the path of the negative stream is not acted upon. I venture to think that, in the case of my bulb, a sensitive plate placed inside would be acted upon provided it lay in the hemisphere of the bulb in which the kathode lies. I intend to test this conjecture experimentally. Should it prove true, the behaviour of both varieties of bulb will probably be capable of description by the following single statement:—

The seat of the origin of the X-rays is where the negative stream first impinges against a solid, and gives up, or partially gives up, its negative charge.

ALFRED W. PORTER.

University College, London, February 28.

IN your "Notes" of last week you refer to a communication of M. de Heen, stating that the X-rays proceed from the anode. Some experiments, which I made at the beginning of last month, bearing on this point, may be of interest to your readers. It is of course not the case that the X-rays proceed from the anode in general, but they may be made to do so by placing a small disc as anode facing the kathode. The kathode streams impinge on the former, and the X-rays being generated there radiate from it. The experiment was made by placing a lead plate (4 cm. by 10 cm.), with a rough circular hole in it, at a distance of 10 cm. above the photographic plate, and the tube (a small one with a curved kathode facing a small disc anode) 10·5 cm. above the lead. After development the negative was replaced exactly in its former position. Several interesting facts showed themselves, the most striking being that the image of the hole consisted of a well-defined circle showing even individual splinters on the edge, and in addition diffused elongation on two sides. On placing the eye so that the hole exactly covered its well-defined image, it was necessary to put it in the position occupied by the anode.

The diffused images in the same way were seen to be due to the fluorescent parts of the glass sides of the tube—a kind of pin-hole photograph, in fact.

The rays leave the anode as if they were the splash of a jet of water occupying the position of the kathode stream. In other words—supposing the plane of the anode vertical and the kathode to the right, then no rays appear to the left of the plane of the anode, whilst on the right the space is exceedingly rich. The negatives show, in every case tried, two well-defined regions, viz. nothing to the left of the intersection of the plane of the anode with the negative, and a dense deposit on the right, the richest part apparently being close to this line. It is difficult to account for this on the supposition that the rays are due to waves generated at the point of impact. We should expect in this case the action on the plate to increase with the visual angle of the anode disc as seen from points on the plate. On the other hand, certain further experiments seem to show that the action is not in all respects similar to the splash of a jet. Whether the effect is due to the fact that the place of impact of the kathode stream is an anode, or simply an internal obstacle, I have not yet determined, but experiments in progress will, I hope, settle this point.

For photographic purposes, the best kinds of tube are those with a curved kathode converging the streams on a small plane anode, remembering, of course, that the strong field is on the kathode side of the anode plane. This behaves very approximately as a radiating point. With this I have obtained, with comparatively short exposures, and a $2\frac{1}{2}''$ to $3''$ spark length, strong negatives of remarkable definition, certainly finer than any I have yet seen.

W. M. HICKS.

Firth College, March 1.

I WAS interested to see in your last issue a letter from Mr. Swinton describing his reproduction of Prof. Salvioni's experiments with phosphorescent screens. Mr. Swinton uses a piece of blotting-paper impregnated with platino-cyanide of barium. I have tried this method, but have obtained better results with a screen prepared with the same salt, as follows:

A piece of fairly stout black paper, free from pinholes, is coated with gum containing a little glycerine, and, as soon as it has

[1] A translation of Prof. Salvioni's paper will be found in another part of this issue.—ED. NATURE.

got tacky, it is dusted over until covered with the barium platino-cyanide, which has been finely powdered.

Greater distinctness is obtained by this method, insuring, as it does, a thin but compact layer of crystals, unseparated by the fibres of the blotting-paper. J. William Gifford.

Chard, March 1.

Crush-Conglomerates in Ireland.

On the sea-coast at Portraine, Co. Dublin, there is an apparent thickness of over 700 feet of conglomeratic rocks, which have hitherto been regarded and described as of volcanic origin, contemporaneous with the Lower Silurian strata and associated felspathic igneous rocks.

This conglomerate is massive in character, and exhibits a structure resembling rude bedding. It consists of sub-angular and rounded blocks and pebbles of grey fossiliferous Bala limestone, calcareous grit, and occasional lumps and fragments of crushed felsite, the whole being enveloped in a brownish-grey argillaceous and calcareous matrix.

The Lower Silurian section here shows grey limestone passing upwards into alternations of grit, limestone, and argillaceous shale, with thick bedded calcareous mudstones at top, the whole series being more or less fossiliferous.

The associated igneous rocks are intrusive basic felsites of several varieties, and, like the sediments, present evidence of intense crushing.

Having had assigned to me, in the Geological Survey, the revision of the Silurian tracts in this part of the east of Ireland, I spent some time on the ground last summer, and was led to form the conclusion that this supposed conglomerate is not of volcanic origin. The work has not yet been officially inspected, but I am enabled, with the sanction of the Director-General, to state here briefly the results at which I have arrived.

I believe that instead of volcanic detritus contemporaneous with the deposition of the Silurian strata, we have here a vast crush-breccia or crush-conglomerate, formed by the breaking-up both of the Lower Silurian sediments and the igneous rocks, along particular zones of earth-movement, and a flowing and subsequent re-cementing together of the broken-up and rolled fragments. So far as I could judge, there are no truly contemporaneous igneous rocks in the district.

Where the intrusive rocks have come within the region of intense squeezing, they are sheared and ground into more or less powdered masses, having a resemblance to volcanic material, and this probably gave rise to the supposition that they were volcanic.

The breaking-up of the hard bedded rocks can best be studied at the south end of the section, and in some cases the beds of limestone and grit can be seen, as it were, in the process of being broken up into detached pieces, the fragments rolling off through the mudstones.

The conditions at Portraine are repeated exactly on Lambay Island, three miles off, but apparently on a grander cale.

I consider this crush-conglomerate rock-structure to be of great importance in connection with many more supposed volcanic areas of Silurian age in Ireland.

Alex. McHenry.

Geological Survey Office, Dublin, February 28.

Science and Morals.

All who are engaged in extending the boundaries of natural knowledge will be interested in the remarkable letter of Prof. Ramsay, in last week's Nature, on the moral claims of original discoverers in relation to the work of subsequent investigators in the same field of research. As one whose experience is of sufficient duration to stand in both these relations, I should like to point out several objections to the position assumed by Prof. Ramsay on this question.

In the year 1866 I announced before the Royal Society the discovery that quantities of magnetism and electricity indefinitely small would induce quantities of these forces indefinitely great, and demonstrated the same, on a large scale, by means of a small magneto-electric, acting in conjunction with a large dynamo-electric machine.[1] The discovery excited considerable interest at the time, and my experiments were repeated by many electricians in Europe and America. Among these were Varley, Wheatstone, Siemens of Berlin, and Farmer in America, who soon found that the residual magnetism of an electro-magnet was sufficient to supply the initial current required for exciting the dynamo; thereby dispensing with the permanent steel magnets of the magneto-electric machine. Although I had actually made experiments in the same direction some time previous to the announcement of my discovery, it never occurred to me, before reading Prof. Ramsay's letter, that I have all these years been a martyr to the injustice inflicted by unscrupulous electricians publishing, without my consent, the happy invention of the self-exciting dynamo machine.

The work of an original discoverer, though popular, is not unfrequently of a very subordinate character; increasing, in some cases, the value and importance of previous discoveries, or preparing the way for still greater ones, which the original investigator may be quite unable to deal with. The pretension set up by Prof. Ramsay, with its personal application, that the permission of an original discoverer should be obtained before the results of subsequent researches in the same field by other workers are published, strikes at the root of all scientific progress, and indicates a simplicity of character rarely to be met with in those engaged in philosophical pursuits.

Prof. Ramsay is again unfortunate in his analogy between the moral questions involved in a scientific discovery and in a patented invention. Law and equity alike encourage the publication of subsequent improvements on original inventions *without the consent of the first inventor*, and only intervene and censure when the right and title *to his own invention* are impugned.

The morality of Prof. Ramsay would suppress all investigations on the Röntgen rays, now being made wherever science is cultivated, or would render it impossible for the original discoverer to consider the numerous applications for permission to publish the results of further experiments.

The policy of secrecy and procrastination suggested as a corrective to the activities of subsequent investigators is not likely to meet with the approval of scientific men who have in mind the history of the discovery of the planet Neptune, and the rival claims of Adams and Leverrier. A great master of science (Sir George B. Airy) has well said with reference to this and other discoveries, "that it is advantageous for the progress of science that the publication of results, when so far matured as to leave no doubt of their general accuracy, should not be delayed till they are worked to the highest imaginable perfection."

February 25. Henry Wilde.

Inverted Images.

In connection with the view advocated by Mrs. Scott in your last number, it may be of interest to state that, in my own personal case, I have been able all my life to read a book with the greatest facility upside down; it making not the least difference to me which way it is presented. I am told—but this is not within my personal recollection—that I learned to read by looking over the book of an elder brother who was being taught in the usual way, standing in front of him, not behind. The singular circumstance to my own mind is that I have precisely the same facility in reading upside-down books written in any foreign language with which I may be more or less acquainted, in which the letters differ from the English, as Greek and Hebrew; and the facility extends, to very nearly the same extent, to handwriting. I have never at any time practised it systematically; it appears to come perfectly naturally.

Alfred W. Bennett.

Remarkable Sounds.

A peculiar sound, apparently similar to the "soughing of the wind" (see p. 78, *ante*), is briefly described by Liu Wan-Ping, a Chinese Commodore, in his journal of voyage made in 1595 from Cheh-Kiang to Shan-Tung, in order to defend the latter province from the attack by the Japanese fleet. (Sie Tsai-Kang's "Wu-tsah-tsu," Japanese edition, tom. iv. fol. 46, *a*.) The passage is as follows: "Same night we anchored near Fuh-shan-tau [in Shan-Tung]. This mountain, as if inhabited by a deity, utters a voice sounding mournfully, although on it neither herb nor tree exists, and neither hollow nor cavern therein." Kumagusu Minakata.

February 8.

THE SHIFTING OF SPECTRAL LINES.

I.

THE *Astrophysical Journal* for February contains some papers of the highest interest, touching small variations in the wave-lengths of spectral lines and the causes which produce them. These are stated to have been, in the first instance, established by Mr. Jewell by an examination of the Rowland series of photographs of the solar and metallic spectra taken by means of a concave grating of 21½ feet radius and 20,000 lines to the inch—an instrument of research which, so far as my own experience goes, is not to be obtained by workers in this country.

Mr. Jewell's investigations began in 1890. Another paper by Messrs. Humphreys and Mohler details the results of work begun last year on the effects of pressure on the arc spectra of the elements, work suggested by Mr. Jewell's prior researches.

Mr. Jewell has, as a basis for his new conclusions, practically studied under modern conditions classes of phenomena which I was the first to observe and describe, as near as may be a quarter of a century ago.

To show the relation of the new work to the old, it is best to begin with a short historical statement, which will have the advantage of giving to non-experts an idea of the meaning of some of the terms employed.

I first employed the method of throwing an image of a light source on to the slit of a spectroscope by means of a lens in 1869, and some of the results obtained by the new method were the following.

(1) The spectral lines obtained by using such a light source as the electric arc, were of different lengths; some only appeared in the spectrum of the core of the arc, others extended far away into the flame and outer envelopes. This effect was best studied by throwing the image of a horizontal arc on a vertical slit. The lengths of the lines photographed in the electric arc of many metallic elements were tabulated and published in *Phil. Trans.*, 1873 and 1874.

(2) The longest lines of each metal generally were wider than the others, the edges fading off; and they reversed themselves; by which, I mean, that an absorption line ran down the centres of the bright lines. These results were afterwards confirmed and extended by Cornu ("Chemistry of the Sun," p. 379).

(3) From experiments with mixtures of metallic vapours and gases, it came out that the longest lines of the smaller constituent remained visible after the shorter lines had disappeared, the spectrum of each substance present getting gradually simpler as its percentage was reduced,[1] the shorter lines being extinguished gradually. Shortly after these observations were made, I included among some general propositions:[2] "In encounters of dissimilar molecules the vibrations of each are damped."

(4) The various widths of the lines, especially of the winged longest ones, were found to depend upon pressure or density, and not temperature.[3]

(5) The "longest lines" of any one metal were found to vary in their behaviour in most extraordinary fashion in solar phenomena, being furthermore differentiated from the shorter ones; and on this and other evidence I founded my working hypothesis of the dissociation of the chemical elements at the solar temperature. In 1876 I set out the facts with regard to calcium.

(6) In 1883, Prof. W. Vogel, in a friendly criticism, pointed out the evidence then beginning to accumulate, that under certain circumstances the wave-lengths of lines are changed.[4] In 1887, I extended this evidence,[5] and I think it was I who coined the word "shift" to express these changes.[1]

I now pass on first to the results which Mr. Jewell claims to have established.

With the enormous dispersion produced by the instruments referred to, it is found that certain metallic lines, but not all, are displaced or "shifted" towards the violet when compared with the corresponding solar lines. "There was a distinct difference in the displacement, not only for the lines of different elements, but also for the lines of different character belonging to the same element."

The "different character" above referred to turns out to relate not so much to the intensity as to the length, and, associated with this, the reversibility of the lines; the longest lines are the most displaced, the shortest, least.

Further, in the spectrum of the arc itself, the position of a line with but little material present "was approximately the same as the position of the line when reversed." Now since the longest lines are most displaced to the violet, this means that the smaller the quantity of a substance present the greater is the displacement towards the violet; and therefore the greater the quantity present, the greater the displacement towards the red.

Further on, Mr. Jewell expressly states "it was found that with an increase in the amount of the material in the arc there was an increasing displacement of the line towards the red," and then he adds, "unless the line became reversed, when all further progress in that direction ceased."

Here is an observation regarding the red line of cadmium. "It was found that if the micrometer wires were set upon it with very little cadmium in the arc, then as the amount was increased the line almost bodily left the cross-hairs, always moving towards the red."

Mr. Jewell considers he has established that the vibration period of an atom depends to some extent upon its environments. "An increase of the density of the material, and presumably an increase of pressure, seemed to produce a damping effect upon the vibration period."

My result of 1872 with regard to pressure is endorsed, "the new results are found to be due to pressure and *not* temperature."

We seem then now to be in presence of two damping effects in the case even of metallic lines, one which extinguishes lines when we deal with dissimilar molecules, and one which changes their wave-length towards the red when we deal with similar molecules.

A carefully prepared table is given by Mr. Jewell, showing the origin, intensity and character of the solar lines considered, the intensity and character of the corresponding metallic lines, the wave-lengths of both, and the observed displacement.

There are many references to solar phenomena in Mr. Jewell's paper, but I do not propose to discuss them now. There is one point, however, I must refer to, in justice to my critics. He considers that the conclusions to be drawn from a study of the new shifts "effectually disposes of the necessity of any dissociation hypothesis to account for most solar phenomena." I have already pointed out that this was Prof. W. Vogel's conclusion with regard to possible shifts, so far back as 1883.

It is quite easy. "Two adjacent lines of iron, for instance, may show the effects of a violent motion of iron vapour in opposite directions, in the neighbourhood of spots, or one line (the smaller one corresponding to one of Lockyer's 'short lines') may show a broadening and increase of intensity in the spectrum of a sun-spot,

[1] *Phil. Trans.*, 1873, p. 482.
[2] "Studies in Spectrum Analysis," 1878, p. 140.
[3] *Phil. Trans.*, 1872, p. 253.
[4] NATURE, vol. xxvii., 1883, p. 233.
[5] "Chemistry of the Sun," p. 369.

[1] Since the parentage is uncertain, I may say that perhaps "shiftings" would have been a better word, as shift is otherwise employed, *e.g.* Love's last shift (translated by a French author, *la dernière chemise de l'amour*).

while the other line (the larger one corresponding to one of Lockyer's 'long lines') is unaffected. But this does not prove that iron vapour is dissociated in the sun. It merely shows that the apparently similar portions of the two lines in the solar spectrum are produced at different elevations in the solar atmosphere. The stronger iron line will be affected in a sun-spot as much as the other one, but it is the portion of the line produced at the same level as the other line, and may be masked completely, or very largely, by the emission line produced at a higher level, while the second absorption line in the solar spectrum may be entirely unaffected, being produced at a still higher altitude."

"This also explains why some of the lines (the short lines generally) of an element may be most prominent in sun-spot spectra, while others (generally the long lines) are those most frequently seen in prominences or in the chromosphere."

My thirty years' work at solar physics leaves me with such an oppressive feeling of ignorance that I willingly concede to Mr. Jewell a knowledge so much greater than my own as to give him a perfect right to dismiss all my work in two lines; but I am compelled to point out that he has not carefully read what I have published.

A comparison of the facts brought together in Figs. 112 and 114 of my "Chemistry of the Sun," for instance, drives his last paragraph into thin air: it is distinctly shown that we have to do with the short lines in the chromosphere and with the long lines in spots, the exact opposite of his statement. Mr. Jewell is not running counter to my views in supposing that different phenomena are produced at different elevations. I thought I had abundantly proved in my eclipse observation of 1882 ("Chemistry of the Sun," p. 363), that the iron lines, to take a concrete instance, are produced at different heights in the solar atmosphere; and that was one among many reasons which compelled me to abandon the thin reversing layer suggested by Dr. Frankland and myself in 1869 in opposition to Kirchhoff's view; but surely the more we consider the solar atmosphere as let out in flats, with certain families of iron lines free to dwell in each and to flit *à discrétion*, the more a dissociation hypothesis is wanted. And beyond all this, we have to take into account that at the sun-spot maximum no iron lines at all are seen amongst the most widened lines, while at the minimum we have little else.

Another very interesting part of Mr. Jewell's paper refers to the phenomena of absorption. There is room for plenty of work here. As I pointed out in 1879, we get unequal widenings, "trumpetings," and a whole host of unexplained phenomena.[1] It is clear that the enormous dispersion at Mr. Jewell's command will largely help matters.

I now pass to Messrs. Humphreys and Mohler's paper.

Messrs. Humphreys and Mohler have used an electric arc enclosed in a cast-iron cylindrical vessel, which enabled them to vary the pressure up to fourteen atmospheres. One hundred photographs have been taken, and the shifts of some lines of twenty-three elements have been measured. The accompanying rough diagram, bringing together specimens of their observations, will indicate the kind of result they have obtained.

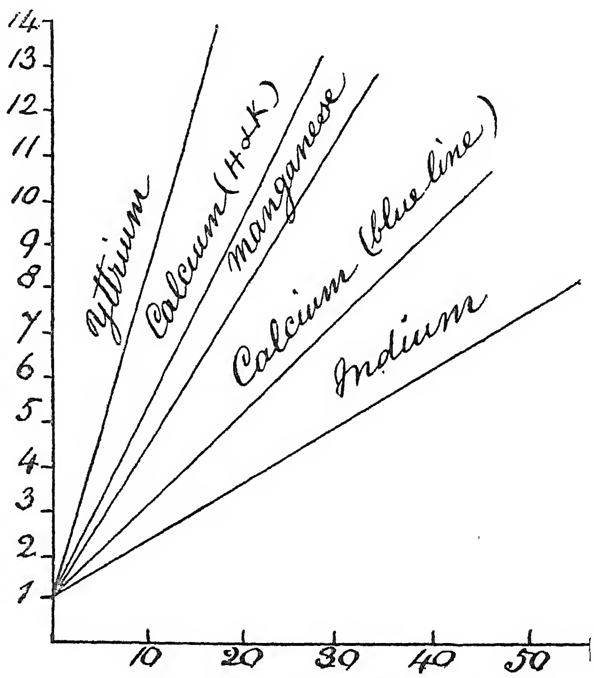
The pressures in atmospheres are shown to the left. The shift towards the red in thousandths of an Angström unit are shown below. The shifts have been reduced to what they would be at λ 4000, in the neighbourhood of which most of the work was done. I must refer to the paper itself for the method of measurement adopted.

The displacement or shift varied greatly for different elements. It was always towards the red, and directly proportional to the wave-length and the excess of pressure over one atmosphere.

Only one exception to this general statement is given; it refers to calcium. "The lines H and K, among others, shift only about half as much as *g* (the blue line at 4226), and the group at wave-length 5600. That *g* should differ in this respect from H and K is not very surprising, since it is known to differ greatly from them in many other respects."

On this exceptional behaviour of these lines of calcium, I quote the following, from a note by Prof. Hale, which appears in the same number of the journal.

"The difference in behaviour of H and K and the blue line of calcium discovered by Messrs. Jewell, Humphreys, and Mohler, seems to support Lockyer's views as to the dissociation of calcium in the arc and sun. The remarkable variations of the calcium spectrum with temperature have long been known principally through the investigations of Lockyer. The writer has shown that the H and K lines are produced at the temperature of burning magnesium and in the oxy-coal-gas flame. They could not be photographed in the spectrum of the Bunsen



burner, though an exposure of sixty-four hours was given. Since these experiments were made, I have been informed by Prof. Eder that his own efforts to photograph the lines in the Bunsen burner were no more successful, though an optical train of quartz and fluor-spar was employed. It would thus appear that the temperature of the dissociation of calcium is between that of the Bunsen burner and that of the oxy-coal-gas flame. The high molecular weight of calcium has hitherto conflicted with our belief in the presence of this metal in prominences. If, however, it be granted that dissociation can be brought about by temperatures even lower than that of the arc, the difficulty is very greatly lessened."

I may add that it will be very interesting to see if the strontium line at 4607 behaves like the calcium *g* in relation to the lines at 4077 and 4215 representing H and K.

I have said enough in the present paper to show the extreme importance of these new results. So much care has been taken, that there is little doubt that subsequent

[1] "Chemistry of the Sun," pp. 380-387.

work will confirm them; and when this is done, students of spectrum analysis will find a new region of the highest importance open to their inquiries.

J. NORMAN LOCKYER.

(*To be continued.*)

THE VARANGERFJORD REGION AND THE FORTHCOMING SOLAR ECLIPSE.

WE expect to have during this summer a good many visitors to the far north of Norway under the 70th parallel of north latitude, and close to the frontier of Russia. The total eclipse of the sun on August 9 (a few minutes before 5 a.m.) will attract many astronomers to these high latitudes. The sun will rise only 14° above the horizon during the eclipse, but the mountains here are not so high as to prevent the selection (though with some little difficulty even on the fjords) of places where their height will not prove an obstacle to the observers. In case one is in doubt, our official almanac gives the time when the sun will be visible on May 3; add nine minutes to that time, and it will be the time when the sun will rise over the mountains at the particular place.

It will be more difficult for astronomers to get a clear sky. The neighbourhood of Vardö, which otherwise would be very suitable, is plagued with fogs in the summer. Vadsö has more advantages, but still better are such inland places as Polmag, Utsjoki, Karasjok, Kautokeino, and Karasuando (in Sweden).

I shall give here some information for the guidance of those who intend to visit this remote corner of the earth.

The Varangerfjord ("ng" pronounced as in singer, not as in anger) runs inland west-north-west; the land lying north of it is called the Varanger Peninsula, and that to the south of it South Varanger. All the land is fjeld (mountainous land, highlands), but it rises nowhere to any great height. There are no good maps of this region, except of the eastern part of South Varanger, of which the Government recently published a map on the scale of 1 in 100,000; it is the best map. There is also the ethnographical map of Finmark, by Friis, scale 1 in 200,000 (Christiania, 1888). On this remarkable map every family is indicated by a separate mark; it indicates also the language they speak, and gives other details. It is, naturally, only in such a very sparsely populated region that such minute details can be represented on a map.

The Varanger Peninsula is a plateau which on its western border attains a height of 2200 feet, and on its southern about 1500 feet. The plateau is, however, not quite level, but presents such long, gentle undulations as are seen on the open ocean in calm weather. The permanent population, which keeps to the sea-coast, has here and there some outlying fields in the open parts of the valleys near the sea.

With the exception of these and the immediate neighbourhood of the settled places, the whole region consists of rolling mountain-tops practically unknown to the civilised world. It can, according to all that we know of it, be described as a wilderness of rocks, a stony desert covered here and there with reindeer moss (*Cladonia rangiferina*), and some swampy places where there thrives a scanty vegetation of green plants. Towards the inner part of the Varangerfjord there are some stretches of damp ground, overgrown with dwarf willows. About the centre of the peninsula are some large lakes full of fish, which only a few Norwegians have visited. However, access to them (apart from the question of distance) is not difficult from the south, for although there is no road, one can be driven there in a little cart. In winter, a few clever snow-shoe skaters have crossed this completely desolate, uninhabited land from north to south, a distance of forty English miles.

The western side of the Varanger Peninsula has a steep coast-line, but between Vardö and Vadsö the slope of the land seawards is very gentle; to those who sail along the coast the country seems quite level.

The appearance of the coast at Vardö is seen in the illustration on p. 418, desolate and dreary, truly an Arctic desert land; to the right is a bay of the sea, and the flat land in the foreground, consisting of gravel, exhibits some characteristic curved lines; they are raised sea-beaches. Probably one must go to the great lakes of America to find equally brilliant examples of former water-levels. The uplifting of the land has not been uniform. On the north side of Varanger Peninsula the old beaches are 70 feet above tide, but on the south, at Vadsö, they have been raised to between 260 feet and 295 feet. Probably the land is rising at the present time. In Vardö, old people point out quays which have risen several feet during their lifetime. The Austrian astronomer, Pater Hall, who came to Vardö in 1769 to observe the transit of Venus, was so much interested in this question, that he caused a little pillar to be erected, the height of which above the then existing tide-level was accurately determined. He inserted in the parish register of Vardö a description of the position of this pillar; but, alas! though the register is still in existence, the pillar has disappeared. The land on the south side of Varangerfjord, South Varanger, is not quite so bleak and bare as Varanger Peninsula; it has some pine forest in the valleys. It also can be considered a plateau; but it is furrowed by valleys and fjords, and is thereby broken up into a multitude of small, flattish, dome-topped mountain masses. The plateau character is shown by the fact that all the mountains rise to about the same height; in the eastern part, near the sea, to about 1300 feet.

These differences in the landscape and in the character of the country are connected with the fact that there are not the same kinds of rocks on the south side of the fjord as on the north side; probably there is a line of faulting along the fjord. On the south side there are Archæan gneiss and granitic rocks; on the north side younger rocks (conglomerates, sandstones, and slates), probably of Cambro-Silurian age; but fossils have not as yet been discovered in them. A remarkable conglomerate occurs in the inner part of the Varangerfjord; it may have been formed during a very remote Glacial period, probably Cambro-Silurian. It contains striated boulders, and rests partly on an underlying bed which shows glacial striations.

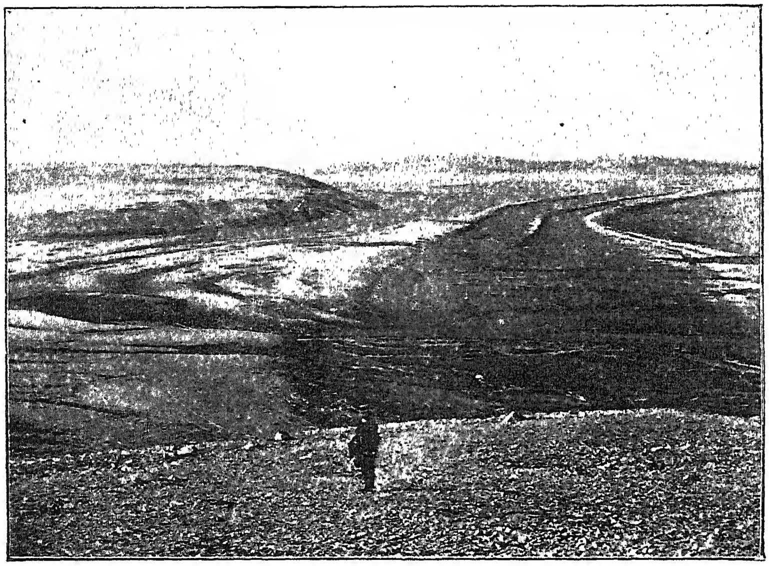
We shall now take a glance at the inhabitants of this province, Finmark, which touches the Russian frontier. The Norwegians gradually migrated into it during the last few centuries, but the Laps were already there. Many of the Laps wander as nomads with their reindeer, and dwell in tents, but the greater part of them live on the sea-shore, poor fishermen and farmers (like the crofters in the isles of Scotland), who grow a little hay for their cattle, and a few potatoes for themselves. There are no cereals in this northerly province.

Many of the inhabitants live in wretched earth-huts, which they share with their cattle. The Fins, who came from the grand-duchy of Finland, were the last to migrate into this district. The immigration commenced more than a century ago; it attained its maximum between twenty and ten years ago, and it is now decreasing. The language of the Laps differs about as much from that of the Fins as English differs from German; the Norsk language, as is well known, belongs to another group, the Germanic. All the three races are Lutherans. Finmark is very thinly peopled; the whole population in 1891 was 23,000 on an area of 47,000 square kilometres, or about two square kilometres to each individual. Finmark

has three small towns, Hammerfest, Vardö, and Vadsö, each with about 2000 inhabitants; the last two are spoken of as astronomical stations; in both there are small second-class hotels, at which the charges are about five shillings to six shillings a day. In Vardö, Hansen's hotel, and rooms may be had from Herr Holte, the baker, and Herr Ness. In Vadsö, Krog's hotel, and rooms from Herr Lindseth. The charges for labour and assistance, such as men to row a boat or to carry things, are rather high in the summer-time in the whole of Finmark, because work is plentiful and labourers are scarce.

Vardö lies on a little island in the Arctic Sea, but quite close to the mainland; it has a more rigorous climate than any other town in Norway; not the smallest tree will thrive upon the island. Sea-fogs in summer, and the tremendous storms of winter, that never cease for a single day, are not at all cheering. It is not surprising that business people there live with their families in Christiania in the winter, and in summer follow the birds of passage to the north.

Vardö's sole source of income is derived from fishery, and fish is cheap; haddock in the season sell at 6 lb. for a penny. A manufactory was started here to make dried fish meal from the flesh of this fish, but the people did not succeed in trying to remove the peculiar odour of dried fish from the material, so they were obliged to convert their works into one for the manufacture of damped fish-balls.



View of the coast at Vardö, East Finmark.

The only entertainment that I can recommend is the Russian vapour bath; it is a primitive installation. The vapour is produced by throwing water on heated stones, and the two women attendants whip the bathers with a bunch of quick-beam rods (*Pyrus aucuparia*). After the bath they offer, gratis, the Russian national drink, kvas, which tastes like ale mixed with water. However, Vardö has made progress in some respects within the last half-century. It was at that time, owing to the slowness and irregularity of the means of communication, so thoroughly out of touch with the world, and even with Christiania, the capital, that the commandant of the miniature fortress, who gave instructions to his orderly that the news from the capital should be laid before him every day, duly received them, but, alas, they were a year old!

Vadsö lies on the mainland on the northern shore of the Varangerfjord. The neighbourhood is a quite treeless pasture. The houses, like those in Vardö, are of wood, small and plain. On a little island opposite the town lies a now abandoned whaling station. Whale fishing began in the Varangerfjord; but reckless over-fishing has driven the whales from this locality, and one can foresee the time when whale fishing will be a thing of the past in the whole of Norway. From Vadsö there is a good driving road to the west, past the little town of Nessby, as far as Seida on the river Tana.

Other places which may be mentioned as stations for observing the eclipse are Polmag, Utsjoki, Karasjok, Kautokeino, and Karasuando. The first three may be reached by the steamer, which enters the Tanafjord between sixty and seventy miles east of the North Cape, and sails in a southerly direction and touches at Vagge, thirty-five miles from the mouth of the fjord. Vagge lies near the mouth of the Tana River, and close by is Guldholm, near Tana Kirke, where boats may be hired for rowing up the river to Polmag, Utsjoki, and Karasjok. At Tana Kirke (church), as well as at Vardö and Vadsö, there are telegraph stations, where astronomical time may be received from Christiania Observatory, but not at Polmag, Utsjoki, Kautokeino, nor Karasuando.

Prof. Dr. H. Mohn and Mr. Schroeter, from Christiania University, will probably take their stations at Vadsö and Bugönes, close by. In Polmag the inhabitants are the most civilised of the Laps; they live in wooden houses, and are comparatively cleanly. A party of observers may live here for some time if they bring provisions with them.[1]

In Karasjok, and, so far as I know, in Utsjoki also, one will get a friendly reception and good food from the shopkeepers. In Karasjok there are about 250 inhabitants, including a clergyman; in Polmag, not so many; but how many in Utsjoki (which belongs to Finland), I do not know. The way to Kautokeino, where living can be had at the Norwegian shopkeeper's, is by steamer to Alten, then forty miles on horseback, and seventy miles on the river by boat, which must be ordered in advance. From Kautokeino one may proceed to the village of Karasuando in Sweden, which also is within the boundary of totality, by taking a boat on the river for fifteen miles, and then on horseback or by walking for thirty-five miles more.

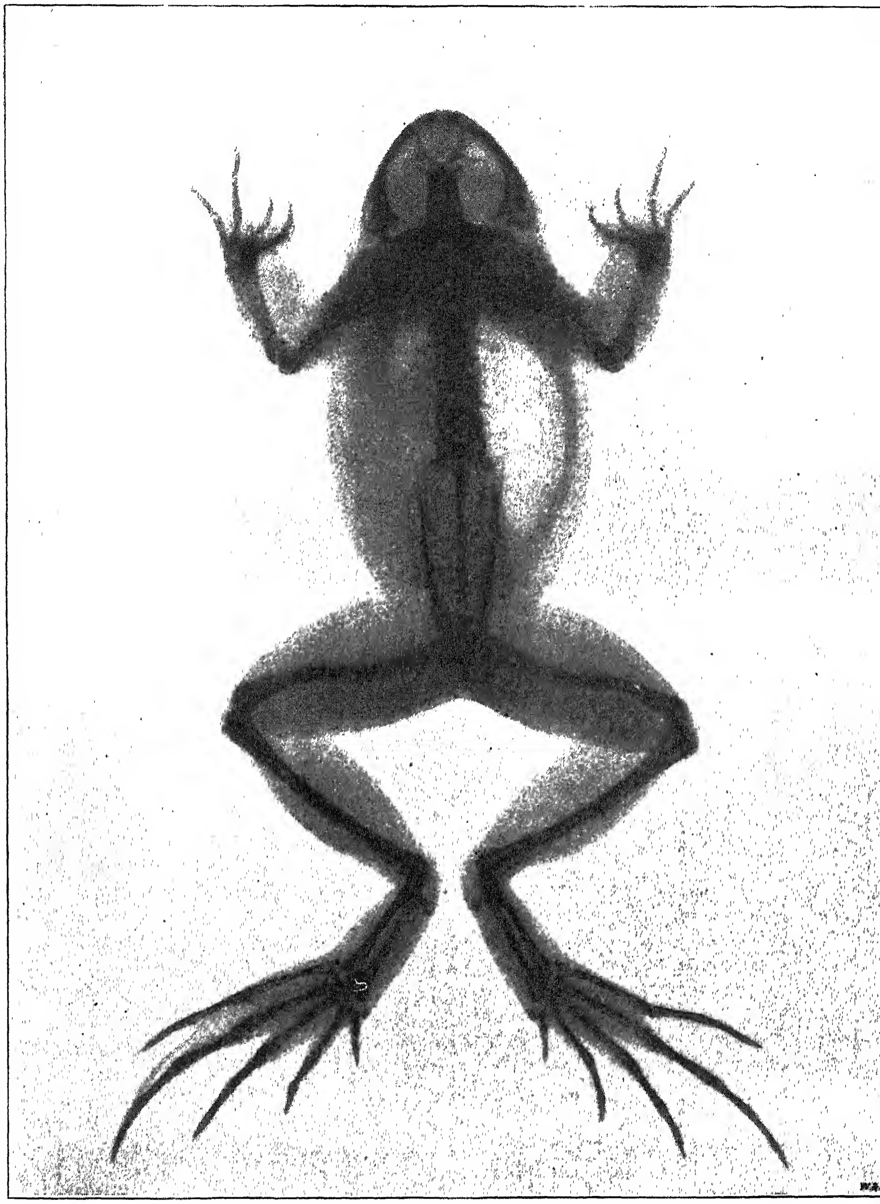
Another less generally known way of reaching Karasuando, because it is newer, is by steamer twice a week from Tromsö to Skibotten on Lyngenfjord, where comfortable accommodation can be had, thence by road thirty-six miles to Lake Kilpisjärvi (half-way to which is the not very comfortable stopping-place Helligskogen), then by rowing-boat to Muotkavuoma in Sweden, and then by road to Karasuando. The return journey from here may be made either by Vitangi to Gellivara railway station, about 100 miles, or by the much-frequented route down the river Tornea to Haparanda on the Gulf of Bothnia.

Hans Reusch.

[1] As the brown (rye) bread in general use in Norway is badly baked and most unpalatable to those unaccustomed to it, and as white (wheat) bread can rarely be had, especially in such places, a supply of biscuits should be taken

THE RÖNTGEN RAYS.

WE beg to send you a negative of a frog taken by Prof. Röntgen's method. The clearness with which the several bones have come out is so remarkable, that we consider the picture well worth reproduction, and trust you will find space for it. The larger transparent patch upon one side of the vertebral column is due to a distended lung, its collapsed fellow being evident upon the opposite side (this was proved by subsequent dissection). If you will carefully look into the larger transparent patch, you will see that the reticulated structure of the lung is evident, but we fear is too slight to bear reproduction by photo-mechanical means.



The negative was obtained by means of a small induction coil (2-inch spark) directly connected to a highly exhausted simple cylindrical Crookes' tube.

E. WAYMOUTH REID.
J. P. KUENEN.

NOTES.

THE Croonian Lecture of the Royal Society will be delivered on March 12, by Dr. A. D. Waller, F.R.S., who has selected for his subject, "Observations upon Isolated Nerve."

WE understand that the editing of the "Icones Plantarum" has passed from the hands of Prof. Daniel Oliver to those of the Director of the Royal Gardens, Kew.

WE learn from *Science*, that an endeavour is being made to establish a permanent scientific head for the U.S. Department of Agriculture. An amendment to the Agricultural Appropriation Bill has just been sent to Congress providing for a "Director-in-Chief of scientific bureaus and investigations, to serve during good behaviour, to have authority to act as Assistant Secretary, and to perform such other duties as the Secretary may direct." This amendment is, we understand, the outgrowth of an effort

to secure a permanent non-political organisation and administration of the various bureaus and divisions engaged in the scientific work of the Government, and at the same time bring about a more intelligent and more effective cooperation than has been heretofore possible. The Department of Agriculture as at present organised comprises a large number of scientific and administrative divisions having for their object the discovery, exploration, and development of the agricultural and other natural resources of the country. The scientific divisions are engaged in researches requiring the highest technical skill, and some of them in the solutions of problems requiring long years of preparation and scientific training. Our contemporary adds that, should the amendment become a law, it is by no means improbable that other scientific bureaus of the Government will seek the protection and support provided thereby, and that in the near future the United States may boast of a National Department of Agriculture and Science.

The Russian National Health Society is reported by the *Lancet* to be making strenuous efforts for the success of the Jenner centenary celebration to be held in May. Although the method in which the Society proposes to commemorate Jenner's great discovery has already been referred to in these columns, a statement of the first arrangements will be of interest. There are offered four prizes, the first equivalent to 100 guineas, and a gold medal, for the best work upon vaccination. English is one of the languages in which the work may be written, and the work must be sent in before March 12 (New Style). An exhibition of relics of Jenner, and of books, pamphlets, prints, tabular returns, instruments, and other objects relating to vaccination or to Jenner will be held. The Society is also publishing a history of the development of vaccination in Russia and other countries, and a full biography of Jenner, together with a portrait, and copies of his drawings. The price of this "centenary edition" which will be edited by Dr. Ladislas Hubert, the Secretary of the Society, will be three roubles (about 6*s.*). All objects intended for the exhibition, as well as any other communication relating to the centenary, should be addressed either to Dr. Hubert, 15 Dmitrofski Pereoulok, St. Petersburg, or to Dr. F. Clemow, 69 Earl's Court Square, London, S.W., who is acting for the Society in England.

Reuter's correspondent at St. Petersburg states that the subjoined telegram from Irkutsk was received there on Tuesday:—The Governor of Irkutsk, in reply to inquiries, has received the following from Yakutsk: "Peter Ivanovitch Kuchnareff, who trades at Ust Yansk, by a letter dated November 10, communicated the following to the merchant Kuchnareff at Yakutsk:—'We learn that Dr. Nansen's expedition has reached the North Pole, has discovered a hitherto unknown land, and has now returned.'" In order to verify the news and in case of necessity to render assistance to the expedition, the Governor of Yakutsk has instructed a member of the administration in the Verkhoyansk district to proceed to Ust Yansk.

A brief summary of the facts concerning the Panama Canal, together with a few words as to the present status of the canal construction, are given in the February number of the *National Geographic Magazine*, by Mr. R. T. Hill. So many misstatements are made as to the condition of the works, that Mr. Hill's article, and the illustrations which accompany it, will do good service in refuting them. It appears that the plant of the Company is not undergoing the ruinous decay that has been represented, both in this country and America, but, on the contrary, it is kept in scrupulously good order, and will be available for the completion of the work, should the Commission which has to report upon the affairs of the late Company decide to carry out the scheme. That the Commission does not consider the route impracticable is attested by the fact that they have kept the work progressing, about two thousand labourers having been employed upon the construction of the canal during last year. When, in February 1895, Mr. Hill took the photograph reproduced as an illustration to his article, he counted five locomotives at work carrying away the excavations from the Culebra summit. It was reported recently that the money to finish the work on the present plan has all been furnished, and that two thousand more men from Jamaica and other West Indian islands are being collected, the intention being eventually to increase the force to six thousand men. It is expected that the work will be completed in six years.

With reference to excavations of the island of Philae, the Cairo correspondent of the *Times* writes, under date February 17:—"The work of clearing the island of débris so as to permit a thorough examination of the ancient monuments, which was entrusted by the Egyptian Government to Captain Lyons, R.E., will probably be completed next month. The satisfactory discovery has been made that the foundations of the main temple of Isis are laid upon the granite rock, being in some places over 21 feet in depth, and the temple has nearly as much masonry below ground as above. The south-eastern colonnade has also its foundations upon the granite, and, so far as excavated, they are curious if not unique in design. They consist of parallel cross walls some metres high, but varying according to the slope of the rock surface, with large stone slabs placed horizontally upon their tops, and the pillars forming the colonnade are erected upon the slabs. The nilometer is marked in three characters—Demotic, Coptic, and another much older, probably Hieratic, of which a copy has been sent to Berlin for decipherment. A stela was found bearing a trilingual inscription in hieroglyph. No traces have been discovered of any buildings anterior to the Ptolemaic periods. M. de Morgan, Director-General of the Antiquities Department, is engaged upon repairing the great hall of columns at Karnak."

At the Royal Artillery Institution, Woolwich, on Thursday last, Dr. G. H. Bryan, F.R.S., lectured on "Flight and Flying Machines." The lecturer pointed out that the power of flying had been developed under more favourable conditions in small than in large animals, both because the risk to life and limb in the case of a fall increased with the size of the animal, and also because, assuming De Lucy's law, large bodies required more power to sustain every pound of their weight in horizontal flight than small ones. These considerations applied equally to flying machines. As Lord Kelvin had said, Maxim's experiments had solved three of the five problems connected with artificial flight, and the two remaining ones were now solved by the soaring experiments of Lilienthal in Germany, and Pilcher in Britain. All that remained was to combine the advantages of Maxim's and Lilienthal's apparatus in a single machine, and in this Dr. Bryan prophesied that artificial flight would be accomplished at no distant date.

At King's College, on Tuesday next, in continuation of the free lectures given to the public, in the theatre of the College, Prof. Bottomley will discourse on the "Romance of Plant Life."

At a meeting of the Royal Geographical Society, to be held to-morrow afternoon, a plan for the geographical description of the British Islands on the basis of the Ordnance Survey will be submitted by Dr. H. R. Mill, and a discussion will take place upon it.

The Council of the Society of Arts attended at Marlborough House on Wednesday, February 19, when H.R.H. the Prince of Wales, President of the Society, presented to Sir Lowthian Bell, Bart., F.R.S., the Albert Medal, "in recognition of the services he has rendered to arts, manufactures, and commerce

by his metallurgical researches and the resulting development of the iron and steel industries."

THE deaths are announced of Dr. G. Wagener, Professor of Anatomy in Warburg University; Dr. R. Benedikt, Professor of Technological and Analytical Chemistry in the Technische Hochschule at Vienna; Dr. Laennec, Director of the Nantes School of Medicine, and formerly Professor of Physiology; and Dr. Per Hedenius, Professor of Pathology, Hygiene, and History of Medicine in the University of Upsala; Dr. D. D. Slade, Lecturer on Comparative Osteology in Harvard University, and known for his contributions to osteology, zoology and botany.

WE see from the *Rendiconti* of the Reale Istituto Lombardo, that, at the recent annual meeting, one of the Cagnola prizes of 2500 lire and a gold medal of 500 lire was awarded to Prof. Ferdinando Sordelli for his treatise entitled "Flora fossilis Insubriæ." The other Cagnola prizes were not awarded. Under the Brambilla bequest a sum of 300 lire and a gold medal was awarded to each of the following for having introduced useful industrial processes:—Messrs. Macchi and Izar, Augusto Stiegler, Anacleto Pastori, Fermo Coduri and Co., Casall Francesco and Sons, Carlo Galimberti and Co.; and 250 lire to Antonio Fusetti for his process of photo-engraving on copper. The Fossabi prize of 1000 lire for a work on arterio-sclerosis was awarded to a work sent in under the motto, *Experientia docet*. The Ciani prize for the best Italian historical reading-book was distributed among the following, who were awarded 500 lire each:—Prof. Francesco Bertolini, "Story of the Italian Revival"; Prof. G. De Castro, "The Mantua Processes and the 6th of February, 1853"; Prof. Pietro Orsi, "How Italy was made." Among the prizes proposed for 1897 are the following:—An Institute's prize of 1200 lire for an experimental proof that an electrified dielectric is in a state of tension in the direction of the field and in a state of compression across it (last date, April 30, 1897). Cagnola prizes of 2500 lire each for works on the orographical conditions of the Alps and the Italian peninsula and islands; and the history of the methods and instruments for registering the phase of alternating currents (both April 30, 1896). Similar prizes for works on the comparative anatomy of the innervation of trophic organs, and on the *rôle* of pathogenic microbes in human pathology (April 30, 1897). Secco-Commeno prize of 864 lire for a work on the genesis, symptoms, effects, and cure of uremia (May 1, 1897). The Tommasoni prize of 500 lire will be given for the best work on the life and work of Leonardo da Vinci, with especial reference to his precepts on the experimental method, and to a project of a national publication of his entire works (May 1, 1896). The competitions enumerated are open to all nationalities, and the memoirs may be written in Italian, French, or Latin. The last-named may also be written in English or German. They must be sent to the Secretary of the Institute, at the Palazzo di Brera, Milan, before the dates named, under a motto or pseudonym, and a statement of the prize competed for.

In reference to the tenacity of life in insects, Mr. J. C. Warburg writes to the *Entomologist*. "When I was still new to collecting in South France, I discovered one day, to my great joy, a large female of *Saturnia pyri* hidden away in some bushes. The specimen was the first I had ever caught, and I decided, on account of its large body, to stuff it (a quite unnecessary operation; I have kept dozens since unstuffed). The moth was first apparently killed by being forced into a cyanide-bottle, where it was left about an hour. The abdomen was then emptied, and the cavity filled with cotton-wool soaked in a saturated solution of mercuric chloride. The insect, pinned and set, was discovered next day attempting to fly away from the setting-board."

THE effect of thunder, or the firing of cannon, on pheasants is very curious; either of these sounds start the cock birds crowing as if in defiance. Mr. G. T. Rope, writing to the *Zoologist*, says that at a place between five and six miles distant from the garrison town of Colchester, he has heard pheasants close to him echoing each report of the artillery practising there, and has on many occasions noticed the same thing elsewhere. The crowing sounds more like the answer to a challenge than the expression of fear. Mr. J. E. Harting points out that the observation is not new. Gilbert White remarked a century ago that the pheasants in his neighbourhood crowed when big guns were fired at Portsmouth, and the wind was blowing from that direction; and, says Mr. Harting, Charles Waterton also, in his "Essays on Natural History" (first series, 1837), makes the following remarks on the subject:—"The pheasant crows at all seasons on retiring to roost. It repeats this call often during the night, and again at early dawn; and frequently in the day-time, on the appearance of an enemy, or at the report of a gun, or during a thunder-storm."

OUR American correspondent writes under date February 21:—"J. Frank Elline, of Baltimore, has demonstrated that ordinary calcium light will produce results similar to the rays from a Crookes' tube. By combining the calcium light with side X-rays, Mr Elline obtained a result directly the reverse of ordinary X-ray pictures, the shadows being darker than the background. Dr. Wellington Adams and Prof. Nipher, of Washington University, St. Louis, have demonstrated that the X-rays can be focussed. Edison is experimenting in the direction of taking pictures by snap-shots, and has already succeeded in reducing the time of exposure to seven seconds, getting clearly-defined images of strips of metal after the rays had penetrated a heavy piece of cardboard and a vulcanised plate. Trowbridge claims to have secured instantaneous results already. Edison reports that his eyes were sore after working for several hours with his fluorescent tubes; but he is not certain that this result is specially attributable to the X-rays. Dr. Wm. J. Morton reports that he sees brilliant flashes of light after he has discontinued work, and, as he has worked with electrical light for many years without injury, he infers that the X-rays are injurious to the eye.

WITH reference to the statement in the foregoing note, as to the effect of Röntgen rays upon the eyes, Mr. Swinton informs us that though Mr. J. C. M. Stanton and himself have worked continuously with the Crookes' tubes for hours together, neither of them has experienced any ill-effects so far as their sight is concerned. In fact, so far as Mr. Swinton has observed, the X-rays do not, *per se*, in any way affect the eye, either at the time of the experiment or afterwards. With regard to Mr. Edison's experiments, a few seconds are found to be ample for taking pictures of pieces of metal. When it is a question of photographing a portion of the body, however, it is a different matter; but even then, with a good tube, thirty or forty seconds' exposure will give a very fair result.

DR. W. J. VAN BEBBER, of the Deutsche Seewarte, has sent us a separate copy of an interesting paper "On the climates of the earth and their influence on mankind," published in *Globus* (vol. lxix. Nos. 6 and 7). After giving a general description of continental and ocean climates, and of the influence of mountains and forests, he discusses in some detail the peculiarities of climate of various zones, and traces their influence on diseases, especially on malarial fever and cholera in the tropics. He finds that the occurrence of the former is closely related to rainfall and temperature; the fevers begin with the rainy reason, usually reach their maximum by the time the rain abates, and decrease as cooler

weather sets in. The malady becomes acute when warm weather occurs after an inundation. During the present century there have been five great epidemics of cholera. In the origin and development of this disease the weather conditions are found to have different effects, according to the locality. In Bombay and Calcutta, for instance, it generally begins before the hot and rainy season, and decreases with increasing temperature and rainfall; while in other parts, cholera is most frequent towards autumn, and decreases with decreasing temperature. The occurrence of land and sea breezes (including monsoons) in various parts of the globe is discussed at some length.

THE relations of the weather to the spread of disease are still involved in obscurity. Prof. Cleveland Abbe defends the general atmosphere from calumny in this connection in the *Monthly Weather Review* (vol. xxiii. No. 8, 1895). History records that, in the fifteenth century, a plague epidemic broke out most violently in a Swiss town immediately after a cloud, coming from an infected but distant region, discharged its rain upon that town. But, as Prof. Abbe points out, without going back to the fifteenth century, there was an excellent opportunity to investigate the subject in 1889-90, when the influenza spread over the whole civilised word. Its progress was so regular that for a long time there was a general belief that the active germs of influenza were carried as dust in the air by the winds, or perhaps by the upper currents. This idea was dissipated by several memoirs that established the fact that the wind and weather were entirely subordinate factors, and that the spread of the disease followed the lines of travel, especially the principal steamboat and railroad routes, and that, therefore, the germs were carried by diseased individuals, or by articles that had been used by or had come in contact with them, and not by the winds. Of course the wind, in the narrow sense, may have carried the germs a few feet or rods from one individual to another, but not for distances of many miles. Several epidemics, such as the yellow fever, small-pox, and cholera, have been traced back to the direct importation of their contagia (whether animate or inanimate) by human agencies. Furthermore, experimental data show that few disease germs can maintain their vitality more than a few hours when freely exposed to the air and sunshine, as would probably be the case if they were carried in the atmosphere as minute particles of dust. Therefore Prof. Abbe thinks it probable that the winds and the rain must not be considered as the means by which diseases are spread between places that are any considerable distance apart.

PROF. SERGI (*Centralblatt f. Anth. Eth.*, &c.) complains that the Indo-Germanic theory of the origin of European peoples has distracted attention from the Mediterranean peoples. For some time past these latter have been studied by him, of whom he recognises four main branches—Lybian, Iberian, Ligurian, and Pelasgian. The Egyptian monuments state that the ancient Egyptians came from the land of "Punt," and anthropologists admit an African origin for that people. Sergi places Punt in Ethiopia, Somali-land, and part of South Arabia, and he finds the same head-forms amongst the ancient Egyptians and modern Somalis. This stock is known under the term "Hamitic," and it differs from the Semitic. Remains of prehistoric men from Spain, France, North Italy, &c., show a close resemblance with each other and with the early inhabitants of North Africa and the Canary Islands. Sergi asserts that the same people form to-day the bulk of the living populations of Spain, Italy, and Greece. He believes that the Hamites arose in East Africa; the first migration entered Egypt, then the stream diverged to the east to Syria and Asia Minor, and spread westwards as far as the Canary Islands; the Iberians, Ligurians, and Pelasgians (with the Etruscans) being branches of the main stem. These Mediterranean folk occupied South Russia, Switzerland, France, and Great Britain. In Neolithic times they were exterminated in the valley of the Po and in Switzerland, were driven beyond the Loire in France, and to the south and west in Britain by the mighty Celts. He describes the physical features of this Mediterranean group as a whole, and declares it to be the most beautiful of all the varieties of man.

THE part of the *Agricultural Gazette of New South Wales* for December 1895, contains a number of papers on the cultivation of fruits, and other crops, and on the diseases which affect cultivated plants in the colony, showing the valuable results obtained by the establishment of a State Department of Agriculture.

IN the *Irish Naturalist* for February is a useful paper by one of the editors, Mr. R. L. Praeger, on the botanical subdivision of Ireland, in which the island is parcelled out into forty districts. The geographical county boundaries are to a large extent preserved, and all the larger counties cut up into several divisions. The paper is accompanied by a map.

FROM the Skandinavisk Antiquariat, Copenhagen, has come to us a catalogue of a good collection of ancient and modern works on geography, ethnography, and travels, together with a number of rare maps and prints, offered for sale. A number of treasures to geographical bibliophiles will be found included in the catalogue.

THE 1896 *Annuaire* of the Observatoire Royal de Belgique has only just come to hand. As in former years (the publication has been issued without interruption since 1834), the contents are composed of ephemerides, containing the principal astronomical date for the current year; geographical, meteorological, and vital statistics; definitions of physical constants, and short articles, chiefly by M. Folie.

DR. G. EISEN reprints, from the *Proceedings* of the Californian Academy of Sciences, a paper entitled "Biological Studies of Figs, Caprifigs, and Caprification." He gives a history of the methods adopted from the earliest times for artificially pollinating the cultivated fig. While the ordinary edible figs grown both in Europe and in America, are independent of artificial pollination, the Smyrna fig will not mature without caprification, since the fig contains no male, but only female flowers.

WE have received a copy of a "Classificatory Chart of the Commoner British Orders of Flowering Plants," by Mr. W. P. Winter. That can hardly be regarded as an ideal selection of the more important orders, which excludes the Solanaceæ, Euphorbiaceæ, and Coniferæ, and admits the Chenopodiaceæ, Alismaceæ, and Naiadeæ. But this is explained by the footnote that "the orders include those necessary for the Elementary Examination, South Kensington." The characters seem carefully drawn up, and the chart will be a useful one to students.

THE development of photography, brought about by the discovery of Röntgen, has afforded the photographic journals excellent opportunities for distinguishing themselves. The special issue of the *Photogram*, brought out under the title of "The New Light," has run into a fifth edition; and the *Photographic Review* for March, apparently aims at obtaining the same measure of success, for its pages are almost entirely devoted to accounts and illustrations of work done by Mr. A. A. C. Swinton and Dr. Hall Edwards with Röntgen rays.

WE again offer our congratulations to the Wellington College Natural History Society. The twenty-sixth annual report of the Society shows that during 1895 the knowledge of the members was improved by means of lectures, and the faculties of a few ardent observers were developed. The Pender prize, founded in 1879, for the best essay on some scientific subject,

written by a member or associate of the Society, was won last year by Mr. H. C. Hayward, with an essay on "Protective Resemblances amongst English Lepidoptera." In awarding the prize, preference is given to essays containing original work.

THE London Amateur Scientific Society held its annual meeting on Friday last, at the Memorial Hall, Farringdon Street. Among the very interesting exhibits were a series of curious botanical specimens shown by Mr. Howell, a collection of rare and abnormal forms of Mollusca, by Mr. S. Pace, and an album of views of the Baku Oil Region, by Dr. W. F. Hume. After the specimens had been described, a paper was read by the President (Mr. W. H. Davis), on the "History of the Determination of Latitude and Longitude." Mr. Davis reviewed the existing state of geographical knowledge from the Homerian period to the time of Strabo and Ptolemy—its eclipse in the Middle Ages, and revival under Arabic influence, and progress up to recent times. He pointed out the method adopted in each successive epoch to determine positions on the earth's surface, and the progressive influences on scientific research induced by these inquiries. The objects of the Society is to further the study of the natural sciences among amateurs and students by the reading of papers, by excursions, lectures, the formation of a library, and in other ways. A Society having for its aim the cultivation of interest in natural knowledge, deserves encouragement and success.

SEVERAL publications have been received from the Meteorological Observatory of the Imperial University of Odessa. The *Annales* for 1894 contain a description of the Observatory; observations made during the year; and an account of the mortality and characteristic elements of the climate of Odessa. In the *Revue Météorologique* (vol. vii.) the meteorological observations made at stations in the south-west of Russia are brought together. The numerous observations at the stations organised in that region by Prof. A. Klossovsky, who is responsible for the whole of the publications, have enabled him to study the question of torrential rains during the period 1886–92, which discussion forms the subject of a separate paper.

THE elaborate "Leçons sur l'Electricité et le Magnétisme," by MM. E. Mascart and J. Joubert, has reached a second edition, the first volume of which, dealing with "Phénomènes Généraux et Théorie," has been received from MM. Masson and Co. Prof. Mascart is alone responsible for the new edition, Prof. Joubert being unable to assist in bringing the work into line with the present state of electrical knowledge. The many modifications introduced into the text, and the additions rendered necessary by the development of the science of electricity, has not resulted in any alteration of the general plan of the work. The second volume will be published at the end of this year, and will be devoted to the study of methods of observation, details of experiments, and the examination of the principal characteristics of industrial applications of electricity.

THE Field Columbian Museum at Chicago, a description of which was given in NATURE of June 6, 1895 (vol. lii. p. 137), commenced last year a series of publications having for its object the description of the contents of the Museum, and the issue of papers which come within the range of scientific or technical discussion. The publications will thus include not only catalogues of collections, but also transactions, memoirs, bulletins, monographs, and handbooks. There will be separate series for botany, zoology, anthropology, geology, and history, and each series is to have a separate pagination and volumes, so that the literature of each science or general subject will be rendered consecutive and complete for binding. No time is being lost in making known the extent of the collections in the different departments of the Museum, and Publications 2 and 3, which have just reached us, show that a high standard is aimed at. In one of these publications (Hist. Series, vol. i. No. 2), Mr. W. E. Curtis describes "The Authentic Letters of Columbus." The original Columbus documents which form the subject of his valuable bulletin were exhibited at the World's Columbian Exposition. Photographs were taken of the entire collection, and the negatives were subsequently presented to the Field Columbian Museum. The facsimiles thus obtained, now form part of the material in the Department of Columbus Memorial of that institution, and from them excellent half-tone plates have been made to illustrate Mr. Curtis's bulletin, which contains translations of all the manuscripts of Columbus existing, arranged in the order of the dates at which they are supposed to have been written; it will, therefore, be of extreme interest and service to students of geographical history. The second publication which we have received (Geol. Series, vol. i. No. 1), is a "Handbook and Catalogue of the Collection of Meteorites," by Dr. O. C. Farrington. Constructed on much the same lines as Mr. Fletcher's "Introduction to the Study of Meteorites," the publication will prove helpful to all who are interested in "holy things fallen from heaven." From the historical portion of the work a knowledge of the principal characters of meteorites will be obtained, while the catalogue of specimens in the Museum will facilitate the study of the collection. Maskelyne's classification of meteorites into aërosiderites, aërosiderolites, and aërolites, is followed in the catalogue. Six plates, each containing several figures illustrating the forms of meteorites, Widmanstätten figures, and microscopic structure, accompany Dr. Farrington's descriptions.

SOME speculations of considerable interest are put forward by M. Guntz in the current number of the *Comptes rendus*. Recalling the observations of Prof. Ramsay on the reduction of the vapour pressure of mercury by dissolved metals, from which the conclusion was drawn, that, at the boiling-point of mercury, the molecular weight of the metal in solution was in general equal to its atomic weight, M. Guntz puts forward the idea that in the case of metals extracted from their amalgams at a low temperature, the residue actually consists, for the most part, of the element in the atomic state. This, and not merely the fine state of division, he regards as the explanation of the energetic properties exhibited by such metallic residues. In support of this, thermo-chemical data are given for ordinary fused manganese, and manganese from its amalgam, the heats of combination with oxygen showing that the conversion of the latter into the former is accompanied with the evolution of heat (3·8 calories for the gram-atom). Besides manganese, both chromium and molybdenum, which after being fused are unchanged in air, are pyrophoric when extracted from their amalgams at low temperatures. M. Guntz proposes to study the heats of polymerisation of several metals, more especially of iron.

PROF. ARCIMIS informs us that the bearings he gave to the diagram (Fig. 1), which accompanied his description of the Madrid meteor (*ante* p. 395), were wrong. The south point should have been at the top of the diagram, and the east to the right.

THE additions to the Zoological Society's Gardens during the past week include three Punjaub Wild Sheep (*Ovis vignei*, ♂ ♀ ♀), from North-West India, presented by Captain R. A. Ogilby; a Vulpine Phalanger (*Phalangista vulpina*, ♂) from Australia, presented by Messrs. Multon and Wallis; a Fraser's Eagle Owl (*Bubo pœnsis*) from Ashanti, presented by Major H. M. Sinclair, R.E.; a Greater-spotted Woodpecker (*Dendrocopus major*), British, presented by Mr. W. H. St. Quintin; two Spiny-tailed Mastigures (*Uromastix acanthinurus*) from Biskra, Algeria, presented by the Lord Lilford; a Collar-

further established fifty scholarships tenable at the Company's school at Woodford in Essex, a first grade modern school, and offered them for competition by boys attending metropolitan public elementary schools. They co-operated in the conversion of one of their charities, now known as the Sir Wm. Bowman's Foundation, Greenwich, by means of which one hundred boys, selected by competition from public elementary schools in Greenwich, are now receiving gratuitously education in the Upper School of Greenwich Hospital. They have established scholarships in connection with the People's Palace Technical Day School, and some two hundred boys from metropolitan public elementary schools are now receiving gratuitous education there of a character to fit them to take their place as apprentices and improvers in workshops and manufactories. These scholarships are also offered for public competition.

In the year 1888 the Company, recognising the value of manual training as an adjunct to the general education of boys and girls, voted £1000 towards the cost of introducing and carrying on such training in metropolitan elementary schools for one year. The grant has annually been renewed since that date, and the manual classes are largely maintained by means of this grant. To places of higher education, both in London and the provinces, the Company have for many years past, and are still voting assistance. They established the spinning department of the Belfast Technical School; the engineering department of the University College of South Wales, Cardiff; the coal-mining department of the Yorkshire College of Science, Leeds; and they were the principal contributors to the establishment of the department of technical education in the University College of Nottingham. They have also made large grants for buildings and apparatus to many other educational institutions. During the year 1892, they expended no less than £26,000 in the promotion of education.

Since 1893, the Drapers' Company have very largely extended the educational work of the People's Palace; in fact, they have contributed about £100,000 to that institution. They have also increased their grants to the various provincial institutions mentioned in the foregoing, and assisted several others. Their School Board scholarships have been annually renewed, and they are maintaining their subscription of £1000 a year to the manual training classes in London elementary schools. About two years ago they established six scholarships with the view to enabling certain selected pupil-teachers from elementary schools to proceed to one of the universities. This scheme is working successfully, and will no doubt be developed. At present the Company are subscribing £400 to £500 per annum for these scholarships. They are also contributing a somewhat similar amount for the apprenticeship of boys to handicraft trades. The foregoing refers to work done by the Company in its corporate capacity. As trustees, they administer several important educational and apprenticeship endowments, and for the most part free of all expense to the charity.

The Fishmongers' Company have contributed a total sum of £68,760 to the City and Guilds Institute, £525 to the Borough Road Polytechnic, £340 to the North London Polytechnic, £52 10*s*. to the Wandsworth Technical Institute, £210 to the Baltimore Fishery School, £4300 to the Marine Biological Association, Plymouth, and £105 to the British Institute of Preventive Medicine. They also grant a scholarship of £60 to a student of the Finsbury Technical College, to be held at the City and Guilds Institute. The Company also grant eighteen exhibitions of £40 each to students of the Universities, and four exhibitions of £20 each to Masters of Arts, four scholarships of £50 each to the City of London School, and four of £50 each to the Central Foundation Schools, besides the large sums expended in the inspection of fish and the protection of salmon.

The Goldsmiths' Company, unlike some of the other great Companies, have no educational trust; but they spend a large proportion of their corporate funds upon technical, scientific, and general education. The Company was one of the first of the Companies to take up the subject of technical education, and they have been connected with the City and Guilds of London Institute from its inception; and to this Institute the Company have been the largest donors, their contributions to the present date exceeding £80,000, in addition to which they give an annual subscription of £4000. The Company have also, at their sole cost, established and endowed their Technical and Recreative Institute at New Cross. The capital expenditure upon the site, buildings, and equipment of this Institution amounts at this date to very little less than £100,000; and the Company have also assigned to it a minimum endowment of £6000 per annum. As regards general education, the Company have established seventy exhibitions of £50 per annum each for poor students at Oxford and Cambridge. These exhibitions are awarded solely for merit, coupled with a careful consideration of the pecuniary needs of the candidates. The Company also contribute to Newnham and Girton Colleges for poor lady students; and they make considerable occasional grants to other educational Institutions. A short time ago the Company granted £1000 to the Royal Institution, for the furtherance of Prof. Dewar's researches at low temperatures; and £1000 to the Imperial Institute, for research work in connection with Indian and Colonial products; and they have also recently given £1000 for the prosecution of research work in connection with the anti-toxin treatment of diphtheria. Altogether, a careful examination of the Company's expenditure during the past ten years shows that during that period thirty per cent. of the *gross* corporate income of the Company has, on an average, been devoted to educational purposes, and, as above mentioned, all this expenditure is made out of the Company's private funds.

The Skinners' Company give £2000 per annum to the City and Guilds Institute and contribute towards the support of the Northampton Institute at Clerkenwell—the chief of the three members of the City group of Polytechnics. Many other grants have been made from time to time for educational and other purposes, scientific and recreative.

The Merchant Taylors' Company expend out of their corporate income between £7000 and £8000 a year on their school at Charterhouse Square, grant £2000 a year to the City and Guilds of London Institute, and make other grants of considerable sums for educational purposes, the total annual average expenditure on general education amounting to 28 per cent. of the net corporate income.

The Haberdashers' Company's donations and grants are, we are informed, mainly devoted to general education; but no specific information has been furnished us with reference to them.

The Salters' Company have founded the following scholarships and Fellowships for the promotion of science, viz.:—£100 per annum to the Pharmaceutical Society of Great Britain for higher scientific research. £100 per annum to St. Thomas's Hospital for a like object. £150 per annum to the City and Guilds Institute for research in chemistry in its relation to manufactures (towards the general objects of which Institute the Company also subscribe nearly 1000 guineas per annum). The Company have founded Natural Science Exhibitions in connection with the City of London School and King's College School, London, which exhibitions are of the annual value of £80 each, as well as scholarships of lesser value at the Guildhall School of Music and the Royal Naval School, and, although perhaps not of a scientific nature, scholarships have been founded in connection with the Philological School in Marylebone Road, and Trent College, Nottingham. In addition to the above, the Company contribute to many objects of acknowledged public utility, the amount of which contributions, in 1894, was some £5000.

The Clothworkers' Company have very generously contributed towards the advance of technical education in London and the provinces, as will be seen from the subjoined statement of grants. The Company have also established a research laboratory in connection with the Clothworkers' Textile, Dyeing, and Design Departments of the Yorkshire College, Leeds. Numerous papers descriptive of work done in this laboratory have been contributed to the Chemical Society and the Society of Chemical Industry. The Company's grants to scientific institutions in London are:—City and Guilds of London Institute (£3500 per annum), £68,250; Imperial Institute, £2500; King's College (Scholarships not exceeding £225 per annum), £2000; King's College (Kensington Branch for the Higher Education of Women), £500; University College (Scholarships, £60 per annum), £650; Northern (Islington) Polytechnic, £17,500; People's Palace Polytechnic, £1000; Borough Road Polytechnic, £1000; Regent Street Polytechnic, £500; South-Western Polytechnic, £100; Finsbury Polytechnic, £100; North-West London Polytechnic, £50; City of London College, £600; Birkbeck Institution, £205; Marine Biological Association, £500; British Institute of Preventive Medicine, £100; London Society for

Extension of University Teaching, £1100; Middle-Class Schools Corporation (now Central Foundation Schools of London), £2500; National Association for Promotion of Technical Education, £150; Bedford College (Physical and Chemical Laboratories), £125; Toynbee Hall, Whitechapel, £125; Society of Arts, £504; Royal Architectural Museum and School of Art, £142; Bethnal Green Free Library, £141; Recreative Evening Schools Association, £340; Froebel Educational Institute, £100; Parmiter Foundation School, £100; University Settlement, Bermondsey, £25; Palæontographical Society, £21; Onslow College of Science, £250—making a total of £101,178. To scientific institutions in the provinces the grants for building equipment and general purposes amount to:—Yorkshire College, Leeds (textile industries, dyeing, and art departments, wholly founded and maintained by the Company), £34,000; Bradford Technical College, £4350; Huddersfield Technical School, £2000; Halifax Technical School, £2100; Keighley Technical School, £1300; Dewsbury Technical School, £825; Salt Science and Art Technical School, Shipley, £825; Bingley Technical School, £350; Batley Technical School, £250; Holmfirth Technical School, £250; Ossett Technical School, £200; Wakefield Technical School, £100. In addition to this, the Company grant to these institutions annually for maintenance a sum amounting to about £4000.

It is interesting to compare with the grants named in the foregoing, the estimate which the Technical Education Board of the London County Council have just submitted to the Finance Committee of the Council, as to the sum required by them for the year ending March 31, 1897. The net probable expenditure will amount to £120,000, of which £9000 is for the equipment and £16,000 the maintenance of technical departments of polytechnics. The other items are £9680 for Shoreditch, Wandsworth, and other technical schools, £20,000 for technical departments of public secondary day schools (including allowance for the fees of the Board's county scholars £70,500), £4000 for higher education, £26,070 for county scholarships, £14,440 for art teaching (including art scholarships), £8985 for science teaching (including science exhibitions and pioneer lectures, technology, and manual instruction), £4200 for domestic economy, £1500 for commercial subjects, £1000 for museums, and £5550 for expenses of administration (including cost of inspection). In 1893-94 the Board's expenditure was £46,000, in 1894-95 £63,000, and in 1895-96 £91,000. The chief causes of the increase are assigned to the development of the board's scholarship system, which has nearly reached its limit, and is costing nearly £40,000 per annum; the increase in the amount of evening educational work carried on in accordance with the Board's regulations, and therefore eligible for the Board's grants; the very great increase in the number of students who are studying science practically, as shown by the recent report of the Board's science inspector, and the consequent expenditure incurred in equipping and maintaining laboratories; the opening of new polytechnics, and the development of the technical departments of other polytechnics, and the establishment of new institutions.

In one respect the Livery Companies are in advance of the Technical Education Board, and that is in the encouragement given to research. The funds of the Technical Education Board are used to create and foster classes and institutions concerned with technical instruction, and probably the Board does not feel at liberty to give any direct assistance to research in the way that some of the Companies are doing. But, at the same time, the Board is doing work which should eventually result in an increase in the ranks of investigators, and it is to be hoped that the time is not far distant when the polytechnics will make those contributions to knowledge which are the only sure indications of scientific advancement.

ZOOLOGICAL NOMENCLATURE.

At the meeting of the Zoological Society on Tuesday, Mr. P. L. Sclater, F.R.S., introduced a discussion on the following rules for the scientific naming of animals, compiled by the German Zoological Society.

A. General Rules.

(1) Zoological nomenclature includes extinct as well as recent animals, but has no relation to botanical names.

(2) Only such scientific names can be accepted as are published in print, in connection with a clear description either by words or figures.

(3) Scientific names must be in Latin.

(4) Names of the same origin and only differing from each other in the way they are written are to be considered identical.

(5) Alterations in names otherwise valid are only permitted in accordance with the requirements of Sections 13 and 22, and further for the purpose of purely orthographical correction when the word is without doubt wrongly written or incorrectly transcribed. Such alterations do not affect the authorship of the name.

(6) Of the various permissible names for the same conception only the one first published is valid (Law of Priority).

(7) The application of the Law of Priority begins with the tenth edition of Linnæus's "Systema Naturæ" (1758).

(8) When by subsequent authors a systematic conception is extended or reduced, the original name is nevertheless to be regarded as permissible.

(9) The author of a scientific name is he who has first proposed it in a permissible form. If the author's name is not known, the title of the publication must take its place.

(10) If the name of the author is given it should follow the scientific name without intervening sign. In all cases in which a second author's name is used a comma should be placed before it.

(11) Class (*classis*), Order (*ordo*), Family (*familia*), Genus (*genus*), and Species (*species*) are conceptions descending in rank one after the other, and are to be taken in the order here given. These terms should not be employed in a contrary or capricious relation or order.

B. Rules for Designating Species.

(12) Every species should be designated by one generic and one specific name (binary nomenclature).

(13) The specific name, which should be treated always as one word, should depend grammatically upon the generic name.

(14) The same specific name can only be used once in the same genus.

(15) In the case of a species being subdivided, the original name is to be retained for the species which contains the form originally described. In doubtful cases the decision of the author who makes the separation shall be followed.

(16) When various names are proposed for the same species nearly at the same date, so that the priority cannot be ascertained, the decision of the first author that points out the synonym should be followed.

(17) In the case of species with a cycle of generation of different forms, the specific term must be taken from an adult form capable of reproduction. In these cases, as also in species in which polymorphy occurs, the Law of Priority must be observed.

(18) The author of the specific name is the author of the species.

(19) The author's name should be placed in brackets when the original generic name is replaced by another.

(20) Hybrids should be designated either by a horizontal cross between the parents' names, or by these names being placed one above the other with a line between. The parents' sexes should be stated, when known. The name of the describer of the hybrid should be added, preceded by a comma.

C. Rules for the Names of Subspecies and other Divergences from Typical Species or Subspecies.

(21) When constant local forms, varieties, strains, &c., require special names, these names should be placed after the specific name. The rules for such names are the same as those for specific names.

D. Rules for Generic Names.

(22) Names of genera should be substantives, and of the singular number. They should be one word and be written with a large initial letter. If a subgenus is used, its name (which follows the same rules as a generic name) should be given in brackets after the generic name.

(23) A generic name is only valid when a known or a sufficiently characterised species (or several species) is referred to it, or when a sufficient diagnosis of it is given.

(24) The same generic name can only be employed once in

zoology. Nor can names already proposed as subgeneric be employed also as generic names in another sense.

(25) When several generic names are proposed for a genus at nearly the same date, so that their priority cannot be settled, the name for which a type-species is given is to be preferred. In all uncertain cases the decision of the author who first arranges the synonymy is to be followed.

(26) When a genus is separated into several genera the old name must be retained for the type-species. If this cannot be positively ascertained, the author who splits up the genus must select one of the species originally in the genus as the type. When a subgenus is raised to generic rank the subgeneric name becomes the generic name.

E. Rules for the Names of the Higher Systematic Groups.

(27) Names for higher systematic groups of animals must have a plural termination.

(28) Names of families and subfamilies must henceforth be taken from the name of one of the genera belonging to the group, and formed from the stem of that name, with the addition of *-idæ* (plural of *-ides* [Gr. -ειδης], masc.) for the families and *-inæ* (fem.) for the subfamilies.

Mr. Sclater pointed out the principal points in which these rules conflict with the Stricklandian Code commonly used in this country. These were three in number, namely :—

(1) The German Rules (Sect. 1) disclaimed any relation to botany, so that, according to them, the same generic names might be used in zoology and botany. This was contrary to the Stricklandian Code (Sect. 10).

(2) Under Sect. 5 of the German Rules the same term was to be used for the generic and specific name of a species, if these names had priority. This was contrary to the Stricklandian Code (Sect. 13).

(3) The German Rules (Sect. 7) adopted the tenth edition of the "Systema Naturæ" (1758) as the starting-point of zoological nomenclature, whereas the Stricklandian Code (Sect. 2) adopted the twelfth (1766).

After a few remarks from the President (Sir W. H. Flower), Mr. Hartert spoke in favour of the modifications proposed in the German Rules. The debate was continued by Prof. Lankester, Mr. H. J. Elwes, Dr. D. Sharp, Mr. Blanford, Dr. H. O. Forbes, and others, but no final resolution was adopted.

SCIENCE IN THE MAGAZINES.

The eleventh instalment of Mr. Herbert Spencer's admirable series of papers on "Professional Institutions" appears in the *Contemporary*, the profession of which he traces the development this month being that of the painter. Mr. Spencer does not concern himself with the rude drawings made by prehistoric man, but deals rather with the development of pictorial art from the point at which the early civilised stage is connected with the uncivilised, illustrating his arguments by reference to the remains and records of historic peoples. The first step in the development appears to have been the painting of the image of a dead man, to be placed on his grave. Priests painted as well as carved these effigies ; in fact, an examination of available evidence shows that "pictorial art in its first stages was occupied with sacred subjects, and the priest, when not himself the executant, was the director of the executants." Painting was originally subordinated to sculpture, which fact accounts for its relatively slow development. It became secularised in the later stages of Grecian life. Mr. Spencer traces these changes, as well as the differentiation of the lay painter from the clerical painter, and the differentiation of lay painters from one another.

Short descriptions of the chief discoveries of Edison and Tesla are given in *Scribner*, by Mr. E. B. Andrews, in the course of his "History of the Last Quarter-Century in the United States," his article being a continuation of previous ones contributed by him to the same magazine. "Edison," he remarks, "is famous less for originality than for dogged patience and subtle insight, enabling him to fructify others' devices. . . . A more original genius than Edison, veritably a wizard, is his young disciple, Nikola Tesla, who was born in Servia, and found employment with Edison on landing in America." *Scribner* also contains an illustrated article on "Carnations," by J. H. Connelly.

Under the title "Ways and Means in Arid America," Mr. W. E. Smythe contributes to the *Century* an account of the influence irrigation has exerted upon the development of Kansas and her sister States during the past fifteen years. The adoption of irrigation in a territory which had hitherto depended entirely upon the rainfall "extended the known limits of arid America hundreds of miles to the eastward [of Garden City] and more than one thousand miles north and south, thus adding to the empire of irrigation all the western portions of the Dakatos, Nebraska, Kansas, Oklahoma, and Texas, together with eastern Colorado." Mr. Smythe's description of what has been achieved during the past few years in these States, and in several widely separated localities in America, is a valuable object-lesson for farmers and fruit-growers.

The following are among other articles of scientific interest in the reviews and magazines received :—"The Increase of Insanity," by Mr. W. J. Corbet, in the *Fortnightly*, and an article in the *Humanitarian*, on "The Multiplication of the Unfit," by Mr. Arnold White, having much the same teachings ; "The Baltic Canal, and how it came to be made," by Mr. W. H. Wheeler, in *Longman's* ; "The Development of Dodos," in the *National*, in which Miss Mary Kingsley shows some of the effects of European culture on the West African, her paper supporting the views expressed at the British Association meeting last year, when a formal discussion took place on the results of interference with the civilisation of native races ; "The Tintometer," and "An Old Geography," in *Chambers's Journal* ; "Niagara Falls and Water Power," by Mr. Alex. Richardson, in *Good Words*.

SMITHSONIAN INVESTIGATIONS.

Mr. S. P. Langley's report of the operations of the Smithsonian Institution during the year ending with June 1895, has come to hand. The report includes a general account of the affairs of the Institution during the period it covers, and also descriptions of the work accomplished in the U.S. National Museum, the Bureau of Ethnology, the Bureau of International Exchanges, the National Zoological Park, and the Astro-physical Observatory. We extract from it the following brief statement with reference to three investigations carried on under the supervision of the Institution :—

The investigation of the infra-red spectrum has been continued in the Astro-physical Observatory during the past year with increased energy, and Mr. Langley says that though only provisional results have yet been published, which are intended merely to show the character and progress of the work, it is because the means of giving greater exactness are constantly growing, so that the result it is now hoped to present will be given with the aim of a still higher standard of precision ; an aim which it may be trusted will be considered a legitimate cause for the delay in the appearance of the final results.

It is stated that a larger number of bolographic records has been obtained than in any previous year, and that these continuous observations have been accompanied by further improvement in the apparatus, a higher standard of accuracy, and a nearer approach to the completion of the research ; but that they have also shown beyond a doubt that the limit of accuracy which is desirable can never be reached in the present most unsuitable, provisional site, which is subject to every kind of disturbance due to the neighbourhood of the streets of a busy city.

Prof. E. W. Morley's investigations on the density of oxygen and hydrogen, referred to in previous reports as aided in part by the Institution, have been completed, and his memoir has been published. The atomic weight of oxygen may be called the base upon which practically our entire system of atomic weights rests, and a small error in its measurement becomes large by multiplication in the higher parts of the atomic weight scale. Hence its accurate determination is of fundamental importance. In his investigation Prof. Morley has studied the problem by two methods : (1) By the synthesis of water, in which he, for the first time, has achieved completeness by actually weighing the hydrogen, the oxygen, and the water formed, whereas all his predecessors took one or another of these factors by difference. (2) By the density ratios between oxygen and hydrogen. In this method he has weighed the gases of greater purity and in larger quantity than hitherto, and he has in some instances operated without the intervention of stopcocks, and therefore with no possibility of error due to leakage. He has also, as a correction to the density ratio,

redetermined the composition of water by volume. By both methods he reaches the same result: O = 15·879, with variation in the fourth decimal place as between the two.

Dr. J. S. Billings and Dr. S. Weir Mitchell have completed the investigations begun by them in 1893, under a grant from the Hodgkins fund, to determine the nature of the peculiar substances of organic origin contained in the air expired by human beings.

In their report the investigators state that for a number of years prior to 1888 the prevailing view among physicians and sanitarians had been that the discomfort and dangers to health and life which had been known to exist, sometimes at least, in unventilated rooms occupied by a number of human beings were largely or entirely due to peculiar organic matters contained in air expired by these persons, and that the increase in carbonic acid due to respiration had but little effect in producing these results, its chief importance being that it furnished a convenient means of determining the amount of vitiation of the air. Recently, however, several experimenters have concluded that the organic matters in the exhaled breath are not harmful, at all events to animals, and the main object of the investigations was to determine the correctness of these conclusions.

The investigators found that the air in inhabited rooms, such as the hospital ward in which experiments were made, is contaminated from many sources besides the expired air of the occupants, and that the most important of these contaminations are in the form of minute particles or dust, in which there are micro-organisms, including some of the bacteria which produce inflammation and suppuration. It is probable that these dust particles were the only really dangerous elements in the air, and it appears improbable that there is any peculiar volatile poisonous matter in the air expired by healthy men and animals other than carbonic acid.

In concluding their report the authors state that the results of the investigations, taken in connection with the results of other researches summarised in the report, indicate that some of the theories upon which modern systems of ventilation are based are either without foundation or are doubtful, and that the problem of securing comfort and health in inhabited rooms requires the consideration of the best methods of preventing or disposing of dusts of various kinds, of properly regulating temperature and moisture, and of preventing the entrance of poisonous gases like carbonic oxide derived from heating and lighting apparatus, rather than upon simply diluting the air to a certain standard of proportion of carbonic acid present.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MISS HELEN M. GOULD has presented a scholarship of 7000 dols. to Wellesley College.

MRS. S. V. HARKNESS, of New York City, has given 50,000 dols. to the Women's College of the Western Reserve University at Cleveland, Ohio, to establish a chair of biblical literature.

MR. W. C. FLETCHER, master at Bedford Grammar School, has been appointed head master of the High School and Commercial School of Liverpool Institute.

A PARLIAMENTARY paper has just been issued containing a Treasury minute to the effect that the grant to King's College, London, which was suspended by the late Government owing to the retention of denominational tests by the college, shall be continued without any stipulation as regards tests. The college will therefore receive, as from April 1 next, an annual sum of £1700 during the remainder of the term of five years, for which period, beginning in 1894, the grant of £15,000 a year to university colleges in Great Britain was to be proposed to Parliament. The other colleges are also to be informed that the increase in their grants caused by the suspension of the grant to King's College will not be continued beyond the end of this month.

IT has been proposed in the Chamber of Deputies (says the Paris correspondent of the *British Medical Journal*) that from the unreclaimed sums of savings banks and other deposit sums to the amount of £10,000 should be paid to the different French laboratories, £2600 to the Pasteur Institute and to the laboratories of higher education in Paris, including the Val-de-Grâce Hospital laboratory and the Alfort School of Veterinary Medicine, for the purpose of aiding researches on contagious diseases, especially those in connection with serums and vaccines; £5000 to the medical school laboratories of Lyons, Bordeaux, Montpelier, Toulouse, Lille, and Nancy, likewise to the veterinary schools of Lyons and Toulouse; also for the purposes of experimental research for contagious maladies, including the further study of serums and vaccines; and £2400 to the therapeutical, pharmacological, and medical chemistry laboratories of the medical faculties and pharmaceutical schools to be devoted to the study of the methods of treating contagious diseases, likewise of the drugs. Every year reports of the work done at these establishments are to be sent to the Minister of Public Instruction. The Minister will afterwards send them either to the Academy of Sciences or Academy of Medicine.

THE views with reference to training in scientific method, which have been advocated with great persistence by Dr. H. E. Armstrong for some years, are beginning to bear fruit. Mr. A. B. Badger, in a scheme for technical education which he has drawn up for the Carnarvonshire County Council, devotes a section to pointing out the advantages of training in observing, experimenting, and reasoning by practice in the methods of science, and he urges the claims of such instruction to recognition. His remarks are so different from those of technical advisers and organising secretaries of most of the County Councils, that we are glad to quote them. "Throughout life we are largely engaged in exercising the faculties with a view to action. We ought, therefore, as early as possible, to be trained to see things as they are, to compare facts together, and to draw just conclusions; such training ought to form part of the fundamental education of all. The highest authorities are agreed that habits of observing accurately, experimenting exactly and reasoning logically, are best formed by practice in the methods of science. For years past science has been taught in schools, but far too often the pupils have only been lectured to and shown experiments, or if they have done practical work, it has been a kind which required the minimum of observation and deduction. Primarily, it is not knowledge of the facts of chemistry, or physics, or mechanics, which is wanted, but training in the methods by which these facts were discovered, thus developing the faculties by which, in every occupation of life, the facts necessary to it are ascertained, and their relative values determined." We trust that the suggestions contained in Mr. Badger's carefully-constructed scheme will be adopted by the Local Governors and Headmasters of the County Schools, who will consider them in conjunction with the Technical Education Committee of Carnarvonshire.

SOME of the tables which form the appendix to volume I. of the Report of the late Royal Commission on Secondary Education are of a most interesting and valuable nature. The first of these sets forth the amounts appropriated and spent during the financial year 1893-4 under the Local Taxation Act, 1890. We find the amount available for educational purposes in the counties was £595,838 16*s*. 6*d*., of which £448,130 17*s*. 1*d*. was actually appropriated by the County Councils for this object, though only £396,143 6*s*. 2*d*. was really spent. This sum was disposed of as follows:—Grants to secondary schools, £17,168 17*s*. 10*d*.; to scholarships and exhibitions, £40,047 19*s*. 6½*d*.; to evening continuation classes, £13,921 14*s*. 10*d*.; special classes for elementary teachers, £22,781 9*s*. 6*d*.; technical and art schools and classes, £191,011 13*s*. 5½*d*. Of the last-mentioned amount no less than £134,578 1*s*. 9½*d*. went to "classes" of one sort and another. The amount available for county boroughs was £152,224 7*s*. 4*d*., but owing to the accumulation of funds in the previous years the amount appropriated reaches £158,687 8*s*. In addition to this, the sum of £8,659 6*s*. 10*d*. was raised under the Technical Instruction Act. A consideration of the expenditure in the boroughs brings forcibly under our attention the part that the School Boards are allowed to take in the disposal of the funds, for we find £13,161 8*s*. was placed in their hands to be dealt with by them. Under the same headings as those used in speaking of county expenditure we find £9,190 17*s*. 1*d*. for secondary schools; £5,444 9*s*. 10*d*. for scholarships and exhibitions; £5,263 7*s*. 6*d*. for evening continuation classes; for technical and art schools and classes the amount reaches £102,147 7*s*. 6*d*. of which only £19,645 5*s*. is spent on more or less detached classes. While Preston devoted none of its share to the purposes of education, and Northampton, Reading, and Great Yarmouth only a part, Coventry, Hanley, Nottingham, Rochdale, Sheffield, and Worcester, not only appropriated the whole of the amounts allocated to them, but also levied rates under the Technical Instruction Act.

SCIENTIFIC SERIALS.

Wiedemann's Annalen der Physik und Chemie, No. 1, 1896.—Absorption and emission of electric waves by resonance, by Max Planck. When a secondary circuit is excited by waves of a period equal to that of the circuit, resonance takes place. Three stages may be considered. In the first, the circuit absorbs energy from the external wave system until it has acquired a maximum of oscillation. The next stage is stationary, the circuit absorbing as much energy as is necessary to compensate for energy radiated and converted into heat. The third stage represents the dying out of the oscillation after the primary wave has ceased. Maxwell's equation enables us to calculate the distribution of energy during each of these stages.—Propagation of electric waves in water, by E. Cohn and P. Zeeman. The method used is an improvement on the apparatus previously employed, the parallel wires being taken through the trough of water and passing beyond it direct into the bolometer. The most important results are that for frequencies ranging from 27 to 97 millions no dispersion is observable, and that the index of refraction for such vibrations equals the square root of the dielectric constant.—On the alleged dissipation of positive electricity by light, by J. Elster and H. Geitel. The illumination of the anode in a vacuum leads apparently to a dissipation of an electric charge similar to that observed when a liquid alkali alloy is illuminated as a kathode. This is, however, due to the effect of the light on the platinum kathode or the interior of the tube after it has acquired a slight coating of alkali metal vapour. When this is obviated, no dissipation takes place.—Change of resistance of a contact by electric irradiation, by V. v. Lang. When a rod of carbon is lightly stood upon a block of carbon, a certain sensitive degree of contact may be found which abruptly diminishes in resistance when electric waves are produced in the neighbourhood, say by an influence machine or even an electrophorus. Any slight concussion tends to restore the original resistance. Similar results are obtained with zinc and aluminium, but the very least shock spoils the experiment in this case.—Longitudinal light, by G. Jaumann (see p. 374).—On the electric arc, by L. Arons. It is well known that an alternate current arc light is much more difficult to produce between metallic than between carbon electrodes. This may be due to the lower thermal conductivity of the carbon, which enables it to retain its heat while the current passes through wires, or to the volatile gases which are always given off by carbon, or to the oxidation of the metals during the passage of the current.

Symons's Monthly Meteorological Magazine, February.—The mild winter, by the editor. Figures are given to show that, though mild, there has been nothing very exceptional in the present winter, although it bears a great contrast to the severe frost of 1895. The temperature of December last in London was only about 1° above the average; the temperature of January 1896 was about 3° above the average, but it has been exceeded in eleven years out of the last thirty-six. In January 1884, the lowest air temperature was 32°·2, and the whole month was 3° warmer than January 1896.—The high monthly mean pressure in January. The mean for the month in Camden Square was 30·360 inches. This has only been exceeded twice since the Camden Square record began in 1858, viz. in January 1880, when the mean was 30·370 inches, and in February 1891, when it was 30·472 inches. A table is given showing the high monthly pressures of 30·360 inches or upwards in the vicinity of London since 1779. This value has only been reached or exceeded on nine occasions, and the mean of February 1891, above quoted, is the highest.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 16.—"Memoir on the Theory of the Partitions of Numbers." Part I. By Major P. A. MacMahon, R.A., F.R.S.

This memoir presented is a natural sequel to the memoirs of 1891, 1893, and 1894, published *in extenso* in the *Philosophical Transactions*. In fundamental idea it is graphical, resting, on the one hand, upon the method of the memoir on the "Compositions of Numbers," of 1893, and, on the other, upon Sylvester's graphical method, set forth in his "Constructive Theory of Partitions," of 1882, published in vol. v. of the *American Journal of Mathematics*.

The memoir is divided into four sections. In § 1 the author gives new notions concerning the partitions of ordinary unipartite numbers, and shows that the theory of the separations of a partition necessitates the consideration of the partitions of multipartite numbers. The two theories proceed in parallel paths. One-to-one correspondence can be established at any point.

In § 2 he is engaged with the graphical representation of unipartite partitions. The graph that, in the memoir of 1893, was employed to denote a principal composition of a bipartite number is shown to be the graph also of a unipartite partition.

A new theory of unipartite partitions is evolved with algebraical developments in correspondence.

In § 3 he investigates a similar correspondence between the compositions of tripartite numbers and certain regularised partitions of bipartite numbers.

The method is of general application, and indicates a one-to-one correspondence between the compositions of $m+1$-partite numbers and contain regularised partitions of m-partite numbers.

In § 4 he takes up the question of the graphical representation of completely regularised multipartite numbers. He follows Sylvester, proceeding from two to three dimensions. Whereas Sylvester employed nodes in a two-dimensional corner, the author employs nodes piled up in a three-dimensional corner. Sylvester obtains a two-fold correspondence from the permutations of his axes x, y. The author obtains a six-fold correspondence from the permutations of the three axes x, y, z. Even Sylvester's two-dimensional graphs permit of six interpretations when viewed from the three-dimensional standpoint.

Physical Society, February 28.—Prof. John Perry, Vice-President, in the chair.—Sir D. Salomons showed some experiments with incandescent lamps. A large electro-magnet is excited by means of a continuous current, while an alternating current is passed through an incandescent lamp. On bringing the lamp near the magnet the filament is set in vibration, which, if the lamp is brought sufficiently near the magnet, is sufficiently intense to break the filament. The number and position of the nodes formed in the vibrating filament are found to be independent of the natural period of the filament, but depend on the frequency of the alternating current. Prof. S. P. Thompson asked whether it was not found that the number of segments into which the filament divides, depended to some extent on the natural period of the filament. Prof. Ayrton said that the magnetic leakage was very large with the arrangement adopted, and he would like to know whether this method was a more sensitive one for mapping out the field than those ordinarily employed. In an instrument designed by Prof. Perry and himself, an alternating current was passed through a wire stretched between the poles of a magnet, and the tension of the wire was altered till the vibrations set up were a maximum. The natural period of the wire, and hence the frequency of the alternating current, was then deduced from the tension, &c. In Prof. Ewing's magnetic curve tracer, on the other hand, the natural period of the stretched wire was made as different as possible from the period of the alternations which were to be observed, so that the natural vibrations of the wire did not influence the results. The author's arrangement appeared to him (Prof. Ayrton) to be intermediate between these two, and it would seem that the natural period of the filament would to a certain extent influence the results. Prof. Perry suggested that the lamp might be held in a very steady support, so that after the large vibrations due to the natural period of the filament had died out, the vibrations of the period of the alternations alone could be observed. Sir D. Salomons, in his reply, said that the arrangement was not intended for making *measurements*. A lamp had been fixed in a steady clamp, and the current passed for many hours, but the character of the vibrations remained unaltered. He had found the vibrating filament useful for microscope work where a surface rather than a line of light was required.—Prof. Fleming read a paper by himself and Mr. Petavel, on an analytical study of the alternating current arc. The first part of the paper consisted of an analytical study of the distribution of light throughout the various radiating regions in the arc, when supplied with electric power of known constant amount, the periodic variations of the current through the arc and of the potential difference between the carbons being at the same time recorded. The power was measured by means of a bifilar watt-meter; while by means of a series of mirrors and a rotating disc carried by a synchronising alternate current motor, the mean value of the light taken from any part of the arc was compared with the instantaneous

value of the light taken from the same part of the arc, and taken at any assigned instant during the period. Thus the arc itself was its own standard, and difficulties due to slow variations in the mean light of the arc disappear. The facts observed may be summed up as follows:—The purple light of the true arc undergoes a periodic variation, and, as far as the eye can judge, is completely extinguished for a certain interval during the phase; it has equal maxima values during the period, at instants slightly lagging behind the instants of maximum power expenditure in the arc. On the other hand, the illuminating power of the carbon crater varies between a minimum value and two unequal maxima; the greater maximum occurring when the carbon is positive, and an instant slightly lagging behind the instant of maximum power expenditure in the arc. The second part of the paper consisted of a comparison of the efficiency of the alternate current arc regarded as a light-giving agent, as compared with that of a continuous current arc taking the same mean power. Using two arcs, which may be regarded as typical of those used in practice, the mean spherical candle-power was compared for equal expenditure of power in the arcs; and it was found that for the alternating current arc employed the total mean spherical candle-power was always less than that of the continuous current arc. Lowering the frequency seemed to decrease the efficiency of the alternating current arc. Prof. Ayrton said the behaviour of the alternate current arc was of great interest, for the power supplied could not be measured by simply multiplying the current by the electro-motive force, since the current lags behind the volts. The resistance, *i.e.* the ratio of the current to the E.M.F., also lags, but the authors do not appear to have made any attempt to measure the *true* resistance. The authors were to be congratulated on the guarded tone they had adopted as to the bearing of these experiments on the question of the relative efficiency of the alternating and continuous current arcs. In a previous communication, one of the authors had stated that the alternating current arc must necessarily be a less efficient light-producing agent than the continuous current arc. Although the last set of curves given in the paper might appear to support this supposition, he (Prof. Ayrton) felt that the difference obtained was probably due to the fact that the alternating current arc was not being worked under proper conditions. The quality of the carbons and the length of the arc have a most important influence on the efficiency of an arc. At present our knowledge is not sufficient to allow of our stating definitely whether or not an alternating current arc can be made as efficient as a direct current arc, but there is no doubt that it will be possible to get much better results than are at present attainable. Prof. S. P. Thompson said that when the fact of the existence of the difference in phase between the current and volts in an alternating arc was first published, he had made some experiments which showed that there was a lag and not a lead, *i.e.* that the arc acted as if it possessed self-induction. The resistance also lagged, and he thought this lag might be due to a thermal lag. The temperature of the arc will lag behind the current, both when it is increasing and when it is decreasing, and if the resistance of the arc depends on the temperature of the vapour in the arc, then the resistance would also lag behind the current. It was not possible from *à priori* reasoning to say whether or no an alternating current arc could ever be obtained of an efficiency equal to that of the direct current arc. With suitable carbons, length of arc, current and volts, it seemed to him that it might be possible to obtain an equal efficiency. The light-giving process in an arc is not merely an irreversible degradation of electric energy into heat, for the difference of potential between the carbons may be written $V = a + bl$, where a may be regarded as a back electro-motive force and bl as a true resistance. The first term of this expression does not vary with the length of the arc (l), but the second term does. Multiplying through by the current (C), the equation: Watts expended $= Ca + Cbl$, is obtained. It is the first of the terms on the right-hand side, which is a reversible effect, and corresponds to the power expended in driving the current against a back electro-motive force, on which the light given out chiefly depends, due to something occurring at the crater surface. Mr. Blakesley asked whether Prof. Thompson's idea of the light being due to the reversible part of the process was not a strong argument in favour of the direct current arc. Prof. Ayrton said that in two communications made to the congress held at Chicago, it was shown that even with direct current arcs there was a certain length of arc for which the efficiency was a maximum. Mrs. Ayrton had quite recently found that the efficiency of arc-lamp carbons altered with time. Prof. Thompson's suggestion as to a thermal lag was a valuable one. Prof. Fleming, in his reply, said that when comparing two agents where there were so many variables it was practically necessary to restrict the investigation. In their case they had kept the mean power constant, and had left the other variables to take care of themselves.—The Society then adjourned till March 13.

PARIS.

Academy of Sciences, February 24.—M. A Cornu in the chair.—On partial differential equations of the second order with imaginary characteristics, by M. E. Picard.—On the radiations emitted by phosphorescence, by M. H. Becquerel. An experimental proof of the fact that light emitted by phosphorescent substances possesses the power of affecting a photographic plate through a screen which is opaque to sunlight.—On the carbide of manganese, by M. H. Moissan. This carbide, Mn_3C, which is easily prepared in the electric furnace from Mn_3O_4 and sugar charcoal, differs from other metallic carbides in the simplicity of its reaction with water, which proceeds thus,

$$Mn_3C + 6H_2O = 3Mn(OH)_2 + CH_4 + H_2.$$

Neither acetylene nor liquid hydrocarbons being formed.—Study of the borides of nickel and cobalt. The borides, NiB, CoB, are easily obtained in the crystalline state from the metal and boron at 1200°, their properties being very similar to those of the iron boride previously described.—On the estimation of arsenic, by M. A. Gautier. A criticism of a paper by MM. Engel and Bernard upon the same subject.—On a colloidal substance elaborated by the lymphatics in the normal state, by M. L. Ranvier.—The relation between muscular work and the albuminoid materials of the body, by M. A. Chauveau.—An experimental study of the question as to whether albuminoids take part in the production of external work. The results show that the amount of nitrogen secreted is practically the same whether the animal is doing external work or not, and thus confirming the conclusion drawn by the author from previous experiments, that it is by the combustion in the muscle of carbohydrates that the energy necessary for external work is produced.—On the corals of the Gulf of Lyons, by M. de Lacaze-Duthiers. A communication from the Arago Biological Laboratory.—On the method employed for conferring immunity from the venom of serpents, from documents furnished by M. de Serpa Pinto, by M. d'Abbadie. A question of priority.—Observations of Venus on Mount Mounier, by M. Perrotin. The results of these observations, which were made under very favourable conditions at a height of 9000 feet above sea-level, are consistent with the slow rotation discovered by M. Schiaparelli.—On the conversion of dextro-rotatory camphoric acid into dextro-rotatory camphor, by M. A. Haller.—Analysis, by volumetric methods, of a mixture of chlorides, hypochlorites, and chlorates, by M. A. Carnot.—Analysis of a mixture of chlorides, chlorates, and perchlorates, by M. A. Carnot.—Observations on the new Perrine comet (1896, Feb. 15) made at the Observatory of Lyons, by M. G. Le Cadet.—Observations on the same, made at the Observatory of Toulouse, by M. F. Rossard.—On the production of Röntgen silhouettes, by M. C. V. Zenger.—On the action of the X-rays on the diamond, by MM. A. Buguet and A. Gascard. The transparency of the diamond and of jet to the Röntgen rays renders it very easy to distinguish them from their imitations, the latter being opaque.—On the cause of the invisibility of the Röntgen rays, by MM. Dariex and de Rochas. It was found that the media of the eye, although perfectly transparent to ordinary light, are nearly opaque to the X-rays.—On the Röntgen rays, by M. G. Meslin.—On some properties of the X-rays of M. Röntgen, by M. H. Dufour. The phenomena are compared to the silent discharge.—On the emission of the Röntgen rays by a tube containing a fluorescent substance, by M. Piltchikof. The length of exposure may be much reduced under these conditions.—On some properties of dark light, by M. G. Le Bon.—On photography through opaque bodies, by MM. A. and L. Lumière. The authors, in attempting to repeat the experiments of M. G. Le Bon, obtained entirely negative results.—On the properties of metals extracted from their amalgams, by M. Guntz (see Note, p. 423).—Action of some hydrogen compounds on sulphuryl chloride, by M. A. Besson. The reactions with hydrogen sulphide, bromide, iodide and phosphide were studied.—On the dry distillation of wood by

M. E. Barillot.—On the temperature of the sparks produced by uranium, by M. Chesneau.—On a new mode of formation of nitroprussides, by MM. C. Marie and R. Marquis. A mixture of an alkaline ferrocyanide and nitrite is treated with carbon dioxide.—On a crystallised ammonio-chromous carbonate, by M. G. Baugé.—On veratrylamine, by M. C. Moureu.—Thermochemical study of orthochlorobenzoic acid and some of its derivatives, by M. P. Rivals.—Conversion of formaldehyde solution into vapour for disinfecting purposes, by M. A. Trillat.—On the Cretaceous fossils of Madagascar, by M. C. Deperet.—Modifications in the structure of some Arthropods induced by their living in caves, by M. A. Viré.—On phagocytosis in the oyster, by M. J. Chatin.—On the combined action of light and water in the disengagement of the perfume of plants, by M. E. Mesnard.—Method for preventing the darkening of cider, by MM. L. Dufour and L. Daniel.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, MARCH 5.

ROYAL SOCIETY, at 4.30.—Contributions to the Mathematical Theory of Evolution. Note on Reproductive Selection: Prof. Karl Pearson.—On the Diurnal Periodicity of Earthquakes: C. Davison.

ROYAL INSTITUTION, at 3.—Masters of Modern Thought. I. Voltaire: Rev. William Barry.

LINNEAN SOCIETY, at 8.—Segmentally-disposed Thoracic Glands in the Larvæ of Trichoptera: Prof. Gustav Gilson.

CHEMICAL SOCIETY, at 8.—On the Explosion of Cyanogen: H. B. Dixon, E. H. Strange, and E. Graham.—On the Mode of Burning of Carbon: H. B. Dixon.—On the Detonation of Chlorine Peroxide: H. B. Dixon and J. A. Harker.—The Constitution of a New Acid resulting from the Oxidation of Tartaric Acid: H. J. H. Fenton.

SOCIETY OF ANTIQUARIES, at 8.30.

FRIDAY, MARCH 6.

ROYAL INSTITUTION, at 9.—The Tunnel under the Thames at Blackwall: A. R. Binnie.

ROYAL GEOGRAPHICAL SOCIETY, at 4.30.—A Plan for the Geographical Description of the British Islands on the Basis of the Ordnance Survey: Dr. Hugh Robert Mill.

GEOLOGISTS' ASSOCIATION, at 8.—"Pebbly Gravel" from Goring Gap to the Norfolk Coast: A. E. Salter.—On some Pleistocene Ostracoda from Fulham: Frederick Chapman.

QUEKETT MICROSCOPICAL CLUB, at 8.

SATURDAY, MARCH 7.

ROYAL INSTITUTION, at 3.—Light: Lord Rayleigh, F.R.S.

SUNDAY, MARCH 8.

SUNDAY LECTURE SOCIETY, at 4.—The New Far East; the War between China and Japan: its True Meaning and its Results: Arthur Diósy.

MONDAY, MARCH 9.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—On the Country of the Shans: Colonel R. G. Woodthorpe, C.B., R.E.

TUESDAY, MARCH 10.

ROYAL INSTITUTION, at 3.—The External Covering of Plants and Animals: Prof. Charles Stewart.

SOCIETY OF ARTS, at 8.—English Book Illustrations, 1860-70: Joseph Pennell.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Paper to be further discussed: On Littoral Drift in relation to River-Outfalls and to Harbour-Entrances: W. H. Wheeler.——Papers to be read, time permitting: The Lixiviation of Silver Ores: J. H. Clemes.—Mining and Treatment of Copper Ore at Tharsis, Spain: C. F. Courtney.—Tin Smelting at Pulo Brani, Singapore: Messrs. J. McKillop and T. Flower-Ellis.

THURSDAY, MARCH 12, 1896.

A GLACIAL HANDBOOK.

Ice-Work Present and Past. By T. G. Bonney, D.Sc., F.R.S., &c. Pp. xiv + 296. (London: Kegan Paul, Trench, Trübner, and Co., Limited, 1896.)

THIS latest addition to the familiar red volumes of the International Scientific Series is in many respects a model of what we may take to be the aim of the whole series. An exposition of the results of modern research and modern thought, which shall be of an unrestricted and international character, written without offence to prejudices or persons, is no mean task for an author to set before himself. And when the subject approaches the chilling atmosphere of the ice-age, we know how frequently the scientific soul waxes warm, and fortifies itself towards the inevitable conflict; while the outer world exclaims,

"That is hot ice, and wonderous strange snow."

Has it been left for Prof. Bonney to "find the concord of this discord"?

The aim of the author in this instance is to give prominence "to those facts of glacial geology on which all inferences must be founded." He begins most appropriately with a description of a "gathering-ground of glaciers" in the Bernese Oberland, a scene as familiar to himself as Bedford Square or King's Parade must be to many of his readers. A sober restraint is put upon his powers as a word-painter, and we have a condensed account of ice and ice-work in Switzerland, crisp and clean as the surface of the snows themselves. It is true that the irrepressible faculty of imagination breaks out occasionally, seeing more before it than the upturned face of the student; and the contrast is almost too abrupt, it betrays the effort at conciseness. Thus we are uncertain whether the "struggle of Solferino" (p. 35) refers to a meeting of descending glaciers, or to the events of recent history, since all the other references in the sentence are to purely geographical features.

In this first chapter, certain conclusions are drawn from the facts described, but so delicately and naturally that they seem to involve no controversy. A confidence is thus established between us and the author, and we follow him with the secure feeling that theories may be suggested, but will not be thrust upon us. If a writer has formulated any opinion of his own, this is the very happiest method of securing a hearing for it.

The second chapter deals with the larger phenomena of arctic and antarctic regions. To some extent this traverses the ground of Prof. Wright's corresponding chapter in "Man and the Glacial Period"; but additional matter is introduced, even in dealing with Alaska. Attention is very properly drawn to the feeble character of the "ground-moraine" in areas covered by an ice-sheet, and to the great accumulation of the materials, in the form of a terminal moraine, as the glacier retreats, when they become (p. 48) "drawn very gradually, like a coverlet, over the bed of the valley." On p. 57, another point of first importance is set down with characteristic delicacy; "it is therefore obvious that in all speculations as to the condition of any region during the Glacial Epoch, account must be taken of the possibility of a not inconsiderable difference in either direction from its present level." The evidence bearing on this subject has been so freely overlooked by those who have felt it easier to accept enormously thick ice-sheets, rather than differential earth-movements, that this innocent little sentence suggests in reality a controversy ranging over both the hemispheres.

The description of the Malaspina Glacier near Mount St. Elias in Alaska, quoted from Mr. Russell, naturally forms the most interesting feature of this chapter. The term "Piedmont Glacier" (p. 68), as it happens, would have been explained more clearly in Mr. Russell's own words. Since the date at which Prof. Bonney wrote this account of the Chaix Hills, with their uplifted marine glacial gravels, he has examined the additional evidence of post-glacial elevation brought forward by Colonel Feilden from Kolguev Island (*Quart. Journ. Geol. Soc.*, London, vol. lii., 1896, p. 57).

After this review of "existing evidence," Part II. describes the "Traces of the Glacial Epoch." The discussion of the origin of lake-basins is concerned with the greater lakes of the world, and the summing-up is in favour of their hollows having been caused by earth-movements. Eskers are dealt with in the same chapter, and the accumulation of sands and gravels in the very areas claimed by some authors as regions of excavation is, in conclusion, neatly pointed out. After Mr. Russell's description, quoted on p. 74, we are left somewhat in the dark (p. 116) as to the probable origin of eskers. The names of Hummel and Holst might well have been quoted in connection with the theories for which they are respectively responsible; and Ireland is so eminently a land of eskers, that one is inclined to ask for a view or section of an esker of home-manufacture, instead of the figure from New Hampshire given us on p. 110.

Why, again, in the next chapter, headed "Ice-work in Great Britain and Ireland," is till illustrated from "Seattle, Washington State," except for the fact that Prof. Wright's block is in the possession of the publishers of this series? All through, Prof. Bonney has been somewhat badly treated in the matter of illustrations. The Alpine drawing in Prof. Wright's book is painfully rigid and antique, and we should consequently have welcomed a photographic view of the Aletsch Glacier to illustrate Prof. Bonney's description. The frontispiece, showing the results of ice-work, is the only novelty of the kind. Even the scratched blocks figured are not from Finchley, or Snowdon, or Glencullen, but from "the till of Boston," which seems far away from an English author, even in an international scientific series.

Such drawings as are given had a special interest when put before us by Prof. Wright; but it is hard that Prof. Bonney, who has trained a full generation of geologists in England, and to whom the Alpine heights are as a garden, should be compelled to select his most effective illustrations from those of an American predecessor. A few views of English boulder-clays, and erratics, and *roches moutonnées*, as they actually appear, would have been at least refreshing. Our students know far too little of their own islands; and, in the case of Ireland, such pictures would have been absolutely novel.

On p. 126, "till" is distinguished from "boulder clay," and Prof. James Geikie is quoted in support of this position; but the reference is to the first or second edition of the "Great Ice Age," since in the third the distinction is abandoned. The third edition is quoted, however, but again without exact specification, on p. 109.

In describing the principal accumulations due to glacial action in our islands, it would be impossible to follow all the literature that has been poured forth in recent years. Prof. Bonney seems to have made a fair and wide selection, perhaps leaving some extreme views charitably alone; throughout, he describes rather than theorises, and follows out, with steady self-denial, the line of work on which he started. From p. 163 to p. 205, we have a discussion of the opinions of other authors; but we read on with a sense that behind all this exposition there is a guiding mind, gently and steadily influencing our own. Yet it seems that no one can complain of having been misrepresented, which is about as much as Prof. Bonney can hope for, when we look back on the amenities of glacial warfare.

The description of the centres of radiation of boulders of various types (pp. 151–161) would be made of singular value to all students, if, in a second edition, a plate showing typical microscopic sections of the rocks referred to could be inserted. In this connection, we note a curious remark in the foot-note on p. 140, where Ailsa Craig is said to be "too small a place to have furnished numerous specimens to such a distant locality." Megascopic and microscopic examination has again and again proved the occurrence of erratics of the Ailsa rock, not that of Mynydd-mawr, as far south as Greystones on the Irish coast, and their existence was thus proved even under Mynydd-mawr itself. The very smallness of Ailsa Craig may surely be adduced in favour of the view that these abundant blocks have been worn away from it. Of course, some of these boulders may have come from the Riebeckite-eurite of Skye; but of this there is as yet no evidence. Here we touch one of the most frequent paradoxes in glacial essays—boulders are assumed to have come from the self-same levels where similar rocks are now exposed. The frequency of the boulders themselves is a fair measure of the former extension of the rock in question, even if we neglect any possible differential earth-movements.

A somewhat startling omission occurs on pp. 200 and 202, where what we may almost style the life-work of Mr. Maxwell H. Close is attributed inadvertently to Prof. Hull. The wide distribution of the "sands and gravels" in Ireland might perhaps have been further emphasised; but the recent observations of Prof. Sollas on Irish eskers find an appropriate place in the concluding sentences of this section.

Chapter iii. of this part goes further afield, particular attention being given to the wide-spread glacial phenomena in North America. And then we find the vexed "Theoretical Questions" summed up in Part III., conveniently shut in by themselves. The concluding words of the chapter dealing with temperature in glacial times again calls attention to the dependence of the successive stages of the cold period upon the variable level of the land; and, similarly, the next chapter on the "causes of a glacial epoch" closes judicially with the statement that probably "some factor which is essential for the complete solution of the problem is as yet undiscovered, or, at any rate, the importance of one which is already known has not been duly recognised."

The final pages of this admirable book, the strength of which lies largely in its reserve, point to a closer study of Greenland as essential to the solution of our problems. Already some comment has been made, through the latest of researches, on the question raised by Prof. Bonney (p. 135) as to the possibility of stratification in the deposits of land-ice. The spirit in which the author has shown how the field is open to the future should now attract a new band of workers, unfettered by their own past utterances.

Critics are most likely to lay hold of the treatment of contemporary literature, when looking for a weakness in this little volume. We have already indicated that the exactitude of a librarian is not always noticeable in the references, and various editions are not separately quoted. On p. 90 the title of Mr. Whymper's book is not precisely given, and the most important reference to the subject is in chapter xvi., not chapter vi.—at any rate, in the last edition. It is not clear from what work a passage on p. 114 is quoted; the reference should be to James Geikie, "Great Ice Age," third edition, p. 171. On p. 139, we might have liked a reference to some of the later literature on Moel Tryfaen, perhaps to Mr. Mellard Reade's examination of the microscopic materials, or to Miss Andrews's record of foraminifera. The difficulty as to the mingling and crossing of erratics borne by land-ice (p. 171) has been to some extent met by an important paper by Prof. Jas. Geikie, published in the *Scottish Naturalist* in 1881, and in "Fragments of Earth-Lore" in 1893. Why, again, are the figures on p. 21 quoted from an abstract in the *Alpine Journal*, and not from Heim's own book? The reference-figure is so placed on the page as to include a calculation which seems really due to Prof. Bonney. And here and there quotations from other authors have not been checked, so that, as they stand, they are not absolutely accurate. The only important case of this kind, however, seems the slip of "shale" for "strata" on p. 70, second line from bottom.

When, in this seemingly trivial manner, we think we have found a plane of weakness in Prof. Bonney's treatment of "Ice-Work Present and Past," it is like pointing out that David, another standard author, was injudicious in discarding the full panoply of armour. The writer of so many voluminous and yet precise papers in our geological journals has again and again protected himself from this attack. He has displayed a generous indifference as to the originality of any statement he may put forth, and has thereby doubtless lost considerable credit which he might otherwise have gained, as well as opportunities for trenchant criticism. "If any one," he wrote in 1890, "has come to conclusions identical with my own, I can assure the author that there is no plagiarism." In 1886, the matter was put still more clearly. "If," Prof. Bonney wrote, "there is any value in my results, it will be that they have been obtained, as far as possible, independently, and sometimes actually in ignorance of the work of others."

This standpoint is heroic, and involves considerable sacrifice of self; the argument has so obviously two sides to it. Is it a wise one to reiterate before us, juniors and pupils as we are; and shall we not remember how in many cases it was from Prof. Bonney that we received our first literary encouragement? Who amongst us, however, shall pose as his critic in this matter? Rather let us ask it of him as a question.

GRENVILLE A. J. COLE.

PHILOSOPHY AND EVOLUTION.

Evolution and Man's Place in Nature. By Henry Calderwood, LL.D., F.R.S.E. Second edition. Pp. xx + 316. (London: Macmillan and Co., 1896.)

IT is not often that the author of a work on science or philosophy so far accepts the verdict of his critics as to entirely re-model and re-write his book. Much to his credit Prof. Calderwood has done this, for the second edition now just issued is not only nearly twice the bulk of the first, but is also full of new matter, and is greatly improved in its scope and arrangement. The first edition (reviewed in NATURE, vol. xlvii. p. 385) contained eight chapters, while the present work has seventeen, the titles and "contents" of which are so different that the two books seem to have little in common. The chapters on "The Nerve System as an Instrument of Knowledge," "Right and Wrong," "Civil Law," "Modern Thought," "The Ape and Man," and "Cosmic Problems," seem to be wholly new and to embody the results of the most recent researches. In other respects the present work is far superior to the former edition, as it not only gives a much larger body of facts, and contains less repetition, but is a more complete presentation of the whole subject, treated from the point of view of philosophy rather than from that of science.

The author's style, which leads him always to go round about a subject rather than to the heart of the problem itself, to take much for granted which requires systematic proof, and to revel in diffuseness of phraseology and of argument, is still a prominent feature, and is wearisome to the reader who wants to get at the author's conclusions and to have a clear presentation of the facts and arguments on which they are founded. But to those who enjoy diffuse philosophical discussion, and especially to those who want a reply to the supposed materialistic tendencies of the works of Darwin and Herbert Spencer, there is here much food for thought. A few passages will serve to illustrate the author's merits as well as his limitations. In the chapter on "Right and Wrong," he thus explains his view of the essential difference between the human and the animal nature.

"The grand distinction of human life is *self-control in the field of action.* Thought not only reaches a generalised knowledge of existence, and of its laws; it leads to rationalised action, within the many and varied fields of human endeavour. The evidence of this appears, as already described, in the control exercised over all the animal impulses, so that these do not spontaneously and of themselves determine activity. Sensibility operates in human life, just as in the life of the animal; but it does not at once direct our action, as the course of the dog is ruled by sense of smell. Sensibility can influence us in the same way, and a similar result is often seen in our life; but that which is peculiar to man is a concentration which overcomes allurements of sense. Animal appetite is stirred in us, as in animals, physiological law being coextensive with the animal kingdom; our speciality appears in the regulation of animal impulse, so that it is repressed, in accordance with the laws of attention, which weaken or strengthen animal propensity; or limited by reference to propriety; or regulated in its indulgence in recognition of a law higher than present desire. These facts are so familiar, that I have only to refer to them to claim their weight of evidence for a power which does not appear in animal life. The value of this evidence will be still more appreciated, if it be observed that the control of animal impulse no more belongs to the animal nature of man, than it belongs to the animals around him. In respect of animal impulse, his experience is as much determined by physiological law, as animals are visibly moved by it. Man being an animal, no one can suggest that the movements of animal impulse are otherwise determined or have their source elsewhere than in the body. The difference between man and animals appears in this, that by thought and imagination passion may be intensified; and by use of these powers it can be restrained. Even within the sphere of passion, the elevation of human life is seen in the control the rational power wields over the animal nature."

The purport of this wordy and laboured passage is clear enough, but its cogency as an argument is certainly not proportioned to its length. The same idea is pursued through two other paragraphs of equal length, but these do not bring any further sense of completeness to the presentation of the subject.

One more extract may be given from the final chapter on "Cosmic Problems."

"With clearest testimony, scientific observation has led us to innumerable points, whence we have seen intelligent purpose at work providing for life yet unborn. We have been arrested first, and afterwards roused to quickened consciousness, realising that we have seen the lesson all the days of our life, in hundreds of forms, but had not read its full meaning, though it had been written large; for is not the whole vegetable kingdom confessedly a preparation for a coming life? In vain does Agnosticism lift its voice in presence of witness such as this. Testimony for an Intelligent cause springs even from the *dust*, and, as it comes thence, thought moves freely along all fields of science, gathering evidence as readily from the vegetable kingdom as from the animal; finding, with ever-increasing surprise, a growing testimony as science conducts us lower in the knowledge of nature. Not to the heights but to the depths we go, in order to witness the most startling condemnation of Agnosticism. It is not merely the myriad dwellers in the insect world which bear witness; but the inanimate creation itself tells us of treasure stored in its keeping, to satisfy animal wants. Plants can manufacture fresh protoplasm out of mineral compounds, whereas animals are obliged to procure it ready made, and hence in the long run depend upon plants. Thus, even from the *soil*, under our feet, comes the evidence calling us to own an Intelligent First Cause."

A number of illustrations, of the lower forms of life, of the sense organs of various classes of animals, and of the brains of many of the mammalia and of man, will render the work more attractive to those who have not acquired a general knowledge of the subject from other sources.

A. R. W.

OUR BOOK SHELF.

Experimental Plant Physiology. By D. T. MacDougal. (New York: Henry Holt and Co., 1895.)

THIS little book is intended primarily for the use of elementary students of vegetable physiology, and the subject-matter is treated in a somewhat dogmatic fashion. This we cannot avoid regarding as a mistake. The elementary, no less than the more advanced, student requires to be made at the outset to *think for himself*, and this is a far more important matter than the mere following out of directions for experiments. But it is just this stimulus that we miss, in the pages before us, and in not a few instances the author has sacrificed reality at the shrine of conciseness; thus it is simply useless to compare the mechanism by which water "is taken up and forced into the root and upward in the stem" to the action of an osmometer, for the conditions are not at all the same. The state of the water, as it exists in, and finds its way upward into, the tracheids, is by no means directly comparable with that of the solution of salts as it occurs in the tube of a thistle funnel, the lower end of which is closed by a piece of membrane. Here was a good opportunity of insisting on the peculiarity of a living protoplasmic structure, and it was lost. Very few teachers, who are at all *au courant* with their subject, will accept the statements as to ascent of sap, given on pages 28 and 29. "The rectangular wood cells are in the form of a series of chains. Water transpired from the topmost cells of these chains, the cell sap becomes concentrated. . . . There is thus formed a series of osmometers extending from the leaves to the roots and capable of lifting water to any height." Surely a slight knowledge of elementary physics, combined with that of the structure of the "wood cells," should have rendered it impossible that such a passage could have been written.

Again on page 46, one is tempted to wonder whether the author can have ever tried the experiment (54) to prove that oxygen is necessary for *respiration*. Any unwary teacher who performed that experiment for the first time before an intelligent class, would probably have a hard time of it if he trusted himself to Mr. MacDougal's guidance.

The above remarks and quotations will show that there are weak points about the book. And, indeed, the general impression left on the reader's mind is the rather painful one, that an important branch of botanical study has here been but superficially handled.

Exercises in Physical Measurement. By Dr. L. W. Austin and Dr. C. B. Thwing. Pp. x + 193. (Boston: Allyn and Bacon, 1896.)

AFTER working through the experiments described in this volume, a student will have a thorough knowledge of the instruments and methods employed in physical measurement, and will be in a position to accurately investigate physical phenomena. The book is a medium between such a hand-book as the last edition of Kohlrausch's "Praktische Physik" and the elementary text-books in which mathematical formulæ are eschewed. The sixty-five exercises in the first part are all quantitative, and they cover measurements in the chief branches of physics, beginning with measures of length, and ending with experiments on polarisation; while the apparatus required for the experiments should form part of the equipment of all physical laboratories in which students can obtain scientific instruction.

In the second part of the book suggestions are given as to methods of computation and physical manipulations, while the third part is taken up with tables. The book is thoroughly practical and trustworthy, and it can be recommended as a suitable introduction to serious work in physics.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Age of the Wealden.

THE Wealden formation of England has long been studied, and is now well known in nearly all its features. Its stratigraphical relations and its Cretaceous age are usually regarded as fully determined, and this is true, also, of the corresponding strata on the continent.

The vertebrate fauna of the Wealden is of special interest, and has attracted much attention ever since Mantell in 1825 unearthed Iguanodon in the Tilgate Forest. Some of the remains, he sent, through his friend Prof. Silliman, to Yale College, where they have proved of much service. In 1865, I examined the same famous locality, as well as others on the south coast of England especially rich in vertebrate fossils, and at all of them secured interesting specimens. A study of these in connection with the collections at London and Brussels first caused me to question the Cretaceous age of the Wealden, and a later comparison of its reptilian fauna with allied forms found in the Rocky Mountains led me to the conclusion that both series were Jurassic in type, and should be placed in that division of the geological series.

At the meeting of the British Association at Ipswich, in September last, I read a paper on European Dinosaurs, including two from the Wealden, and thus the question of their geological age came up for determination. The facts I then presented, based mainly upon the reptilian fauna, strongly indicated the Jurassic age of the Wealden, and I urged a re-examination of the question by English geologists. The subject has since been taken up by Smith Woodward, with special reference to the fossil fishes. In the *Geological Magazine* for February 1896, he gives the main results of his investigation, which prove that the fishes, also, of the Wealden are of Jurassic types, thus placing the geological age of this formation beyond reasonable doubt. The concluding statement of this interesting article is as follows:

"The Wealden estuary seems to have been the last refuge of the Jurassic marine fish-fauna in this part of the world, not invaded even by stragglers from the dominant race of higher fishes which characterised all the seas of the Cretaceous period. The Wealden river drained a land where a typically Jurassic flora flourished; the only two known Mammalian teeth from the Wealden resemble those of a Purbeckian genus; and now it is clear that the fishes agree both with these and the reptiles in their alliance with the life of the Jurassic era." O. C. MARSH.

Yale University, New Haven, Conn., February 22.

The Röntgen Rays.

THE following fact regarding the X-rays of Röntgen may be of interest.

I have found that it is possible to obtain a photographic image by these rays, using a "pinhole camera," having the aperture pierced in a piece of sheet-lead backed with aluminium. The Crookes' tube was illuminated by discharges from a Thomson high-frequency coil. The photographs taken in this way show very distinctly the two electrodes, while the glass bulb, which appeared to be brightly illuminated to the eye, is scarcely perceptible It would appear from this that nearly, if not all, the so-called X-rays proceed directly from the electrodes of the tube, and not from the glass where this is acted on by the kathode rays. It likewise affords further illustration of the rectilinear motion of the X-rays. Experiments are in progress with a broken current, and also to study the effect of a magnetic field.

Previous observation has shown that photographic effects were produced equally whether the kathode rays impinged upon the glass, or upon other phosphorescent material (*e.g.* aragonite) within the tube. It has also been noticed in experiments in this laboratory, that the appearance of the tube to the eye affords no criterion of its efficiency in producing the X-rays; tubes showing but little fluorescence of the glass composing them often giving admirable photographic effects, which in some cases are obtainable even from a low-vacuum Geissler tube. But the rays

producing photographic effects always appear to produce strong fluorescent effects on platino-cyanide of barium, so that the fluorescence of this affords an indication of the photographic efficiency of the radiations emitted from the tube.

RALPH R. LAWRENCE.

Massachusetts Institute of Technology, Boston, February 26.

Is it quite correct, as Prof. Lodge puts it, to call the X-rays *anodic* because they start from a point (surface of glass, or of metal foil, &c.) opposite the kathode? It may be true that a surface upon which the kathodic discharges are being directed acquires thereby some properties common to the anode: but it is not an actual anode. Further, I think that so far there is no proof that these rays start from an anode unless that anode is itself in the line of the kathodic discharge. Hence I submit that *anti-kathodic* would be a more correct term to use in describing them. They can certainly be made to start from a portion of the kathode itself by shaping it so as to concentrate the kathodic discharges (or "radiant matter") upon a prolongation of itself.

Whilst dealing with this point, might I mention that a phosphorescent enamel, made by incorporating calcium sulphide in a very fusible enamel-glass, appears to form an excellent anti-kathodic surface for generating X-rays.

SILVANUS P. THOMPSON.

Finsbury Technical College, March 9.

WE enclose a print of a "Röntgen" photograph taken by us some time ago, which shows very clearly that it is to the mineral constituents that bone owes its opacity to the "X-rays." Two human finger-bones were obtained as nearly alike as possible. One was decalcified by treatment with dilute hydrochloric acid for some days, the other being soaked in water for the same period. The calcium phosphate, carbonate, &c., dissolved by the hydrochloric acid, were precipitated by ammonia and ammonium carbonate, and the precipitate, after washing, was spread on paper, so as to cover an area about equal to that which would be covered by the original bone. This precipitate, together with the bone which had merely been soaked in water, and the "decalcified" bone (which had shrunk during treatment with the acid), were then placed upon a photographic plate and exposed in a cardboard box to the radiations from a Crookes' tube excited by a small "Tesla" apparatus.

The picture thus obtained, shows clearly that while the decalcified bone is almost without action on the "X-rays," the mineral matter is practically as opaque as the bone before treatment with acid.

The print shows, however, that both the original bone and the calcium phosphate are only relatively opaque, but that they do allow some "rays" to pass, for the photograph shows half-tones, and not merely an outline.

HERBERT INGLE.

The Yorkshire College, Leeds, March 4.

REMEMBERING that scientific men are pledged, beyond all others, to accuracy and observance of rule, I am emboldened to protest against the use of two words which are sometimes employed to describe the pictures produced through the agency of Röntgen's rays. I mean "shadowgram" and "radiogram."

Both of these offend against a primary rule for the formation of new compound words, which requires that all of the component parts of any word shall be derived from one and the same language.

If a word be desired which shall signify a picture produced by rays, let us go to the Greek language only, and form the word "actinogram"; or to the Latin language only, and form the word "radioscript"; or else let us be content with some purely English compound, such as "ray-sketch."

The Aurora at Waterford.

AFTER a boisterous day and a barometer that went down to 28·85, we were favoured last (Wednesday) night with an auroral display. It was first seen here at 8 o'clock, when it appeared in a cloudless, starlit sky as a sheaf of light springing from the western point of the horizon, and stretching along an arc of 30° up towards the Pleiades.

Its colour, at first silvery white, gradually faded away, reappearing in thin streaks and irregular patches of yellowish light in various parts of the sky between north and west.

At 10.30, it was round in the north. At one time, six well-distanced streaks were counted. They seemed to converge slightly towards the zenith. The light was mainly yellowish, but tinged here and there with pulsating reddish rays. The flickering, or fluctuation in colour and brightness, was distinctly noticeable.

The phenomenon was not observed after 11.30.

As auroræ are essentially electrical in character, having some analogies with the brush discharge, it would be interesting to know whether, like the brush discharge from induction coils and influence machines, *shadowgraphs* might be taken by means of these weird rays. Opportunities for testing their photographic qualities occur very frequently in higher latitudes than ours, and even nightly in circumpolar regions, the home of this interesting phenomenon.

De La Salle Training College, Waterford, March 5.

An Unusual Meteor.

AT 8.31 on Sunday evening, March 1, when half a mile north of York Minster, I caught sight of a meteor slowly falling vertically almost due east. It was then passing over the two small stars ν and ξ Ursæ Majoris, which at the time were at an altitude of 43°, azimuth 5° north of east. Seeing that it meant to last awhile, I proceeded to repeat the alphabet in the orthodox manner (once through, each letter quickly but distinctly enunciated, requiring 4 seconds). Having gone over it twice, I must confess that my amazement at the meteor's duration made me pause. But it kept on, so I continued, getting through it twice more. Then, after a second involuntary but very unscientific pause, I finished the alphabet a fifth time before the phenomenon came to a close. In all, I must have watched it at least 25 seconds. After some 10 seconds, when about the same altitude as β Leonis (24°), a smaller meteor (fourth magnitude) appeared 1° to the left, at an angle of about 40°, and, proceeding at the same speed of under 2° per second, lasted 3 or 4 seconds. The original, of which this was doubtless a fragment, was between first and second magnitude, but with a distinct disc, and was followed by a train of sparks, reddish like itself, which was never more than 2° or 3° long, or lasting only 1 or 2 seconds. The fragment had also a slight train. The main mass seemed to pause slightly about this spot, perhaps because of this explosion. From the first it moved slower and slower, doubtless an effect of perspective, and finally disappeared almost due east (within 5° north of east), only 5° or so above the horizon, in the unusually clear sky just above the rising moon.

Whilst making notes, a gentleman came by, who said that he had seen it earlier, when as high as, and very near τ and μ Ursæ Majoris (the hind paw), or about an altitude of 58°, 5° north of east. Thus its angular path was 53°. As the additional distance was nearly half that observed by myself, it must have been visible for at least 7 seconds before I saw it, or 32 seconds in all. This makes due allowance for its apparently quicker motion at first. But the gentleman himself thought that he had not seen the actual commencement.

It is to be hoped that some other reports will be received, for its path must have been of extraordinary length, even if it was only travelling at ten miles per second, which is the almost irreducible minimum for a meteor.

A third observer saw it from indoors, appearing from above the window and falling vertically down the panes. It is a reasonable assumption, for a meteor of so great duration, that it first appeared at a height of 100 miles and reached within 30 miles of the earth. If so, its approximate path would be from above 25 miles off Bridlington to the coast of Denmark, north-east of Heligoland. The flight would be 360 miles, or rather over 10 miles per second.

Bootham, York.

J. EDMUND CLARK.

RECENT WORK OF THE GEOLOGICAL SURVEY OF THE UNITED STATES.

I.

OWING to the fact that much of the sphere of operations of this Survey lies in a new country, it is compelled to undertake a great deal of work of a class which does not usually fall to the lot of a body of geologists; chief amongst this stands topographical

work. It was found that large tracts of country were unmapped, or else that such maps as did exist were worthless for geological purposes; so the Survey set itself to produce the necessary maps, and a very considerable advantage is likely to accrue to the country from the two types of survey being directed by one organisation. A map that is good enough for the reception of geological lines, is capable of all the uses for which a small scale map is ever available, while the employment of men who understand something more of the origin and types of topographic features than map-makers usually do, must conduce to the more accurate generalisation and delineation of surface features.

It is from this point of view that the monograph of topographic methods by Mr. H. Gannett[1] is likely to be of considerable use, both on the staff of the Survey, for whom it was primarily designed, and elsewhere. In addition to giving a concise description of the chief instruments employed and the methods of using them, this work contains a set of logarithmic and other tables for use in the field, with a short account of the method of origin of the chief surface features; this shows the usual types of contour and outline special to different cases, and it is so written as to give those charged with the sketching of these features some rough guides for the better delineation of them. The same work gives a map to show the progress of the topographic map executed by the Survey, and the contributions toward this work by other bodies, such as the following: The survey of the Fortieth Parallel, Hayden's survey of the Territories, Powell's Rocky Mountain survey, the U.S. Coast and Geodetic survey, the U.S. Lake survey, the General Land Office, the surveys of various States, the Engineers of the U.S. Army, several railway, astronomical, and private surveys, and the Town and County maps.

The completed maps will be on the scales of one mile and two miles to the inch, and the size of the sheets will be so regulated that all sheets on the latter scale will contain one-half, and those on the former, one-quarter of a degree, both of latitude and longitude.

One of the bulletins[2] contains a series of sketch maps showing the systems of primary triangulation adopted by this Survey and its predecessors and coadjutors. Another most useful publication, also by the same writer, is a set of geographical dictionaries of the several States; of these, the following are already published: Rhode Island,[3] Massachusetts,[4] Connecticut,[5] New Jersey.[6] Each of these "is designed to aid in finding any geographic feature upon the atlas sheets of the State, published by the U.S. Geological Survey. It contains all the names given upon those sheets, and no other. Under each name is a brief statement showing the feature it designates and its location, and opposite to it is the name of the atlas sheet, or sheets, upon which it is to be found." The heights of many important points, the length of many streams, and the areas of townships are given. It need hardly be said that such a task as this is one which might with great advantage be taken up by the Ordnance Survey at home, and the exact latitude and longitude, as given on the map, might be added for the purpose of precision in location.

An article by Mr. Gannett, in one of the annual reports,[7] deduces from the contoured maps some useful estimates of the height of most of the States in the Union, and the average elevation of the whole country. From this we gather that, while the country contains 200,000 square miles under 100 feet in height, there are nearly 20,000 square miles above 10,000 feet. The largest part of the area, half a million square miles, is between 500 and 1000 feet; the loftiest State is Colorado, closely followed by Wyoming 6700, and Utah 6100 feet, while the average elevation of Delaware is but 60 feet. The average height of the United States is 2500 feet. This article is illustrated by a beautiful orographic map of the country.

Turning now to publications of a more strictly geological interest, we may say a word or two about their character as a whole. In addition to the maps, of which the issue has now begun—these consist of three sets, the annual reports, monographs, and bulletins—statistical papers on the mineral resources of the States are published annually as well.

It is not quite easy to see what is the guiding principle underlying the division of these different works. The monographs are of course reserved for important and original researches bearing on all branches of geology. The annual report contains an account of the work executed within the year, together with a collected set of the more important investigations completed within the same period. These do not appear to differ in any marked degree from the bulletins in character, while they are decidedly bulky and difficult to handle and read. They are, however, profusely illustrated, and may presumably be taken as the more popular of the publications —works intended to be used by those seeking for information on soils, water, mines, and such-like topics—and as containing the researches of interest to the ordinary citizen or reader. This idea seems to be borne out by the amount of rather rudimentary matter given, occasionally in somewhat high-flown language, in these papers. Presumably the form of language employed is well understood in the States; but, over here, one cannot help thinking that simpler language would be a more fitting garment for such elementary ideas. The bulletins as a rule contain simple and straightforward statements of fact, with theory kept well in subjection; they consist of descriptions of particular areas, accounts of work in the field, the laboratory or the cabinet, palæontological and correlation papers, and compact pieces of petrological investigation.

Hitherto the annual reports have been loaded with a mass of details which, after once being presented to Congress, need hardly have gone further, such as the travelling bills of each exploring party, and other statements of accounts. We are glad to notice that now the administrative report of the director and those of the heads of divisions are bound with that account in a separate volume, while for several years the work on irrigation has been placed within separate covers.

We pass now to papers dealing with physiography from a standpoint more or less geological, and generally with the idea of providing matter of use to the general public. In the first place stands the treatise by Prof. Shaler on soils.[1] After a preliminary description of the average soil and its composition as regulated by the amount of stony and organic constituents which it contains, certain types of soils are classified as follows:—

Cliff-talus soils.
Glaciated soils.
Volcanic soils.
Soils of recently-elevated ocean-bottoms.

The chief formative agencies are in each case described, and the peculiar suitability of certain soils for particular purposes, such as talus soils for vineyards, is

1 Twelfth Annual Report of the United States' Geological Survey, 1890-91. (1891.)

pointed out. The author then turns to the slow disintegration of glaciated surfaces contrasted with the easily rotted and fertile volcanic soils, and describes the succession of vegetable organisms in reclaiming new soils, and gradually rendering them suitable for tillage, beginning with the most humble, and passing up to the more conspicuous plants, and those useful for the purposes of man.

We next proceed to the ordinary types of soil in the valleys and plains, and opportunity is taken to give the life-history of soil from its first separation from the parent rock, all through its slow journey down the hillside, until it passes out to the streams and the sea. The action of frost and rain, of snow and wind, of carbonic acid and oxygen, but not of the very important humus acids, is given in full detail, and the great importance of widespread forest vegetation in preparing the soil for subsequent tillage by deep disintegration is rightly insisted on. The pumping of air in and out of the soil by rain and evaporation is shown to be of vast use, not only to the larger plants, but to the bacteria and fungi, which are of such great import in the life and death of higher organisms.

A capital series of pictures illustrates this monograph; one can only wish that in all cases the localities were specified. The function of roots, whether alive or dead, is well described. Darwin's work on earth-worms is referred to, and the operation of beetles, ants, crawfish, burrowing birds, reptiles, and rodents dealt with. A section of the paper relates to deposited soils, and great stress is laid on the circulation of soil and the functions of materials, which are the survivals of rocks which may have long ago disappeared, but whose influence in the soil does not pass away for very long periods. Certain peculiar soils, such as those of swamps, marine marshes, and sand dunes, are not neglected, and prairie soils are explained as due to the destruction of forests by fire. Man and the soil succeeds, and it is pointed out how great an action and reaction there is between these two, so that not only the distribution of disease, but even that of slavery can be shown to have a distinct direction with the soil. The following words may be noted in conclusion: "A heedless neglect of our duty toward it has led to the destruction of the soil over an aggregate area of not less than 4000 square miles. This means the loss of food-giving resources which would be sufficient, with proper care, to support a population of about one million people."

Prof. Shaler contributes to another annual report[1] a valuable and original article on the geological conditions of harbours. The following types are of importance in the United States, and it would be easy to recognise them elsewhere:—

Delta harbours; the Mississippi.
Re-entrant Delta harbours; Mobile Bay.
Glacial or Fiord harbours; Cape Breton.
Mountain Range harbours; Lower California and North of Puget Sound.
Moraine harbours; East end of Long Island.
Lagoon and Sand-bar harbours; Chatham harbour.
Sand-spit and Travelling Beach harbours; Provincetown harbour on Cape Cod.
Coral Reef harbours; Florida and Atolls.
Volcanic Crater harbours; not known in the States.

Prof. Shaler points out how important good harbours are in developing a race of sailors, and through them acquiring commerce and influence. His text is pointed by reference to the fact that the English-speaking race, or their kindred, the Dutch, possess nine-tenths of the valuable islands beyond the limits of Europe, and that North Europeans bid fair in time to dominate every part of the world fit for their occupation. "These considerations make it plain that the way to national power is over the waves, and that this way is the natural path of our race."

It is essential that a good harbour should fulfil the following conditions:—

It should be protected from the incursion of heavy waves.

There should be a deep and roomy channel from the anchorage to open water.

There must be ample room to receive and discharge cargoes.

It should be convenient for access from the interior.

In addition to this, it should be roomy, not in the path of heavy currents, not liable to shifting channels or deposits, nor likely to be obstructed at any time by ice. Harbours may be injured in greater or less degree by floods, winds, tides, by movements of the solid land, and by the indirect consequences of all these causes. The great preservers are the scour of tides and currents; the great destroyers, sediment and the growth of organisms. The action of sediment is fairly well understood and allowed for by engineers, but the influence of animals and plants is here dealt with in more detail than we remember to have seen elsewhere. The protecting work of algæ and seaweed is thoroughly explained, and the "eel-grass" (*Zostera maritima*) described in detail; this seems to have great influence in arresting the deposit of sediment, and causing the silting-up of harbours. The general operation of the tide-water grasses is to diminish the area of the harbour, and to deepen the channels which remain; that of mangroves is to occlude the harbour by cutting out the storage of water at high tide. The destructive work of plants appears to far exceed that of polyps. The article concludes with a review of the whole coast-line of the States, and the origin of all the important harbours.

The article on potable waters, by Mr. McGee,[1] contains a good deal of useful information, from the building of cisterns to the fouling of well-water by cesspools. Direct rain-water supplies are first dealt with, and the necessary filtering, which such water needs, described; next stream-water, and then that from shallow and deep wells, the latter source being termed *phreatic* water, whether from deep-seated springs, from artesian wells, or deep-pump wells.

Dr. A. C. Peale, who has done such an immense amount of unassuming and scarcely appreciated work for the survey in past years, contributes a much more important paper on natural mineral waters of the country.[2] This includes a table of all mineral springs which yield more than 1000 gallons per hour; these number more than 120. Mineral springs are found to be usually associated with areas of sedimentary rock, particularly in the neighbourhood of mountain ranges, where they have suffered much disturbance, and where volcanic action is now, or recently has been, rife. The annexed classification is adopted:—

(A) Non-thermal.
(B) Thermal.
(1) Alkaline.
(2) Alkaline-saline.
(3) Saline.
(4) Acid.

Each of the four last divisions is again divided into sulphated and muriated, and the last into siliceous as well. It is recommended that, in future, analyses shall conform to the scheme laid down by the Chemical Society of Washington, the most important points in which seem to be that solids shall be expressed in parts per million, and that the radicles actually found shall be expressed; while the chemist is at liberty to express, in addition, the probable state of combination in which the different ingredients occur. A brief account is given of the various

[1] Thirteenth Annual Report of the United States' Geological Survey, 1891-92. (1893.)

[1] Fourteenth Annual Report of the United States' Geological Survey, 1892-93. (1894.) [2] *Ibid.*

purposes for which the more important waters are used, and two maps are appended; the second of these indicates the distribution of waters used commercially, and the first shows, as might be expected, the much wider dispersal of springs used as health resorts. A complete list of known springs closes the paper.

Mr. Merrill follows[1] with an account of the results of stream measurements. These are carried out by means of current meters, while the fluctuation of streams is recorded by nilometers. The "run-off" is expressed in second-feet (*i.e.* the water carried by a stream 1 foot wide and 1 foot deep flowing 1 foot per second), and the total discharge in acre-feet. The records have been continued monthly for many years, and yield a vast body of useful hydrographic information with regard to such rivers as the Missouri, Yellowstone, Rio Grande, Arkansas, Bear, and Snake Rivers. Curves are drawn where possible, and there are two maps, one delineating the rainfall of the States, and the other the run-off of the principal river basins. The latter quantity reaches a maximum in the eastern States, and at the southern end of the Rocky Mountains in Wyoming. Run-off is a function of rainfall and topography, with modifications introduced by other conditions, such as climate, structure, and vegetation; the ratio of run-off to rainfall is greater in mountain districts than in valleys.

A list of Californian earthquakes in 1893, by Mr. C. D. Perrine, is given in *Bulletin* 114.[2]

We have reserved till last the modestly told account of Mr. I. C. Russell's exploration of the Malaspina glacier, and his plucky attempt to reach the summit of Mount St. Elias.[3] Although unsuccessful he appears to have done enough to be able to point out a route which, with better luck and weather, will probably lead the way to this coveted point; and one cannot but hope that it may fall to the lot of this explorer to be the first climber to reach the top.

The Malaspina glacier is fed by all the southern and western ice-streams of the St. Elias range, which is but an outpost of a vast mountain area to the north. From the highest point which he reached, Russell saw this new land spread out before him like a map; but the point of view was not reached without much labour in the carrying of camp equipments, and in step-cutting up the great ice-falls. The glacier seems to be a great reservoir or sea of ice, stagnant or retreating, rather than a living and growing river of ice, and it deserves the term "piedmont glacier" bestowed on it by our author. It only pushes out into the sea at one point, Icy Cape, to the west, but elsewhere it is separated from the ocean by a belt of flat land of varying width. This border gave the same trouble to Russell's party that it has done to English explorers, on account of its icy-cold rivers and dismal swamps, somewhat mitigated in this case by the vast strawberry meadow in which the first camp was pitched.

Cutting a way through the great forest-belt, and pushing through the thick moraine at the margin of the ice, the party went across the glacier in the direction of the Chaix Hills, noting here and elsewhere the astonishing feature that the live moraine was often covered with a dense coat of vegetation, including trees of considerable age and size.

The Chaix Hills are made of stratified sands and clays containing marine shells, and some 4000 or 5000 feet in thickness; these deposits were evidently formed in the sea at the extremity of a glacier, and subsequently uplifted The uplift appears to have taken place along a line of fault extending from the Robinson Hills at the west, past the Chaix Hills, and on to the Samovar Hills and Pinnacle Pass at the east. Thence they pushed across the Agassiz and Newton glaciers, passing many ice-falls, the surface between which had a gentle and, even in some cases, a reversed slope. Capital descriptions of the scenery are often given, and numberless glacial observations recorded.

Although the party camped for twelve days at the entrance of the amphitheatre at the head of the Newton glacier, the weather only permitted of one advance during the time. They then reached an altitude of 14,500 feet on the col between the summit of Mount Newton and that of St. Elias; but here they found themselves forced to return, as they had not strength to accomplish the 6500 feet between themselves and the summit in addition to the labour of returning to camp that night. It was concluded that it would be necessary to camp on the col itself, when a final attempt of the peak was made. A second effort was made, but the avalanches and the dangerous condition of the snow compelled a speedy retreat, and, bad weather setting in, they were obliged to abandon the attempt, and confine themselves to investigations on the glacier at lower levels, and on its margin. They had, however, reached high enough to obtain a glorious panorama extending to Mount Fairweather, 200 miles away to the south-east, and to mountains of equal altitude and distance to the north-west. They looked to the north over a great "land of nunataks," a vast area of snow 8000 feet high, dominated by peaks rising yet 4000 feet higher.

The expedition then retreated down the glacier to where the Yahtse River emerges from its cavern of ice; thence they went along the shore to Yakutat Bay, exploring the edge of the ice on the way, and then they extended their survey along Disenchantment Bay, which, judging from the vivid description given, might well dispense with the first syllable of its name. It appears to be a charming region of mountains, glaciers, and bays, which may well in the future attract the notice of travellers and climbers in search of new ground.

The height of Mount St. Elias was determined, within a plus or minus error of 100 feet, as 18,100 feet. The work at the edge of the ice gave many useful results. The supremacy of the water action in the sea, and even in the rivers, soon made itself felt in the characters it induced on the material transported by the ice, but laid down in the water; the ice frequently traversed unconsolidated material without disturbing it, and ridges of gravel, very like kames and eskers, were found to have been deposited by glacial rivers when at a higher level than that at which they at present flow.

On the main mass of the glacier there are many new facts recorded; but we have room for only a few of them. Dykes of veins of hard ice, frozen in fissures, are added to the many structures in which ice resembles less transient rocks. A rough sorting of débris takes place on the ice surface as the rocks roll down the numerous irregularities, due to melting and other causes; moulins become filled with gravel when the water-action ceases, and then, becoming preserving causes, give rise to "sand cones," which recall the earth pillars of the Tyrol. In the stationary parts of the ice numerous lakelets of strange hour-glass-shaped section occur. Lakes of the same method of origin as the Märjelen Lake are frequent where the ice passes nunataks and valleys. The main drainage of the ice is englacial or subglacial, and surface streams are rare and evanescent. Finally, these streams tend to cut their channels upward through the ice as their floor gets coated with débris, which not only checks mechanical erosion, but is a bad conductor of heat. An immense amount of water-rolled material takes its place amongst the more truly glacial detritus, and it is somewhat noteworthy that nothing corresponding to *moraine profonde* is described by Mr. Russell in his report.

The strictly palæontological work in the period under

[1] Fourteenth Annual Report of the United States Geological Survey, 1892-93. (1894.)

[2] *Bulletin* 114, "Earthquakes in California in 1893," by C. D. Perrine. (1894.)

[3] Thirteenth Annual Report of the United States Geological Survey, 1891-92. (1893.)

review is rather scanty. It includes a short paper on the American Tertiary Aphidæ, by Mr. Scudder.[1] This comprises a list of known species and five plates. A monograph, by the same author, on the Tertiary *Rhynchophorous Coleoptera*[2] contains descriptions and figures of a great number of new genera and species, 193 species having been found in the older American Tertiaries, while only 150 species have been described from the whole of the European Tertiary rocks. This makes a first instalment towards a history of fossil Coleoptera.

Mr. Whitfield has written a description of the mollusca and crustacea of the Miocene formation of New Jersey.[3] This work, which is illustrated by twenty-four plates, describes the only brachiopod and cirripede found in these beds, with a large number of gasteropoda and lamelli-branchiata, many of which are now described for the first time.

Mr. C. R. Keyes gives, in *Bulletin* 121,[4] a bibliography of North American Palæontology 1888-1892. This comprises 251 pages, and in an alphabetical series are included a list of names of authors, with a short synopsis of essential points, including lists of genera and species described and figured, a title-index, and subject entries and cross references. A list of subjects is given in the introduction, and also a list of works examined, which may save a good deal of trouble. The list is by no means perfect, but it is undoubtedly a most important contribution to bibliography.

In a subsequent article it is proposed to deal with researches in petrological, dynamical, and stratigraphical geography.

OSTWALD'S ENERGETICS.

IN the February number of *Science Progress* there is an interesting article, by Prof. Ostwald, on "Emancipation from Scientific Materialism." There are so many vague fallacies underlying it, that it would hardly be worth answering, only that there is considerable risk that others, chemists especially, may be carried away by the arguments of one whom they rightly value as a leader in their own domain when he descants positively about the realm of mechanics.

Prof. Ostwald begins by saying that the current view of a mechanical universe fails in two respects. (1) It does not fulfil the purpose for which it was designed, and (2) it is inconsistent with known truths. It is, in the first place, to be remarked that nobody who has considered the matter really seriously can maintain that atoms and motion must constitute the whole universe. Such a view leaves thought out of account, and all that can be held is that material phenomena are so explicable. Prof. Ostwald ignores such theories as that of vortex atoms, which postulate only a continuous liquid in motion; but, it may be, this is omitted because it is merely a way of explaining the atoms. He also ignores metaphysical questions, such as whether motion be not only the objective aspect of thought, and also whether an intuitively necessary explanation of the laws as distinct from the origin and consequent arrangement of phenomena is not postulated by the fact that the universe must be intelligible. Consequently his attempt to deal with nature in a purely inductive spirit is unphilosophical as well as unscientific. The view of science which he puts forward—a sort of well-arranged catalogue of facts without any hypotheses—is worthy of a German who plods by habit and instinct. A Briton wants emotion—something to raise enthusiasm, something with a human interest. He is not content with dry catalogues; he must have a theory of gravitation, a hypothesis of natural selection. This deadly science without hypothesis is far worse than the materialistic *ignorabimus* of Du Bois Reymond; it is the culmination of the pessimism of Schopenhauer.

Prof. Ostwald's first line of attack is that the materialistic hypothesis does not fulfil the purpose for which it was designed. When this is investigated, it turns out that all he means is that everything in nature has not yet been explained on mechanical principles. And long may it be so. The zest of science is discovery. If everything were explained—well, it is so far off we may wait till it comes to describe what will happen. He notices several things which are certainly not explained yet. Such, for instance, as why when atoms combine they produce a result so very different from their components. As nobody has yet suggested any reason why the atoms themselves possess the very curious properties they do, we can hardly expect a satisfactory explanation of why these properties change when they combine. Any way, the existence of an uninvestigated region of this kind does not create any reasonable doubt as to the foundations of the road that has led us well so far.

His second attack is deliberately founded on this, that mechanical hypotheses have not yet been found to explain everything. "I grant," he says, "that for many individual phenomena the mechanical analogues have been given with more or less success. But all attempts to completely represent the whole of the known facts in any department by means of some such mechanical analogue have resulted without exception in some unexplainable contradiction between what really happens and what we should expect from our mechanical model. This contradiction may long remain hidden; but the history of science teaches us that it sooner or later makes its inevitable appearance, and that all we can say with complete certainty regarding such mechanical similes or analogues—usually termed mechanical theories of the phenomena in question—is that they will doubtless on some occasion fail."

All that this really means is that we have not yet explained everything on mechanical principles, and that when we do get a little way on, we are delayed again by something more that requires explanation. But surely this and nothing else is what we ought in all reason to expect. It is about the best test we have that we are on the right track. Prof. Ostwald cites optical theories as an example of the kind of failure he refers to. He seems for some extraordinary reason to imagine that the *elastic solid* theory of the ether is in some curious way specially connected with the mechanical hypothesis of the universe. It is far from being so. The mechanical theory of an elastic solid itself has been only very dimly foreshadowed, and Prof. Ostwald's contention that transverse vibration "presupposes a solid body" is in direct contradiction to Lord Kelvin's theorem that a liquid in turbulent motion could transmit transverse vibrations. Even Lord Kelvin's elastic solid ether in a state of tension could exist if it be infinite, so that here again Prof. Ostwald is mistaken in saying that, because it could not be stable if finite, it can have no physical existence. And finally Prof. Ostwald takes refuge in the as yet unexplained constitution of an ether whose properties were discovered by assuming them to be mechanical, and were only discovered about thirty years ago, and have not been seriously investigated until within the last ten years. Surely no argument can be based upon the fact that there are limits to our present knowledge.

Prof. Ostwald's third attack opens out a new view. We see here a human reason for his desire for emancipation from the mechanical hypothesis. He is dissatisfied with Du Bois Reymond's *ignorabimus*. But even Du Bois

[1] Thirteenth Annual Report of the United States Geological Survey, 1891-92. (1893.)
[2] *Monograph* xxi., "The Tertiary *Rhyncophorous Coleoptera* of North America." By Samuel Hubbard Scudder. (1893.)
[3] Monographs of the Geological Survey of the United States, vol. xxiv. (1894.)
[4] *Bulletin* 121, "A Bibliography of North American Palæontology, 1888-1892," by C. R. Keyes. (1894.)

Reymond is not infallible, and most prophecies as to the limits of human knowledge have turned out to be only limits to the ingenuity of the prophet. It is very much more likely that Du Bois Reymond's apparently resistless logic has a flaw, than that the path of progress of science for three hundred years has been along the wrong route. There are plenty of philosophical speculations, which no doubt Du Bois Reymond brushes aside as hardly worth consideration, which would entirely invalidate the greater part of his arguments. Even though they do not, it is certainly quite unscientific to leave a road that has led to great discoveries merely because you imagine that there is some curious spectre in the distance to which you think it is leading you.

Prof. Ostwald's fourth attack is based on the fact that seeds grow into trees, but that trees do not grow back again into seeds. He thinks that if the universe were a mechanical system, there is no more reason for one than the other, and that they should occur equally often. As he says, "the tree could return again to the sapling, &c." But that is not the question. The question is, *must* it, if this is a mechanical universe. The order of events depends entirely, in a mechanical universe, upon the *initial conditions*, and all we can say is that the initial conditions of this earth were such that trees generally grow from seeds, and that the reverse operation has never been known to occur. That it *has* never occurred has nothing on earth to say to the question of whether this is a mechanical universe. As a matter of fact, I believe that this and other much simpler cases, such as are usually classed under irreversible actions in thermodynamics, can be shown to be not only, as I have here argued, *possible* mechanical processes, but to be *the most probable* mechanical processes. Hence it is quite possible that the actual sequence of events which Prof. Ostwald cites as disproving the mechanical theory of the universe may be the very best proof extant, not only that the mechanical theory is the most probable theory, but it may even lead us to conclude that it is the only possible theory.

Finally, Prof. Ostwald tries to build up something instead of what he thinks he has demolished. A vague energetics is what he presents instead of the mechanics of the past. He advocates the deadly view that science should be a catalogue, well arranged, no doubt, but free from those dreadful hypotheses. He prefers volume energy to the molecular theory of gases. He criticises this latter by neglecting to see that the quantity often quoted as energy per cubic centimetre of the gas is really momentum per second carried across a plane, and has consequently that very element of direction which he accuses it of not possessing, and the absence of which in volume energy one might possibly expect him to explain. Prof. Ostwald's idea of science as free from hypothesis is the most advanced form of pure positivism. If he were consistent, he should deny the existence of thought in the moving coloured, soft, objects he sees and feels around him, and calls men. That other men think is a hypothesis; and if he rejects all hypotheses, why not this?

In conclusion, Prof. Ostwald seems to have some dim doubt whether energetics will explain everything. As the doctrine of the conservation of energy will not determine by itself the motion of even a single planet round the sun, it is somewhat curious to see the doubt that seems to haunt him in answering this question. The doctrine of the conservation of energy is most valuable, but it goes only a very little way in explaining phenomena. More than energetics is certainly required unless we are prepared to endow energy with all sorts of curious properties after the manner of our predecessors, who used to invent a new subtle fluid with convenient properties in order to explain every new difficulty. Prof. Ostwald's energy seems more like one of these subtle fluids than any product of modern thought.

GEO. FRAS. FITZGERALD.

THE HIGHLANDS OF PERU.[1]

THE two first volumes of this work were noticed in NATURE, vol. li. p. 388, and the general remarks made there apply in great measure to the new volume also. We must, however, observe that the highlands of Peru afford material for a much more interesting description than the coast and the capital, which were dealt with in somewhat wearisome detail. Here the narrative form is not unwelcome, for there is always a charm in the

The Andes from Chililaya, Lake Titicaca

[1] "Beobachtungen und Studien über das Land und seine Bewohner während eines 25-jährigen Aufenthalts." III. Band. Das Hochland von Peru. Von E. W. Middendorf. Pp. 604. (Berlin: Robert Oppenheim [Gustav Schmidt], 1895.)

record of travel in the Cordillera, even upon the beaten tracks.

A short general introduction gives some account of the Andes as a whole, with remarks on the characteristic scenery, on the roads, the methods of travelling, and a few pages on the vegetation. Then follows the description of a series of four journeys through different parts of highland Peru, with observations drawn from official sources regarding some places not personally visited, such as the Amazon territories and the Bolivian coasts of Lake Titicaca. The first journey led over the Cordillera Negra and the Cordillera Blanca in Central Peru to Huanuco and the famous mining town of Cerro de Pasco, 4350 metres in elevation, with great silver-mines tunnelled into the mountains. The best room of the best hotel in this loftiest town in the world was found in such a condition that Dr. Middendorf could not say whether its floor was of tiles, mud, or boards, and he hailed the invitation of the Scotch engineer in charge of the mines as a happy deliverance.

The second journey was in the northern part of the republic, from the seaport of Pacasmayo by Cajamarca to the Maranon valley and Chachapoyas, returning across the Cordillera by Huanachuco to Trujilla. A short account of the Amazon province of Loreto is added, and an historical narrative of the discovery and exploration of the Amazon.

The third journey was a visit to the great plateau-lake of Titicaca, with many particulars regarding the ancient ruins of the Inca time. The concluding section, on the mountains of Southern Peru, describes the return journey down the long valley to Cuzco, and thence over the Cordillera past Ayacucho to Lima.

Throughout the work there are happy descriptions of the native peoples, the scenery, and the incidents of the journey. Dr. Middendorf seems to have paid considerable attention to linguistic studies, and also to the architecture of the ancient ruins. He especially remarks the contrast between the mud-huts, or dwellings built of sun-dried bricks, which characterise the arid coast-strip, and the megalithic masonry of the lofty plateaus and high mountain valleys.

The illustrations throughout are extremely well chosen, really illustrative of the natural features of the great Cordillera, and they are numerous enough to satisfy the most exacting. An index to all three volumes completes the work.

SEKIYA SEIKEI.

ALL students of seismology and vulcanology will learn with regret that Prof. Sekiya has passed from amongst us. He was born towards the end of 1855, a year well remembered by the inhabitants of Yedo as that of the great earthquake. In 1876, whilst on a visit to England to complete his studies as a mechanical engineer, he fell a victim to consumption, the symptoms of which gradually grew more and more severe until January 9 of this year, when they culminated in his death.

After acting as assistant to Prof. J. A. Ewing, in 1886 he was appointed to the newly-created chair of Seismology at the Imperial University of Japan.

A lasting testimony to his ingenuity and perseverance, which is to be seen in many museums, is a model illustrating the path followed by an earth particle at the time of an earthquake. Although he wrote much in Japanese, he contributed many valuable papers and memoirs in English or French to the journal issued by his own college, to the *Transactions* of the Seismological Society, and to other periodicals.

The impetus he gave to seismology by the enlargement of the University Laboratory, the establishment of instruments throughout Japan, and to the extension of the seismic survey of that country, which now boasts of 968 stations, is well known to his colleagues and acquaintances. Sekiya was a kind and sincere friend, and his honesty and unflinching straightforwardness of speech were a by-word amongst all who knew him. J. M.

NOTES.

PROF. J. J. SYLVESTER, F.R.S., has, with the approval of his Majesty the King of Italy, been elected a Foreign Member of the Royal Academy of Sciences of Turin.

A NUMBER of admirers of Prof. Mittag-Leffler, the founder of the *Acta Mathematica*, will shortly present him with a congratulatory address, written in four languages—German, French, Italian, and English—and expressing the appreciation of mathematicians of the services he has rendered to their science. It is proposed to present him at the same time with his portrait in oils, and a subscription list has been opened to obtain funds for that purpose. Prof. Appell, 6 rue Le Verrier, Paris, will be glad to receive subscriptions.

SIR J. RUSSELL REYNOLDS has expressed his intention to retire shortly from the Presidency of the Royal College of Physicians.

THE Chairman of the Local Committee for the Toronto meeting of the British Association for the Advancement of Science is Dr. A. B. Macallum.

AT the ordinary meeting of the Royal Meteorological Society, on Wednesday next, a lecture will be given by Mr. Frederic Gaster, on "Weather Forecasts and Storm Warnings, how they are prepared and made known."

A LIVE gorilla, said to be the largest ever imported into this country, has just been received at the Zoological Gardens, Regent's Park. The animal comes from near Ngove or Iquela, on the French Congo, and is in excellent health.

THE De Morgan medal, which is given triennially by the London Mathematical Society, will be awarded in June next, and nominations may be made at either the March or April meetings of the Society. Prof. Klein, of Göttingen, editor of the *Mathematische Annalen*, was the last recipient.

THE Paris correspondent of the *Times* states that a tablet commemorating Franklin's residence at Passy, then a village outside Paris, was unveiled on Sunday in the wall of the Christian Brothers' School, Rue Raynouard. M. Faye, of the Academy of Sciences, and M. Guillois, a local antiquary, delivered addresses.

SIR W. M. CONWAY proposes to take a party to Spitzbergen next summer, for the purpose of exploring the interior. He expects to be accompanied by Mr. Trevor-Battye, and by four others, all of them scientific experts in different branches, so that the journey may result in valuable increase to scientific knowledge.

WE regret to announce the deaths of Mr. James Abernethy, past-President of the Institution of Civil Engineers, and a Fellow of the Royal Society of Edinburgh; Dr. Alfred D. Kennedy, a distinguished chemist and toxicologist, of Philadelphia; Dr. H. Ernest Goodman, Professor of Surgery in the Medico-Chirurgical College, Philadelphia; Dr. R. M. Hodges, Professor of Surgery at Harvard; and Christophe Negri, the Italian economist and geographer.

THE second International Horticultural Exhibition will be held at Dresden, from May 2 to 10 next, under the patronage of

the King of Saxony. Prizes will be awarded for exhibits of flowers and plants, cut flowers, arrangements of flowers for decorative purposes, plans of gardens and greenhouses, garden buildings, heating appliances, and other horticultural requisites. Applications for space to exhibit flowers and fruit, as well as for forms of entry and programmes of the exhibition, must be made, not later than April 10, to the "Geschäftsamt der II. Internationalen Gartenbau-Austellung, Dresden."

HERR ANDRÉE'S balloon for his polar expedition is taking shape. The upper half is already sewn together, and the parts of the lower half are cut out. The Société Nordenfelt, who desired that this trust might be given to them, are superintending and controlling the work on the balloon. Arrangements have been made with the builder, Mr. F. O. Peterson, in Gothenburg, to construct a balloon house, to be ready by May 25, and two competent men, who are assisting in the construction, will go to Spitzbergen to erect the house. The *Virgo*, the steamer in which the aeronauts will set out for Spitzbergen, will carry about thirty-five tons of sulphuric acid to generate the hydrogen. Great interest is felt in the enterprise all over Sweden.

IN the House of Commons on Tuesday, for the first time since the question of the opening of museums and galleries was raised in Parliament, a majority was obtained in its favour. Mr. Massey-Mainwaring's motion was:—"That, in the opinion of this House, it is desirable that the national museums and art galleries in London should be open for a limited number of hours on Sundays, after 2 p.m., upon condition that no officer shall be required to attend on more than six days per week, and that any who may have conscientious objections shall be exempt from Sunday duty." On a division, an amendment to the resolution was rejected by 178 votes against 93, and the resolution was then agreed to. It only remains now for the Government, and the Trustees of the British Museum, to put the resolution into effect.

THE Lord Mayor presided on Friday, at the Mansion House, over a meeting held for the purpose of discussing the arrangements for the International Horse and Horseless Carriage and Roads Locomotion Exhibition, which it is proposed to open at the Crystal Palace in May next. Mr. A. Sennett was elected honorary executive commissioner, and executive committees for horse-drawn and mechanically-propelled vehicles respectively were appointed, the members including Sir Frederick Bramwell, Sir Douglas Galton, Sir H. Trueman Wood, Prof. Boys, Sir David Salomons, Mr. G. N. Hooper, Mr. Jacobs, Mr. W. Warby Beaumont, and Mr. E. Macrory, Q.C. It was announced by Sir David Salomons, who occupied the chair during the latter part of the proceedings, that Lord Kelvin had consented to join the honorary Council.

WE learn through the *Engineer* that the management of the *Cosmopolitan*, a monthly magazine, is offering £600 in premiums to be awarded to horseless carriages presenting the greatest number of points of excellence, as exhibited in a trial trip to be made on May 30. This trip will be from the City Hall Park, in New York, to Irvington and back, a total distance of 52 miles. The award will be made upon the following points, the maximum aggregate being 100:—Speed, 50; simplicity and durability of construction, 25; ease in operating, and safety, 15; cost, 10. The route will be along Broadway, through Central Park and over the Washington Bridge, thence along the main road to Yonkers, where the course will include five miles of asphalt paving, and then on to Irvington, on the Hudson River, 26 miles. There is a good road for the entire distance.

A BRIGHT aurora was seen at Worcester and other places on Wednesday, March 4. Mr. Lloyd Bozward says that at 7.30 on that evening "a remarkable beam of white light of dazzling brilliancy, far exceeding anything of the kind of recent years, arose from a point in the north-west, extending to the zenith, and spreading out fan-like in rising. So rare have been the appearances of the aurora here of late, and so startling the radiant effulgence, that many persons attributed the beam to the effect of an electric search-light."

A DISCOVERY of much interest has, says *Science*, recently been made in Western Kansas of an extinct species of Bison, the skull having an expanse of nearly four feet. Embedded below the humerus of the skeleton was a small but perfectly formed arrow-head. The Bison has not yet been identified with certainty, but seems closely allied to *B. antiquus*, though evidently larger. The formation is apparently the same as that which yielded the skeletons of Platygonus, recently obtained by the University of Kansas. The Bison skeleton, that of a bull, will shortly be mounted in the University museum.

THOUGH the coral rock in the northern part of the island of Ceylon has long been used in many departments of building, the *Ceylon Observer* thinks that builders do not avail themselves of the material so fully as they might. The stone is admirably suited by its lightness and toughness of texture for use as arch stones, being very readily shaped by an ordinary saw. Several long arched bridges have been built with it in the Jaffna Peninsula, and have proved its great durability as a building stone. It has also been applied to ornamental uses, the dressings and Gothic windows of St. John's Church at Chundikuli having been constructed of it. Cut into slabs, it has furnished the covering for nearly all the road drainage of the same locality. It is suggested that much employment could be economically found for this rock in the southern districts of Ceylon, its extreme lightness favouring the cost of freightage.

THE effect of African grass-fires in changing the aspect of the vegetation, forms the subject of a short paper by Mr. Scott-Elliot in the current number of *Science Progress*. Owing to the annual clearing of the ground by these fires, there is no accumulation of leaf-mould and stems, and the soil therefore never becomes improved. The season of flowering for many trees and herbaceous plants is completely altered, a large number of the latter sending up flowering stems, entirely without leaves, after the first shower of the rainy season; and the stems only begin to produce leaves when the rains have well set in. Another curious effect of the fires is the manner in which trees are either kept down or obliged to protect themselves in some way against their action. Of the trees which do manage to exist in spite of the annual conflagration, the most remarkable are the tree Euphorbias, which seem to come out of the most violent fire with only a few scorched branches. Mr. Scott-Elliot brought home with him several specimens of the bark of the six or seven forms of trees which manage to survive the ordeal by fire, and an examination of them led Prof. Farmer to conclude "they all agree in possessing cells which show a certain amount of gummy degeneration of the cells in the bark, together with the presence of a considerable amount of sclerotic cells; it seems not impossible that these two facts may be connected with the resistance of the plants to the fires."

AN ambitious scheme, but, at the same time, one which deserves the careful consideration and full support of all British geographers, was laid before a technical meeting of the Royal Geographical Society, held last Friday, by Dr. H. R. Mill. Dr. Mill proposes that a complete geographical description of the British Islands should be prepared from existing data, supplemented to a small extent by new researches and by the collection of unpublished information. This should be done on a uniform scale for every small selected unit of the country; then combined into a series of regional memoirs dealing with natural

districts; and ultimately the whole would be generalised into one memoir on the whole country, the result of a series of generalisations carried out much in the same way as the various maps of the Ordnance Survey are obtained by successive generalisations from the largest scale produced. The chief sources of information would be the topographical map of the Ordnance Survey, the maps of the Geological Survey, the charts of the Hydrographic Department, the publications of the Meteorological Office, the Census reports, the reports of the Board of Trade and other Government departments, the publications of such societies as the Royal Agricultural, the Archæological, the Statistical, the Institution of Civil Engineers, and many others, and the pictures of amateur photographic societies. Dr. Mill explained in detail the plan of the proposed memoir, and the method in which it should be carried out. After a discussion, Mr. Clements Markham, who occupied the chair, said he should certainly recommend to the Council that the memoir be prepared under the Society's auspices. The practical problem of expense has, however, to be solved before the plan can be developed.

An important contribution to the knowledge of the origin and movement of sand, shingle, and alluvial matter around our coasts, was made by Mr. W. H. Wheeler at the meeting of the Institution of Civil Engineers last week. It appears that the generally accepted theory, that the travel of drift along a coast is due to and is in the direction of the prevailing wind, is contrary to fact. In England the prevailing winds are from the south-west; whereas the travel of drift on the east coast is southward, on the south coast from the westward, and on the west coast northward, in each case being in the same direction as the flood tide. Mr. Wheeler has been unable to find a single instance where the regular and continuous travel of drift along a coast is in the opposite direction to that of the flood tide. While winds and waves are the agents which operate in eroding cliffs and producing the supply of drift, the continuous progressive movement of sand and shingle along the sea coast is caused by the wave action of the flood tide, which is increased when the wind blows in the same direction as the flood tide. With regard to alluvial matter in estuaries, this is derived from detritus brought down by rivers, and does not come from the sea, nor is it supplied from the waste of clay or chalk cliffs along the sea coast. The only current along the coasts of England which can transport material in suspension is that due to the tidal wave, which travels each way for about six hours at the rate of between 2 knots and 2½ knots. It is known that the material in suspension is not carried upwards for any great distance above the mouth of a river or estuary. The tidal wave propagated up a river creates only an oscillating current, and the same quantity of tidal water which goes up returns on the ebb, with the addition of the current produced by the fresh water; the tendency of movement is, therefore, downward, and not upward. Mr. Wheeler applied these and other facts to determining the principles which are essential in the construction of harbours on shingly or sandy coasts.

The current number of the *Comptes rendus* (March 2) contains a paper by M. Henri Becquerel, on some invisible radiation emitted by phosphorescent bodies. In some previous experiments the author has shown that phosphorescent bodies give out radiation which is capable of traversing bodies which are opaque to ordinary light rays. The great interest at present shown in this subject has induced him to give an account of a number of recent experiments. The phosphorescent bodies employed have been crystals of the double sulphate of uranium and potassium. The phosphorescence of this body is very marked, but only lasts, as far as the rays which affect the eye are concerned, at any rate, for less than one-hundredth of a second. It can easily be shown that the rays emitted by this body when exposed to diffused daylight or to direct sunlight are capable of traversing not only black paper, but also aluminium and thin sheets of copper. For if an ordinary dry photographic plate, enclosed in a tin-plate slide with an aluminium window, is exposed to sunlight even for a whole day, the plate is unaffected. If, however, a crystal of the uranium salt is placed on the aluminium window, and the whole is exposed to sunlight for a few hours, then on developing the plate a shadow of the crystal will appear in black. If a thin plate of copper, cut into the form of a cross, is placed between the crystal and the aluminium window, a clear image of this cross is formed on the plate. The curious result has, however, been obtained that although the plate-holder and the uranium salt are not exposed to the light, but kept inside a wooden or cardboard box, the photographic plate shows the same images as when the salt is exposed to light. The author rather tentatively suggests that the uranium salt may continue to emit by phosphorescence radiation that is invisible to the eye, but which is capable of traversing paper and aluminium for a time infinitely great compared with the time during which it continues to emit visible rays.

The February number of the *Journal de Physique* contains a paper, by M. C. Limb, on the determination of the electromotive force of a Clark cell in absolute measure. Instead of adopting the usual method, which is to compare the difference of potential at the ends of a known resistance when traversed by a known current with that of the cell, the author has adopted a novel method which is independent of the units of current and resistance. A magnet is rotated inside a long helix about an axis perpendicular both to its own magnetic axis and the axis of the coil. The magnetic moment of the magnet is determined by Gauss's method. If H is the field which would be produced at the centre of the long coil if the spirals were traversed by unit current, ω the angular velocity of the magnet and M its magnetic moment, then the maximum value of the electromotive force induced in the coil will be $HM\omega$. A correction has to be applied on account of the finite length of the coil which involves the distance between the poles of the magnet. The angular velocity is measured by simultaneously registering the turns made by the magnet and the beats of a seconds pendulum, the velocity being maintained constant by a specially designed tachyometer. By means of a commutator fixed to the axle of the magnet, the circuit of the coil is only closed at the moment when the induced electromotive force is a maximum. This maximum electromotive force is compared with that of the cell by means of a modified form of Clark potentiometer, a Lippmann capillary electrometer being employed to indicate when the balance is secured. This electrometer is capable of indicating a difference of potential of 0·00005 volt. The Clark cell was of the H pattern, and the author gives as his final result for the electromotive force of this form of cell at 0° C. the number 1·4535. The number obtained by Lord Rayleigh was 1·4527 volts.

The habit of opium-smoking forms the subject of a paper, by M. H. Moissan, in the *Annales de Chimie et Physique*. M. Moissan finds that the Chinese do not smoke crude opium, but a preparation of it called *Chandu*, which, when heated to about 250° produces a smoke formed of volatile perfumes and a small quantity of morphine; this appears to produce no more ill-effects than tobacco-smoking. The commercial quality of opium, however, is very different; the residues that remain after opium-smoking are sold as dross, and when this is treated to a temperature of 300° to 325° various toxic compounds are given off.

We have received, from Mr. E. Kayser, a pamphlet containing a considerable number of measurements of cloud-heights taken at Dantzig last summer. The observations were taken

by various kinds of instruments, but the principle was the same throughout—viz. two corresponding stations of known base were selected, and the apparatus directed at the same instant on the same point of the sky. A full description of the instruments and method is given in the text, and printed in vol. ix. of the *Schriften* of the Dantzig Philosophical Society. The publication of the work is timely, as on May 1 next a year of special cloud observation in all parts of the world is to commence, under the auspices of the International Meteorological Committee. The pamphlet contains much useful information for intending observers.

The *Verhandlungen* of the German Geographical Society (No. 1, 1896) contain a lecture, by Mr. A. Berson, on the use of balloons for geographical purposes. As Mr. Berson has made many ascents, both in free and captive balloons, in connection with the Berlin Meteorological Office and other German institutions, his remarks possess considerable interest. He refers to the importance of captive balloons in voyages and in Arctic expeditions, and regrets that Dr. Nansen did not take one with him as he originally intended. He strongly condemns the proposal to use a free balloon in the Andrée polar expedition, and thinks it must certainly end in disaster. Mr. Berson found during his ascents that in all types of weather, and at all seasons, the temperature at great heights decreases more rapidly, or at least as quickly, as in lower altitudes, and that at a height of over 5000 metres much lower temperatures exist than those assumed after Mr. Glaisher's ascents. Also that the increase of wind velocity is much greater than was supposed; in one ascent, when the wind velocity was only about seven miles an hour at a height of between 1000 and 3000 metres, it reached thirty-seven miles an hour, between 4000 and 6000 metres. A preponderance of winds with westerly components was also observed in great altitudes, as is shown by cloud observations made at the earth's surface.

Dr. C. Sapper has studied the customs and religious views of the Kekchi Indians of Guatemala (*Internat. Arch. f. Ethnogr.*, viii. p. 195), and it is interesting to trace the Pagan-Christian overlap in the religion of these professed Roman Catholics. They will not worship in a church out of their own district, as they believe that the god of that church cannot understand them; indeed, when they go to neighbouring places, they renounce all religious exercises. Crosses are erected on mountain-passes by all the Maya Indians, and a native on first crossing a pass puts a stone at the foot of a cross, and often offers flowers and incense, and sometimes he will dance before it. If there is no cross on a pass, the Kekchi Indian prays and brings offerings to the heathen god. In order to make green parrots tender—for they are very tough—the natives put them in a hammock before cooking, and rock them, whistling to them, as if they were sleepy children. Money presents, formerly to the value of 2½ dollars, were paid by the bridegroom's father to the bride's father, but the price has now risen to 7 dollars. A girl can have a husband bought for her, but it is more expensive, as he costs 10 dollars.

In the same journal (p. 215), Dr. J. Walter Fewkes gives a "Provisional List of Annual Ceremonies at Walpi," his idea being to bring together in proper sequence the prescribed yearly observances of the Tusayan Indians. It appears that the dates for the various festivals and ceremonies were fixed by the extreme summer and winter solstitial points of risings and settings, and by certain hillocks, notches, or trees on the horizon. When the sun appears to rise or set behind recognised definite points on the horizon, certain religious ceremonies are announced, and secular occupations, as that of planting, initiated. The author briefly describes the various annual ceremonies, the period of their commencing, and their duration. It will be evident that this is an important paper, as it coordinates previous observations.

Until Busse last year proclaimed the existence of a species of yeast possessing pathogenic properties, this class of microbes had escaped all imputation as regards disease-producing characteristics. Busse's researches have been followed up by others from Colpe, and Sanfelice, but the latest contribution to the subject has been received from Dr. Lydia Rabinowitsch, who has worked at it under the superintendence of Dr. Robert Koch at Berlin. Fifty different varieties of yeast were collected, and out of these, seven were found possessing pathogenic properties. These yeasts appear to be distinct from those pathogenic varieties isolated by other observers. Amongst them is *Monilia candida*, a yeast already investigated by Jörgensen, and of considerable interest on account of its remarkable fermentative properties, but which Dr. Rabinowitsch found was fatal to both rabbits and mice, although guinea-pigs were in no way affected by it. Another yeast, pathogenic to mice, was obtained from some figs which had been allowed to ferment, whilst a so-called "wild" yeast, found on grapes, killed both rabbits and mice. A variety of yeast isolated by Prof. Delbrück from ale, and sent from America, was also found to be fatal to rabbits in from nine to ten days, and to mice in from four to six days when subcutaneously introduced. The fact that these pathogenic yeast cells were usually found abundantly present in the blood, and in the various organs of the animals' bodies, justifies, says Dr. Rabinowitsch, the assumption that the effect produced by them was not due to intoxication from the products elaborated by them, but to direct infection through their copious multiplication within the animals' system. Sanfelice's observation that the yeast cells presented a different appearance when taken from artificial cultures, and from the bodies of animals respectively, was not confirmed by Dr. Rabinowitsch, who could detect no difference.

Among the excursions which the Geologists' Association are arranging for the coming season, the farthest afield are those to the Dorsetshire coast (Easter), Chippenham and Calne (Whitsuntide), Ipswich, the new railway at Catesby (Northants), and West Somerset and North Devon (in July). Nearer town, Galley Hill (Kent), Hendon, Leith Hill, Chingford, Reading, Hitchin, and High Barnet will be visited.

The present volume (vol. xiv.) of the *Proceedings* of the Geologists' Association will be largely devoted to Indian geology. The two presidential addresses of the late President, Lieut.-General C. A. McMahon—the first published in the number for May 1895, the second not yet published—deal with the Himalayas. The February number, which has only just been issued, contains a paper, by W. H. Hudleston, on the geology of India in general, with special notes on a journey from Bombay to Kashmir. The first part gives an excellent summary of the geology of India, illustrated by a coloured map; while a number of sections accompany the second part.

The monthly notes on Petrography, contributed by Dr. W. S. Bayley to the *American Naturalist* for 1895, have been reprinted and issued together as a "Summary of Progress in Petrography," which should be welcomed by those who are unable to keep themselves abreast of the rapid increase of knowledge in this department. A subject- and an author-index are added. As the author omits his own papers, with one exception, from the list, we may add that his researches on the Basic Massive Rocks of the Lake Superior region, published in the Chicago *Journal of Geology*, should not be overlooked by students of Petrography.

An order has been made by the Home Secretary, which prohibits the taking or destroying of the eggs of the following species of wild birds throughout the administrative county of Durham:—

Blackheaded gull, common buzzard, kestrel, merlin, owls (all species), bittern, curlew, dipper, dotterel, dunlin, golden plover, goldfinch, heron, hawfinch, kingfisher, martins (all species), nightjar, nuthatch, pied flycatcher, peregrine falcon, raven, ring ouzel, snipe, swallow, treecreeper, water rail, wagtails, woodpeckers (all species), woodcock. It is also ordered that the Wild Birds Protection Act, 1880, shall apply throughout the county of Durham to the following species of wild birds:—Bearded tit, buzzards (all species), hobby, kestrel, martins (all species), merlin, osprey, peregrine falcon, swallow, swift, wryneck.

IN the *Entomologist's Monthly Magazine* for March, Dr. T. A. Chapman records an experiment on the artificial prolongation of the larval stage in Lepidoptera, which, although brief and incomplete, indicates an important line of research in connection with metamorphosis. Caterpillars of *Agrotis comes*, on reaching the last normal stadium, were starved so as to delay growth, and after six weeks were then placed on abundant diet. Some died, several turned normally to pupæ, and others endeavoured to prolong the larval condition. Two alone succeeded, and assumed a further larval instar, accompanied by modifications in the antennæ, maxillæ, legs and eyes. Those which failed were shown by dissection to be endeavouring to accomplish similar changes. In this way an aberrant larva, with certain pupal or imaginal characteristics, was obtained. These experiments have some analogy with the production by Grassi of intermediates between the normal forms found in a nest of Termites, and perhaps with certain phenomena of hypermetamorphosis. Further and more complete experiments will be awaited with interest.

CREMATION as a means of disposal of the dead is steadily gaining favour. From the report of the Council of the Cremation Society for 1895, we see that 150 cremations were carried out at Woking during the year, and fifty-eight at Manchester. When the Society commenced operations in 1885, only three bodies were cremated, but this number has continuously increased since that year. At the present time, the crematorium at Manchester is the only one in operation in England besides the one at Woking. Another is, however, being erected near Liverpool, and will shortly be opened for use; and last November, a building, comprising a crematorium, chapel, and waiting-rooms, situated on the outskirts of Glasgow, was opened by Sir Charles Cameron.

WE have on our table the sixth edition of M. P. Schützenberger's well-known work on "Les Fermentations," published by M. Félix Alcan in the comprehensive Bibliothèque Scientifigue Internationale. The whole of the text has been revised, and numerous additions have been made. The "Résultats de l'examen de dix mille observations de hernies," communicated to the last French Congress of Surgery, by Prof. Paul Berger, has been published in volume form by M. Félix Alcan. Mr. Ernest Hart's criticism of "Hypnotism, Mesmerism, and the New Witchcraft" (Smith, Elder, and Co.) has blossomed into a second edition. A chapter has been added, embodying the confessions of a professional medium, and some new matter has been placed in an appendix, but no other changes have been made.

A NEW monthly magazine—the *Ornithologist*, edited by Mr. H. K. Swann—has just appeared, its claim to distinction among the periodical literature of natural history being that it is the only monthly journal of ornithology published in the British Islands, though there are several which devote a large share of their space to the subject. The first number of the new publication contains, among other contributions, notes on birds seen during a continental tour, by Mr. O. V. Alpin, notes on the nesting habits of the oyster-catcher, by Mr. F. B. Whitlock, and on British birds at Wiesbaden, by Mr. Graham W. Kerr. There is also a full-page plate showing the nest of a wheat-ear, built in an old tin can, and a portrait of the late Mr. Seebohm. We welcome this addition to the ranks of scientific journals, and hope that it will long live to encourage observation and research.

THE recent discovery of argon in atmospheric air, by Lord Rayleigh and Prof. Ramsay, aroused such great interest, that it has been resolved, on the repeated request of the "general public," to prepare a volume containing an account of the methods of extracting the new gas from air, and of its properties, explaining, where necessary, in popular language, the basis of the reasoning employed in drawing conclusions relative to argon. But the whole history of the determination of the gases in air is so closely related to this recent discovery, that it would hardly have been possible to present the subject in its entirety without a preliminary sketch of the discoverers and their work. The little work, which has been written by Prof. Ramsay, and will be published by Messrs. Macmillan and Co., therefore treats of all the progress made in this fascinating branch of chemistry by a number of men, almost all of them English. In this sense, England may be said to "rule the air," as in another she rules the sea. The volume will contain portraits of Cavendish, Boyle, Lavoisier, and other early discoverers.

THE additions to the Zoological Society's Gardens during the past week include a Hairy Armadillo (*Dasypus villosus*) from La Plata, presented by Mr. A. H. Robinson; two Fennec Foxes (*Canis cerdo*) from Egypt, presented by Mr. Dixon Bey; a Pale Genet (*Genetta senegalensis*), two Home's Cinixys (*Cinixys homeana*), an Eroded Cinixys (*Cinixys erosa*), a Delalande's Gecko (*Tarentola delalandii*) from West Africa, presented by Mr. W. H. Boyle; a Lesser Kestrel (*Tinnunculus cenchris*) captured at sea, presented by Mr. A. J. Leith; a Greater Black-backed Gull (*Larus Marinus*), British, presented by Mr. G. Smith; one Slender-billed Cockatoo (*Licmetis tenuirostris*) from Australia, presented by Mr. John J. Sapp; a Laughing Kingfisher (*Dacelo gigantea*) from Australia, presented by Mrs. Hillier; a Hawfinch (*Coccothraustes vulgaris*), British, presented by Mr. C. Bates; two Black Swans (*Cygnus atratus*, ♂ ♀) from Australia, purchased; a Gorilla (*Anthropopithecus gorilla*, ♀) from Naove or Iquela Congo Français, four Short-Death Adders (*Hoplocephalus curtus*) from Australia, deposited; an Eland (*Oreas canna*, ♂) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

PERRINE'S COMET (1895).—Some interesting photographs of Perrine's comet were taken at Prague by J. and J. Fric, during its appearance in November last (*Acad. Sci. de l'Emp. Fr. Jos.*, 1896). One of the photographs was taken on November 23 with an exposure of thirty minutes, and another a week later with an exposure of twenty minutes. The nucleus resembles an ordinary star in both cases. The tail proceeds from the head in the form of a fan opened out to about 30°, and is clearly divided into two parts. In the first photograph the northern part of this double tail is curved, and has a length of about 30′, while the other is straight, and can be traced through about $3\frac{1}{2}°$, the width being about 5′. Notwithstanding the shorter exposure of the second photograph, both tails are extended, the curved one being 50′ in length, and the other very nearly 7°. The principal tail is only 3′ wide for the first degree of its length, but it suddenly widens out and forms a band 10′ broad. We seem to have here the long straight "hydrogen" tail and the strongly-bent "iron" tail which Bredichin's theory attempts to explain.

Photographs taken at the Lick Observatory also exhibit the double tail, and Prof. Campbell's observations show that the spectrum of the comet was one consisting of carbon bands. The comet is still visible, and rises some hours before the sun. Dr.

E. Lamp gives the following ephemeris for Berlin midnight (*Ast. Nach.*, 3338).

	R.A. h. m. s.	Decl. ° ′	Brightness.
March 12	19 45 30	+5 12·8	0·09
14	45 0	5 46·4	
16	44 25	6 20·2	0·09
18	43 44	6 53·9	
20	42 56	7 27·7	0·08
22	42 3	8 1·7	
24	41 3	8 35·7	0·08
26	39 57	9 9·8	
28	38 45	9 44·0	0·07
30	19 37 26	+10 18·2	

COMET PERRINE-LAMP.—The revised elements of this comet, which have been arrived at by Dr. Lamp, indicate the following places for Berlin midnight (*Ast. Nach.*, 3338):—

	R.A. h. m. s.	Decl. ° ′	Brightness.
March 12	3 1 59	+48 34·4	0·15
14	15 11	47 41·2	0·12
16	26 9	46 51·8	0·10
18	35 25	46 6·5	0·08
20	43 21	45 25·4	0·07
22	50 17	44 47·9	0·06
24	56 25	44 13·9	0·05
26	4 1 53	43 43·1	0·04
28	6 51	43 15·1	0·03
30	4 11 22	42 49·4	0·03

The unit of brightness is that of February 15·7. On March 14 the comet will be nearly 2° south of α Persei.

ORBIT OF δ CEPHEI.—From an investigation of the displacement of the lines in the spectrum of δ Cephei, Dr. Belopolsky came to the conclusion in 1894 that the light changes of this short period variable are closely associated with an orbital movement (NATURE, vol. li. p. 282). The results have been generally confirmed by another series of photographs which were taken last year, but there are some differences in the numerical data (*Ast. Nach.*, 3338). For the velocity of the system towards the sun the later value is 15·2 English miles per second, and the time of periastron passage is altered from 1·05 days after minimum to 0·9 days. The following data for the construction of a curve of velocities of the bright star relatively to the dark one, with which we must suppose it to be associated, are derived from the figures given by Dr. Belopolsky:

Interval from minimum in days.	Relative velocity in Eng. miles per sec.
0·8	+13·4
0·5	+ 7·8
1·0	− 1·8
1·5	−10·6
1·7	−11·5
2·0	−12·9
2·5	−10·6
3·0	− 6·5
4·0	+ 1·4
5·0	+ 8·3

A + sign indicates a movement in a direction away from the sun, and a − towards the sun. The period of revolution is equal to that of the light changes, 5d. 9h., and the maximum occurs 1d. 15h. after the minimum. At the time of minimum the stars lie very nearly along a line at right angles to the line of sight, so that the reduction of light cannot be produced by an eclipse.

Attention is drawn to several notable differences in the intensities of the lines in the star spectrum and in the spectrum of the sun. Mr. Lockyer has also recognised such differences, and has shown that the spectrum of δ Cephei is practically identical with that of γ Cygni, a star of increasing temperature; four other variables of the δ Cephei class have also been shown to give a similar spectrum.

THE ABSOLUTE VELOCITY OF 61 CYGNI.—The combined results obtained for the proper motion of a star by meridian observations, and for the velocity in the line of sight by the spectroscopic method, enable the absolute velocity and direction of movement to be determined. Dr. Belopolsky has recently applied this to the brighter component of 61 Cygni, employing the velocity derived from spectrum photographs taken at Pulkowa. The mean velocity in the line of sight, corrected for the earth's movement, and thus referred to the sun, is 33·7 English miles per second towards the solar system. Taking the position of the apex of the sun's way as R.A. 267°, decl. +31°, and supposing the velocity of the solar system in space to be 9·3 English miles per second, the correction to be applied to 61 Cygni for the movement of the sun is 6·9 miles per second. Thus, the velocity of the star towards a fixed point in the direction of the sun is 26·8 miles per second.

Adopting a parallax and proper motion of 0″·5 and 5″·2 respectively, the linear velocity across the line of sight will be 30 miles per second, or, when freed from the velocity of the solar system, 22·6 miles. The resultant absolute velocity is accordingly 35 miles per second, the direction of movement having a position angle of 61° and being inclined at an angle of 140° to the line of sight.

ON THE APPEARANCE OF THE SPECTRAL LINES OF CLEVITE GAS IN STELLAR SPECTRA.

IT is very rarely that so rapid progress is made as that which followed Prof. Ramsay's discovery of the line in the yellow, corresponding with the solar line D_3, in the spectrum of the gas obtained from the mineral clevite. As early as May 9, Mr. Lockyer communicated a paper to the Royal Society,[1] in which a table was given showing that many of the unknown lines in the stars with few lines in their spectra were really due to the new gases. It seems to take some considerable time for English work of this kind to get to Berlin, for on October 24 Prof. Vogel made the same announcement to the Berlin Academy.[2] His confirmation, therefore, is of great interest.

It is not a little curious that the first star which he discusses is not one of the stars in Orion to which Mr. Lockyer had specially referred, but to β Lyræ, which the same observer had demonstrated a year or two ago to be a double star, the spectra of the components resembling that of Rigel and Bellatrix, both in Orion.

Vogel found that a comparison of the lines of this star with those in the spectrum of clevite gas showed in an unexpected manner a great number of coincidences.

His attention having been directed, in this perfectly independent manner, to the question, he was led to examine the spectra of many other stars, and to this end he employed the rich material collected by Dr. Wilsing. In the communication to the Academy, Prof. Vogel gives only a general survey of the work, leaving a more detailed account for a later publication. The first series of stars investigated were those in the constellation of Orion, for there the line λ 447 μμ plays an important part. The comparison, the results of which are here given in tabular form, exhibited many coincidences; the lines of clevite gas most common to the stars β, γ, δ, ε, ζ, λ, ν, π_3, π_5, ω of Orion were those of wave-length 382·0*, 388·9*, 402·6*, 414·4, 438·8, and 447·2*, those of helium being marked with an asterisk.

It was at first thought that, in consequence of the paucity of stars of the Orion type in other parts of the heavens, few would be found exhibiting the lines of clevite gas. An examination, however, of 150 of the brighter stars of Class I. disclosed the fact that no less than twenty-five, in which the characteristic Orion lines, or, in other words, the lines of clevite gas, were visible, were observed.

Prof. Vogel informs us that until the spectra of all the stars of Class I., down to about the 5th magnitude, have been obtained and examined, an accurate idea of the distribution of these stars in the sky cannot be formed. He further adds that a third part of this work is already accomplished. Some of the stars in which the lines in the clevite gas spectrum are well pronounced are: 102 Herculis, ι Herculis, α Virginis, γ Pegasi, β Piscium, β Cephei, *u* Herculis, ι Andromedæ, τ Herculis, ζ Draconis, η Leonis, ρ Pegasi, β Persei, η Aurigæ.

The above-mentioned investigation leads Prof. Vogel to form the following deductions with regard to stellar classification. These we give in full, remarking that while Dr. Vogel had previously classed the stars which now turn out to contain the helium lines with stars like Sirius, Mr. Lockyer had classed them apart.

[1] *P.R.S.*, vol. lviii. p. 117.

[2] *Sitzungsberichte der Königlich-Preussischen Akademie der Wissenschaften zu Berlin*, October 24, 1895.

"By an inspection of the numerous spectra my opinion is strengthened that in arranging stars according to their spectra only general marked characteristics should be considered, and a rational classification can only be thought of if based on the supposition that the various stellar spectra indicate different phases of development.

"I think it is much to be regretted that, in the extensive spectroscopic examination of all stars down to about the seventh magnitude, which Pickering by means of an objective prism has undertaken, the classification of stars, based on no general grounds, but only according to the appearance of the spectrum, which is very often misrepresented by incorrect exposure, especially in the case of brighter stars, leads him to adopt sixteen classes, denoted by the letters A–Q."

On this it may be remarked that Mr Lockyer has already shown in NATURE that Prof. Pickering's classification is quite philosophical, and that, moreover, it brings stars together to which he also has assigned special places in his classification on account of their special features.

Prof. Vogel then continues:—

"The attempt, on the lines mentioned above, which I made twenty years ago, with regard to the classification of stellar spectra has for the most part been corroborated, in spite of the great progress of stellar spectroscopy during the last few years, namely by the fine detailed researches of their spectra by Scheiner.

"In relation to the stars of Class III., direct observation of the less refrangible part of the spectrum of the photograph is yet to be considered. Of my two suggested divisions, *a* and *b*, the criterium as to which belongs to the more advanced stage of development is entirely absent. One can only say this, that in both divisions the almospheres of the stars have so far cooled as to stop the dissociation of the materials and allow compounds to be formed. There is therefore, no reason given why stars of Class III.*b*, in which chiefly the absorption bands are produced by carbon compounds, should be placed in a special Class IV. For the same reason direct observation is a good means of recognising spectra of Class II. Also here there is no reason to adopt subdivisions other than the two already assumed by me before we are in possession of more accurate investigations of the spectra of Class II.*b*.

"It is different in the case of the spectra of Class I. In these spectra the application of photography makes it in general possible to step further and obtain more minute points of difference than was the case before. It appears also that the study of the spectrum of these stars is of special interest, inasmuch as, starting from the simplest spectrum, in which only hydrogen lines are visible, the first traces of a further development can be found by the appearance of lines of other substances, and we can follow them up to the numberless lines exhibited in the spectra of Class II. Perhaps it will be possible by a more extended investigation of the details of the spectrum of Class I. to find the first beginnings and individual parts of both from successive series, the extremities of which, so different in appearance, are spectra of the type of Class III.*a* and III.*b*.

"The observations mentioned above have led me to the opinion that the appearance of the lines of clevite gas in stellar spectra, if closely watched, may give us a good basis for the classification of these spectra.

"The spectrum appearance of clevite gas has such a similarity with that of hydrogen, as has long been known to be the case, through the constant appearance of the D_3 line with the hydrogen lines at all parts of the chromosphere of the sun, as well as in the prominences, that one may expect to find, after the appearance of the hydrogen lines in the first place, that of the lines of clevite. The paucity in lines of the spectrum of this gas makes it especially easy to be at once recognised. Although the brightest line, λ 388·9 $\mu\mu$, as already mentioned, falls so near constantly the present hydrogen line $H\zeta$ in the spectrum of Class I. that a separation is impossible, and although in only very few cases does the sum-total of both these strong lines appear distinct—as, for instance, in the spectrum of β Lyræ—the lines λ 382·00 $\mu\mu$, λ 386·8 $\mu\mu$, λ 402·6 $\mu\mu$, and λ 447·2 $\mu\mu$, on the other hand, and those in the less refrangible part of the spectrum, namely λ 492·2 $\mu\mu$, λ 501·6 $\mu\mu$, and D_3, λ 587·6 $\mu\mu$, are so easy to find and recognise that the proof of the presence of clevite gas is not beset with difficulties.

"As a second point of difference for subdivisions of Class I. the presence of the calcium lines λ 393·38 $\mu\mu$ and λ 396·86 $\mu\mu$ is convenient, the second of these lines coinciding nearly with the hydrogen line $H\epsilon$ (λ 397·02 $\mu\mu$). If the first of these lines be thin and sharp, the second only influences the hydrogen line $H\epsilon$ to a very small extent. If the lines of calcium increase both in intensity and breadth, then $H\epsilon$ broadens in a very distinct manner; both lines then very soon excel with respect to intensity and thickness, the strongest and broadest hydrogen lines in the spectra of Class I. On further development they form together the characteristic pair of lines in Class II. which Fraunhofer called H."

Prof. Vogel then concludes his paper with a re-division of stars of the first class into three parts, *a*, *b*, and *c*.

Although *c* includes stars having spectra which exhibit bright lines, he suggests that from the present point of view it would be perhaps better to place them first, as they represent the first stage of development. The fact that they are here retained in subdivision *c* is because a definite conclusion has not yet been arrived at as to their true position, so the old position has, *pro tempore*, been maintained.

THE RÖNTGEN RAYS.

THE following is a summary of some of the work with Röntgen rays brought under our notice during the past week:—

The results of a scientific study of the properties of Röntgen rays are stated in a paper by Prof. G. Vicentini and Dr. G. Pacher. in a paper read before the Reale Istituto Veneto di scienze, lettere, ed arti, on January 26, and now issued as an excerpt from the *Memorie* of the Institute (vol. xxv. No. 7). The authors found distinct evidence of an irregular reflection from a parabolic brass mirror; the Crookes' tube and the sensitive plate were placed on opposite sides of an iron plate, so that the rays to reach the plate had to be reflected from the mirror. No effect was observed with a similar glass mirror, or with the arrangements used by previous observers to test the existence of reflection. Photographs accompany the paper, showing shadows of fish, a hand, two feet, and a rat with mercury introduced into its intestines. Experiments showed that a gold-leaf electroscope, turned towards the kathode, became charged positively; a wire cage, however, completely annulled the action. The following list of transparencies to Röntgen rays is interesting:—Solid bodies (opaque): Potassium, phosphorous, fused sulphur, glass, sealing-wax, tin, zinc, iron, brass, copper, lead, platinum, mercury, crystallised sulphur, rock-salt, quartz, calc-spar, fluor-spar, topaz, beryl, aragonite, baryta, lead carbonate, tourmaline, borax. Semi-transparent: Aluminium, sodium, ebonite, retort-carbon, mica (along both axes). Transparent: Cardboard, wax, paraffin, sugar, wood-charcoal, amber, shellac. Liquid bodies (opaque): Carbon disulphide, sulphuric acid (saturated solutions of), sulphates of zinc, copper, iron, cobalt, nickel and magnesium, bichloride of mercury, chlorides of sodium, ammonium and platinum, neutral oxalate of potash, potassium bichromate, and ammonium nitrate. Semi-transparent: Acetic acid, nitric acid, glycerine, ammonia, and, in a less degree, distilled water and alcohol. Transparent: Ether, benzene, in a less degree vaseline, petroleum, aniline, and olive oil. There appeared to be no clear relation between the opacity and density of the substances experimented upon.

In order to get distinct shadows of objects opaque to Röntgen rays, it is obviously necessary to avoid a penumbra, by employing a source of the rays approaching as nearly as possible to a point. The Crookes' tubes, however, as usually put on the market, are given a pear-shape, for the purpose of having as extended an area as possible under the action of the kathode rays. To obtain clear shadows with such a tube the objects must be very close to the sensitive plate or the fluorescent screen, a condition which cannot always be realised if the objects are enclosed in envelopes of considerable thickness. Prof. E. Salvioni described to the Accademia Medico-Chirurgio di Perugia, on February 22, two methods whereby the kathode rays may be brought to a point on the walls of the tube, producing a very restricted but intensely fluorescent area. In Crookes' tubes, with the usual spherical cup-shaped kathode, the rays issue from this normally, and meet in a point generally inside the tube. By moving a magnet in the neighbourhood of the tube, this focus may be brought on to the tube wall. A more convenient method of arriving at the same result was found by chance. On moving the hand over the tube, the position of the focus of the kathode rays is altered, and the same action takes place on touching the tube

with a metallic point connected to the ground or to the kathode. The rays then are attracted to a point on the tube exactly opposite to that touched by the conductor; the best position for the latter is at a distance from the kathode equal to its radius of curvature. Tubes could, of course, be constructed so that the focus of the kathode rays fell normally on the wall of the tube; it is found, however, that after some time the glass loses its fluorescent property, showing a dark spot at the incident point of the rays. The device with the metallic point enables the fluorescent spot to be changed from time to time.

The surgical aspects of photography with Röntgen rays are considered by Mr. Albert Carless in the March number of the *Practitioner*. The conclusion arrived at with reference to radiography is "that it can be of real value in a certain limited number of cases there can be no doubt, but unless very considerable improvements are made in the technique, it will be but little resorted to in practical work."

Prof. M. J. Pupin contributes to the March number of the *Engineering Magazine* (New York) an account of his experiments with Röntgen rays. He has obtained excellent results with a pear-shaped Crookes' tube, of five inches diameter, excited by a six-plate Holtz machine. He finds that a cylindrical vacuum tube without internal electrodes, but with external tinfoil coatings at the extremity of the tube, will do very well as a substitute for a Crookes' tube.

Our American correspondent writes, under date February 28: "The new art of 'radiography' is still prosecuted in America with unabated ardour. The most successful apparatus yet devised seems to be that of Prof. John S. McKay, of the Packer Institute, Brooklyn. It is a small tube five inches long, and an inch, or rather more, in diameter, which is known and sold by instrument-makers as a 'perfect vacuum' tube. This is attached directly to the terminals of the secondary coil. The copper electrodes are less than an eighth of an inch apart; but the vacuum is so perfect, that the spark will leap the whole length of the tube outside rather than cross this small interval inside. The tube produces very little light, and is sometimes, when in use, perfectly dark. This tube is light and convenient, and does not become hot like the Crookes' tube. After running it continuously for half an hour with a pressure of 200,000 volts, it is scarcely warm to the touch. But the special advantage is that the rays radiate in all directions from the centre, so that exposures may be made simultaneously within a radius of two feet from the centre of the tube. The best results were found at a distance of one foot, and with an exposure of five minutes. Experiments to determine the relative opacity of different substances show that the opacity to X-rays is generally in inverse proportion to the diathermancy of the substances tested. Thus rock-salt is most opaque; next comes alum, then glass, then quartz. Camphor gum, gum copal, and vulcanite are almost equally transparent; amber somewhat less so, and sealing-wax quite opaque. Iceland spar, mica, and selenite are quite transparent. Iceland spar seemed to give evidence of double refraction. Charcoal is quite transparent, more so than wood. Anthracite coal is somewhat opaque, but not so much as glass. Egg-shells, like bones, are opaque. Of liquids tested, mercury, sulphuric acid, glycerine, and kerosene were somewhat opaque, the opacity varying about as the density. Prof. McKay has also produced pictures on a sensitive gelatine film wrapped in paper with some metallic object upon it, and placed in the dielectric of an electric condenser, the terminals of which are connected with an induction coil or Holtz machine. After rapidly charging and discharging this condenser or Leyden jar for two or three minutes, a distinct image of the metallic body is found to be radiographed upon the sensitive film.

"A remarkable application of Prof. McKay's apparatus has been made by Edward P. Thompson, an electrician, who has devised a fluorescent screen on which shadows may be thrown showing the action of the bones in motion, as of the hand, and he hopes to show the motion of the bony skeleton of a bird in flight. It has been stated that the great drawback to aerial locomotion is our ignorance of the exact way in which a bird flies. Hence the inventor attaches much importance to his apparatus, which he calls the 'kinetoscotoscope.' It will show, among other things, the motion of the parts of a broken bone, indicating the locality and nature of the fracture, as the bones may be moved or bent back and forth before the screen, thus opening and closing the crack. The taking of pictures is not the design of this apparatus. The fluorescent screen is prepared by pulverising barium platino-cyanide to a fine powder, and pouring upon a draughtsman's tracing cloth a small quantity of varnish, or of a mixture of oil and turpentine, stirring the powder in with it, and drying."

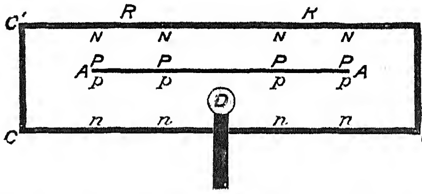
With regard to seeing Röntgen shadows by means of a fluorescent screen, Mr. Swinton informs us that he finds that instead of employing blotting-paper saturated with barium platino-cyanide, it is much better to make a hot emulsion of the barium platino-cyanide in gelatine and water, and apply this in a thick coat to a piece of glass On cooling, the barium platino-cyanide crystallises out, and the gelatine protects it from abrasion. A thick and uniform coating is what is wanted. The glass being rather opaque to the X-rays, but transparent to light, the plate should be obviously placed with the gelatine side next to the Crookes' tube, and the glass side next the eye.

ON THE GENERATION OF LONGITUDINAL WAVES IN ETHER.[1]

In a short note published in NATURE of February 6, I suggested an arrangement of four insulated and electrified spherical conductors with their centres in one line, giving rise to ethereal waves in the surrounding atmosphere, of which the disturbance in the line of centres is essentially longitudinal. But at any finite distance from this line there must also be laminar or distortional waves of the kind expressed in Maxwell's equations. The object of my present communication is to show an arrangement by which a large space of air is traversed by pressural disturbance, or by waves essentially longitudinal, or by condensational-rarefactional vibrations; with but a very small proportion, practically evanescent, of laminar waves.

Let AA be a plane circular metal plate insulated within a metal case CCC′C′, as indicated in the drawing. Let D be a discharger which can be pushed in so as to make contact with A.

Let A be charged to begin with, positively for instance as indicated by the letters PP*pp*; NN*nn* showing negative electricity



induced by it. Let now the discharger be pushed in till a spark passes. The result, as regards the space between AA and the roof RR over it, will be either an instantaneous transmission of commencement of diminution of electrostatic force, or a set of electric waves of almost purely longitudinal displacement, according as ether is incompressible or compressible.

Hence, if the theory of longitudinal waves, suggested by Röntgen as the explanation of his discovery (for the consideration of which he has given strong reasons), be true, it would seem probable that a sensitive photographic plate in the space between AA and RR should be acted on, as sensitive plates are, by Röntgen rays. Either a Wimshurst electrical machine or an induction-coil, adapted to keep incessantly charging AA with great rapidity so as to cause an exceedingly rapid succession of sparks between D and A, might give a practical result. In trying for it, the light of the sparks at D must be carefully screened to prevent general illumination of the interior of the case and ordinary photographic action on the sensitive plate.

The arrangement may be varied by making the roof of sheet aluminium, perhaps about a millimetre thick, and placing the sensitive photographic plate, or phosphorescent substance, on the outside of this roof, or in any convenient position above it. When a photographic plate is used there must, of course, be an outer cover of metal or of wood, to shut out all ordinary light from above. This arrangement will allow the spark gap at D to be made wider and wider, until in preference the sparks pass between AA and the aluminium roof above it. The transparency of the aluminium for Röntgen light will allow the photographic plate to be marked, if enough of this kind of light is produced in the space between the roof and AA, whether with or without sparks.

[1] A paper by Lord Kelvin, read before the Royal Society on February 13

The new photography has hitherto, so far as generally known, been performed only by light obtained from electric action in vacuum; but that vacuum is not essential for the generation of the Röntgen light might seem to be demonstrated by an experiment by Lord Blythswood, which he described at a meeting of the Glasgow Philosophical Society on Wednesday, February 5. As a result he exhibited a glass photographic dry plate with splendidly clear marking which had been produced on it when placed inside its dark slide, wrapped round many times in black velvet cloth, and held in front of the space between the main electrodes of his powerful Wimshurst electrical machine, but not in the direct line of the discharge. He also exhibited photographic results obtained from the same arrangement with only the difference that the dark slide, wrapped in black velvet, was held in the direct line of the discharge. In this case the photographic result was due, perhaps wholly, and certainly in part, to electric sparks or brushes inside the enclosing box, which was, as usual, made of mahogany with metal hinges and interior metal mountings. It is not improbable that the results of the first experiment described by Lord Blythswood may also be wholly due to sparking within the wooden case. I have suggested to him to repeat his experiments with a thoroughly well closed aluminium box, instead of the ordinary photographic dark slide which he used, and without any black cloth wrapped round outside. The complete metallic enclosure will be a perfect guarantee against any sparks or brushes inside.

If the arrangement which I now suggest, with no sparks or brushes between AA and the roof, gives a satisfactory photographic result, or if it shows a visible glow on phosphorescent material placed anywhere in the space between AA and the roof above it, or above the aluminium roof, it would prove the truth of Röntgen's hypothesis. But failure to obtain any such results would not disprove this hypothesis. The electric action, even with the place of the spark so close to the field of the action sought for as it is at D, in the suggested arrangement, may not be sudden enough or violent enough to produce enough of longitudinal waves, or of condensational-rarefactional vibrations, to act sensibly on a photographic plate, or to produce a physical glow on a phosphorescent substance.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—At a Congregation held on Tuesday, the series of resolutions relating to the claims of women, the consideration of which was adjourned last week after the rejection of the proposal for admitting women to the B.A. degree, were discussed and rejected.

CAMBRIDGE.—Mr. Charles Davison, well-known for his researches on earthquakes and and other seismic phenomena, has been approved by the General Board of Studies for the degree of Doctor of Science.

The Isaac Newton Studentship in Astronomy and Physical Optics has been conferred on Mr. John Gaston Leathem, Scholar of St. John's College.

Dr. Joseph Griffiths has been appointed an additional Examiner in Surgery.

The Panjab University has, like the University of Calcutta and Allahabad, become affiliated to the University of Cambridge. Graduates in Arts of the Panjab are thereby exempted from the previous examinations, and may proceed to their degree by means of a Tripos Examination after two years' residence in Cambridge.

The Syndicate for the consideration of the question of degrees for women has been nominated, and consists of the Vice-Chancellor, Dr. Butler, Master of Trinity, Dr. Peile, Master of Christ's, Mr. Austen Leigh, Provost of King's, Prof. E. C Clark, Prof. Clifford Allbutt, F.R.S., Prof. Sidgwick, Dr. Jackson, Prof. Forsyth, F.R.S., Dr. Keynes, Prof. Armitage Robinson, Prof. Foster, F.R.S., Mr. R. T. Wright, Mr. W. L. Mollison, and Mr. R. A. Neil. Its appointment will be opposed on the ground that an excessive proportion of its members have already committed themselves to definite views on the questions at issue, and that only two members of less than twenty years' standing are included.

The Examination in Sanitary Science for the diploma in Public Health will begin on April 7, and will extend over ten days.

A conversazione will be held to-night in the Cavendish Laboratory, in commemoration of the opening of the new buildings. The President of the Cambridge Philosophical Society (Prof. J. J. Thomson) and Mrs. Thomson are the hosts.

THE hall which Mr. M'Ewan has added to the Edinburgh University buildings, at a cost of between £60,000 and £70,000, will be opened early in the ensuing summer.

THE University of Indianapolis has just been organised by representatives of Butler College, the Medical College of Indiana, the Indiana Dental College, and the Indiana Law School.

PRESIDENT JOHN M. COULTER, of Lake Forest University, has resigned in order to accept the head Professorship of Botany in the University of Chicago, which has been endowed with 1,000,000 dollars in its Botanical Department.

THE following are among recent appointments:—Dr. Christopher Childs to be Assistant in the Hygienic Department at University College, London, under the direction of Prof. Corfield; Dr. Allan MacFadyen to act as hon. secretary of the British Institute of Preventive Medicine; M. Salih Zéky to be Director of the Observatoire Impérial Météorologique et Séismique at Constantinople, in succession to the late M. A. Coumbary; Dr. W. Kurchinski, of Kieff, to be appointed Extraordinary Professor of Physiology at Turieff (Dorpat).

THE Executive Committee of the City and Guilds of London Institute have awarded the second Salters' Company's Research Fellowship, for the encouragement of higher research in chemistry in its relation to manufactures, to Dr. Sidney Williamson, who was for two years a student at the City and Guilds Technical College, Finsbury, and subsequently for three years at the City and Guilds Central Technical College. The Fellowship is tenable at the latter, and Dr. Williamson proposes to work on some questions bearing on food-stuffs generally, more particularly the examination of some definite albumenoids, with the ultimate object of ascertaining the influence of various manures on the growth of crops in so far as *quality* of produce is concerned.

THE Middlesex County Council have voted the sum of £10,785 for the purpose of technical education classes in the county during the current year. This is a slight increase on the amount appropriated during 1895, but since the available amount exceeds twenty-two thousand pounds, there still remains a large surplus which ought to be devoted to its proper purpose. The explanation of the unwillingness of the Council to benefit education in their midst to the fullest possible extent may be found, perhaps, in the falling off in the number of candidates for county scholarships. This diminution is most marked. For the fifteen scholarships of £20 each for three years for boys, there were 100 candidates fewer than in 1893, in which year the scholarships were first offered. The decrease in the number of competitors has been gradual. In 1894 the number was 220, in 1895 it had fallen to 184, and it is less again this year. As there are at least 80,000 children in elementary schools in Middlesex, the number of candidates ought certainly to be much larger.

The Report of the Director of Technical Instruction to the County Council for the County Palatine of Lancaster for the year ending August 31, 1895, which was presented to the Council at a meeting held on the 6th ultimo, contains many interesting statistics of the work which is being accomplished in Lancashire. The work in many departments is pre-eminently satisfactory. We are glad to notice that the Committee have made a grant of £250 to each of the University Colleges of Liverpool and Manchester, for we believe that one of the surest ways of improving the education of any county is to strengthen the centres of higher instruction within its borders. It is certainly one of the weaknesses of the Lancashire scheme for technical education that they give no assistance to secondary schools in their county. The middle classes are as much in need of all kinds of education as any section of the community, and though in Lancashire the following annual grants can be afforded—viz. horology, £500; plumbing and sanitary science, £750; horticulture and bee-keeping, £500; practical agriculture (including veterinary science, poultry-keeping, and allied subjects), £1000; as well as grants to encourage the study of music, yet for the development of the modern side of their secondary schools nothing is allowed. It is interesting to compare the decision of the Lancashire Committee with the recommendation of the recent Commission, "that this grant . . . ought to be all of it paid in future to the local authorities for secondary education . . . not merely to technical education,

but to secondary education generally." The work completed during the past year on the County Council Farm at Hutton has been very successful, both as regards the instruction given and the amount of research work carried out. It seems rather anomalous that while Preston devotes no part of its share of the Customs and Excise Fund to the purposes of education, yet, as the report shows, the County Committee make a grant of £650 a year to the Harris Institute in that town. Surely the borough authority will not abstain much longer from following so good an example.

We learn from the February number of the *London Technical Education Gazette*, that seventeen secondary schools in different parts of the metropolis have been aided by grants from the Technical Education Board of the London County Council. These grants have been very useful in encouraging the establishment of laboratories and science lecture-rooms in schools which have hitherto been without these advantages, and in improving the equipment and teaching in schools in which practical science has been taught. We notice with much satisfaction that in a large number of these schools physical laboratories have been provided, and that every facility is being given for the study of practical physics as well as chemistry. Too much stress cannot be laid upon the incompleteness of that practical science teaching which confines the student's attention to elementary qualitative analysis, and we note that it has been already found that "the influence of the Board's grants is as much apparent in the character of the teaching given in the several schools as in the appliances available for such teaching." The old method of teaching practical chemistry is giving place "to a more rational system, in which the laboratory and the lecture-room are brought into close relation, and in which the importance of measurement is insisted upon as the basis of all scientific work." Two at least of the schools receiving aid are for girls. A laboratory and lecture-room in James Allen's Girls' School, Dulwich, and a laboratory for practical science and school of domestic economy at the Camden School for Girls, have been equipped at the cost of the Board. The London Committee are, in this matter, as in so many others, setting the country local authorities an example which we hope soon to see emulated. The development following upon these grants can be seen at a glance from the statistics collected by the Board's science inspector, and published in these columns on February 13 (p. 357).

The cost of the new technical school at Salford, which is to be shortly opened by the Duke and Duchess of York, is likely to amount to £70,000. This amount is in excess of the anticipated cost, and the original loan of £55,000, sanctioned by the Local Government Board, is to be augmented by a further one of £13,500. Even then the difficulty of the expenses of maintenance will have to be faced. The experiences of the Salford Committee show only too plainly the necessity for legislation to prevent the appropriation of accumulated funds from the technical education grants of former years for ordinary purposes in the district. The Technical Instruction Committee of Salford had up to March 1894, been holding in reserve moneys received under the Local Taxation (Customs and Excise) Act of 1890, but the corporation becoming involved in financial difficulties, laid hands on these moneys, which amounted to £12,000. It is now left to the Committee to meet a heavy annual expenditure out of their revenue from the rate of a penny in the pound, the fees, grants, and other sources of income.

As a supplement to last week's account of what has been done for the support of education by some of the London Livery Companies, it is interesting to note the efforts in the direction of (probably) the only surviving provincial Company of the same type—the Master, Wardens, and Commonalty of Merchant Venturers of the City of Bristol. The supreme importance, for a commercial and manufacturing people, of what is now known as "technical instruction" seems to have been realised in Bristol earlier than in most other parts of England; for as long ago as 1856 there was founded in that city the Bristol Diocesan Trade School (afterwards called the Bristol Trade and Mining School), for the express purpose of providing sound and systematic education for the industrial classes. The school, being appreciated by those for whom it was intended, soon acquired a more than local reputation, and steadily grew in numbers, up to the limit which its buildings and its finances imposed. In 1880, when this limit had been reached, it happened that the Merchant Venturers—whose work of creating, and governing for centuries, the port of Bristol was then accomplished—resolved to devote their energies for the future to the furtherance of education; and, seeing the position of the Trade and Mining School, and the great value of the kind of teaching which it supplied, agreed to adopt it. Accordingly, at an outlay of some £45,000, they provided it with new buildings, upon a larger site, and with a more complete equipment; they also undertook to maintain it and develop it upon existing lines; and they gave it their own name. The Merchant Venturers' Technical College, as it is now called, has a junior department, a senior department, and a multitude of evening continuation classes; so that any boy, or young woman, destined for an industrial occupation of whatever kind—whether as architect, engineer, designer, chemist, dressmaker, or the like—may both begin and finish his or her entire education within its walls. The total number of students now exceeds 2000. In keeping with the special object of the institution, its curriculum is limited to comparatively few of the main branches of knowledge, and necessarily leaves out many of the most important. It hardly touches, for instance, the fascinating realm of literature, ancient and modern, or the subjects of music, medicine and law; and it ignores altogether the whole range of the mental and moral sciences. But ample provision for the teaching of all these exists, or can be made, in the other schools and colleges which Bristol is so fortunate as to possess, and thus the Merchant Venturers are enabled to occupy, with undivided attention, their own restricted field of operations, and to carry out, with ever-increasing thoroughness, their scheme of industrial or technical education sketched out forty years ago. Not a term passes without some addition to the apparatus with which their College is equipped, and hardly a session without provision for some newly-recruited trade or class; and it is an open secret that, as soon as the necessary land can be acquired, the extent of the buildings, and the convenience and efficiency of every department, will be very largely increased. It may well be supposed that no effort will be spared to enable the College to keep the lead, which it has hitherto held, in matters pertaining to technical instruction, or to ensure that, in this respect, it shall remain without a successful rival in the West of England. The Merchant Venturers, like their brethren in London, have a position to justify, a character to maintain, a distinguished past which they must not disgrace; and it is likely that, in the new work to which they have set their hands, they will evince the same activity and perseverance, and the same prudent liberality in furnishing means for the attainment of their ends, as characterised them in olden times, when their ventures were mostly for their own private gain, rather than, as now, for that of the community.

SCIENTIFIC SERIALS.

American Journal of Science, February.—Researches in acoustics, by A. M. Mayer. This paper, dealing with the variation of the modulus of elasticity with change of temperature, and the acoustic properties of aluminium, was read before the British Association at the Oxford meeting.—On the improbability of finding isolated shoals in the open sea by sailing over the geographical positions in which they are charted, by G. W. Littlehales. Suppose that A discovers, in the open ocean, a shoal r miles in radius, and determines the geographical position of its centre subject to extreme errors of m miles in longitude and n miles in latitude; and that B, who is able to establish his geographical position within the same limits of extreme error as A, attempts to find the shoal again by proceeding to the geographical position assigned to it by A, what is the probability that he will find it? The author works out this probability mathematically, and finds a general formula for it. If $r = 1$ mile, and m and $n = 10$ miles, B would stand one chance in 6173 of coming within two miles of the shoal. This shows that the reported non-existence of a charted shoal must be accepted with great care.—The counter-twisted curl aneroid, by Carl Barus. A curl aneroid, less than a metre long, provided with a mirror for registry, will indicate variations of atmospheric pressure of a thousandth of a millimetre of mercury, provided the mounting is sufficiently free from tremor, and the temperature is kept constant to a few thousandths of a degree during the interval of observation. The conditions are made much less severe if the coiled tube, after being twisted, is kept untwisted by a spiral spring. Effects of viscosity and rigidity may be thus compensated.

Wiedemann's Annalen der Physik und Chemie, No. 2.—Methods of determining dielectric constants, by W. Nernst. The author employs a bridge in which two branches are always equal; the third contains the dielectric trough, and the fourth a variable resistance and a variable capacity in parallel. Connecting two opposite terminals with a high-frequency induction coil, and the two others with a telephone, the latter is only silent when the resistance and the capacity in the fourth branch are equal to those of the dielectric in the third. An attempt to verify this by comparison with the electrometer method was foiled by the uncertainty of the latter.—A modification of the electrometer method, by J. F. Smale. This is based upon the attraction of a needle immersed in the dielectric by conductors kept at a constant potential. The conductors are two semi-ellipses nearly surrounding the flat needle of platinum, which is suspended by a quartz fibre. The deflection of the needle from its position of rest is proportional to the dielectric constant of the medium. A comparison with Nernst's method gave practically identical results.—An apparatus for varying self-induction, by Max Wien. This consists of a fixed and a movable coil. The fixed coil is subdivided into four, each of which can be placed in circuit, so that the self-induction can be abruptly changed. The interval between each abrupt change is filled up by moving the movable concentric coil about its diameter, by means of an arm travelling over a graduated circle. The range of the apparatus is very large, and self-inductions from 5×10^{3} to 10^{10} can be measured.—Refraction and reflection of electric waves by water and alcohol, by A. D. Cole. For waves 300 to 600 cm. long, water has an index of refraction of 8·95, alcohol 5·20. Calculated by Fresnel's formula from the reflection of polarised rays, the refractive indices for wave-lengths of 5 cm. come out as 8·8 for water, and 3·2 for alcohol; so that alcohol shows a remarkably higher refraction for long than for shorter waves.—Lowest temperatures and the liquefaction of gases, by C. Linde. Air is liquefied exclusively by the action of its own expansion, each portion of the expanded air being conducted past the next expanding proportion, and cooling it down to a lower temperature. The apparatus is almost identical with that recently described by Prof. Dewar, but the author claims priority.—The wave siren, by Rudolph König. This paper contains the results of a minute and careful investigation of the behaviour of the air current in a wave-siren. The air is blown through a slit, which is lengthened or shortened by the curved edge of a plate rotating in front of it. Any tone is thus directly reproduced from its wave-form. The air current remains sharply defined to a distance of about 1 cm. from the slit, and the wave-plate need therefore not be mounted very close to it. There is no accumulation of air by the closed portions of the slit leading to irregularities in the tone, and the vortex effects at the edges are without any influence upon the tone. The loudness of the sound produced by a simple sine curve increases with the width of the slit, reaching a maximum where the width is half the wave-length. Most vowels can be correctly reproduced from their known wave-forms.

Bollettino della Società Sismologica Italiana, vol. i., 1896, No. 9.—Review of the principal eruptive phenomena in Sicily and the adjoining islands during the four months, May-August, 1895, by S. Arcidiacono.—Notices of Italian earthquakes (July-August, 1895), by M. Barratta, the more important being those of the Comacchio earthquake of July 30, and part of those of the Adriatic earthquake of August 8.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 30.—"On the Rhythmic Contractility of the Spleen." By E. A. Schäfer, F.R.S., and B. Moore.

The authors have investigated the rhythmic contractility of the spleen, which was discovered by Roy (*Journ. Physiol.*, vol. iii.), and the influence of nerves, drugs, and animal extracts upon it. For this purpose the changes in its volume have been studied by aid of a specially constructed plethysmograph, so arranged as to afford the least possible obstruction to the blood-vessels entering and leaving the hilum. Under these circumstances, the spleen exhibits evidence of responding immediately by alterations in volume to every alteration in blood pressure, respiratory and cardiac, and *à fortiori* to such greater changes as are produced by compression of the aorta (contrary to Roy). This is even manifest when the organ is left connected with the rest of the vascular system by one artery and vein only. The conclusion which Roy arrived at, that the spleen is practically cut off from the arterial system, and that its circulation is maintained by its own contractions, is thus shown to be incorrect.

The rhythmic contractions are independent of the central nervous system.

They are excited to increased activity by intravenous injection of certain drugs and animal extracts which act specifically upon the organ. Indifferent fluids, such as normal salt solution, produce in moderate quantity no such effects (contrary to Roy).

Dyspnœa causes marked contraction of the spleen. This contraction is of central origin, for after severance of all nerves to the organ it is replaced by a passive dilatation, due to the rise of general blood pressure, followed by an increase in extent of the rhythmic contractions. Temporary cessation of the blood flow through the organ also has the effect of increasing their extent, probably because the splenic tissue is thereby deprived of oxygen.

The splanchnics contain not only nerve fibres which produce contraction of the spleen, but also others which cause dilatation.

There is no evidence that the vagi contain any centrifugal fibres which influence the volume of the spleen (contrary to Roy). Provided their inhibitory action upon the heart is neutralised by atropine, even the strongest stimulation of the peripheral end of either cut vagus produces no direct effect upon the spleen.

There is evidence of the existence of numerous afferent (sensory) fibres in the nerves supplying the spleen.

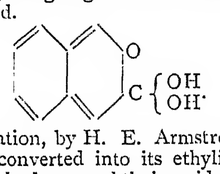
Entomological Society, February 19.—Prof. Raphael Meldola, F.R.S., President, in the chair.—Dr. D. Sharp, F.R.S., exhibited preparations of *Dytiscus latissimus* and *Cybister roeselii*, to show the so-called secondary wing, noticed by Meinert. He stated that this structure is only a part of the elytron, to which it is extensively attached, and that he considered that it corresponded with the angle at the base of the wing seen in so many insects that fold their front wing against the body. He could not consider that this structure afforded any support to the view that the elytra of beetles correspond with the tegulæ of Hymenoptera rather than with the front wings. He also exhibited specimens of Neuroptera, and pointed out that this secondary wing agreed in position and structure with a small lobe on the front wing of Raphidia. Mr. McLachlan, Prof. Meldola, and Mr. Gahan made some remarks on the subject.—Mr. C. G. Barrett exhibited, for Dr. H. G. Knaggs, cells of *Retinia resinana* formed of resin but lined with wax. A portion of the cell had been removed and the resin dissolved away with spirit, leaving a slight film of wax. Mr. Tutt stated that a secretion of wax had been detected by Dr. Chapman in *Parnassius apollo*. Prof. Meldola suggested that as Dr. Knaggs had shown how to separate the resin from the wax, it would be of interest to make a chemical investigation of the latter, since a sufficient supply of this material could easily be obtained. No insect wax, with the exception of that of the bee, had been submitted to investigation by chemists. Mr. Hampson and Mr. Blandford continued the discussion.—Mr. Gahan exhibited drawings of the dorsal segments of the abdomen of *Dyscritina longisetosa*, formerly described by Prof. Westwood in *Trans. Ent. Soc.*, 1881, a specimen of which was shown by Mr. E. E. Green at the last meeting of the Society. He regretted that no drawing, showing the ventral service, had yet been prepared.—Mr. B. A. Bower exhibited specimens of *Argyresthia atmoriella*, Bankes, taken in Kent, in June 1894, a recent addition to British Lepidoptera.—Mr. Green read notes on the habits of the Indian ant, *Œcophylla smaragdina*, Fabr. He said he believed that at some previous meeting of the Society, Mr. Ridley, of the Singapore Museum, made some remarks on this ant and its supposed habit of using its own larvæ as web-spinners in the formation of its nest, but he had not been able to find anything on the subject in the *Proceedings*. Mr. Green stated that he was now able to produce corroborative evidence from an independent source. The facts were noted by his friend Mr. W. D. Holland, of Balangoda, Ceylon, a most careful observer. Mr. Green exhibited the specimens referred to by Mr. Holland, and pointed out that the larvæ were still tightly grasped by the jaws of the ants, and he thought it probable that other web-spinning ants utilised their larvæ in the same way. Mr. Hampson said he could confirm this statement.—Mr. G. F. Scott-Elliot read a paper entitled "Notes on Flower-Haunting Diptera." The author pointed out that some of the higher types of Diptera

appeared to prefer red and blue flowers, and more often visited the complicated types of plants than the smaller Hymenoptera. He also alluded to the effect of insect visitors in isolating particular individuals. Prof. Meldola stated that although he was aware, from the writings of Hermann Müller and others, that Diptera played an important part in the fertilisation of flowers, he was unaware of the very great importance which these insects possessed for the function of pollination until he heard Mr. Scott-Elliot's paper. He also called attention to the urgent need of a manual of British Diptera. Mr. R. Trimen, F.R.S., mentioned that in South Africa some species of Orchidaceæ were fertilised by Diptera. Dr. Sharp said Prof. Plateau thought that neither the colour nor form of the flower played any part in attracting insects. Mr. McLachlan remarked that the flowers of Scrophularia possessed a great attraction for wasps. Lord Walsingham, F.R.S., inquired whether any observation had been made as to the Diptera which visited differently coloured flowers of the same species, such as Petunias. Mr. Barrett, Mr. Green, and Mr. Scott-Elliot continued the discussion.—Mr. Tutt read a paper, by Prof. A. Radcliffe-Grote, entitled "On the Nomenclature of the Geometridæ."—A discussion on the rules of nomenclature followed, in which Lord Walsingham, Prof. Meldola, Mr. Hampson, and Herr Jacoby took part.

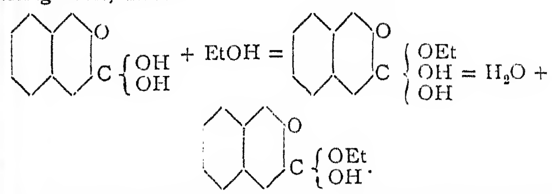
Royal Meteorological Society, February 19.—Mr. Edward Mawley, President, in the chair.—The report on the phenological observations for 1895 was presented by Mr. Mawley, in which it was shown that, owing to the great frost at the beginning of the year, all the first spring flowers made their appearance very late; and it was not until the middle of June that plants began to come into blossom in advance of their usual time. During July the dates recorded were, as a rule, exceptionally early. The yield of all the farm crops, except potatoes, was exceedingly poor. Pears and plums yielded badly, but there was a splendid crop of apples, and also of all the small fruits. As regards vegetation generally, seldom has a year ended under conditions as favourable for the one succeeding it.—Mr. R. H. Scott, F.R.S., read a paper on the recent unusually high barometer readings in the British Isles, in which he stated that the Daily Weather Chart for 6 p.m. on January 8, was the first in these islands that ever showed 31 inches. The station was Stornoway, and by the next morning all over the northern portions of Great Britain and Ireland the barometers were above 31 inches. The highest reading of all was 31·119 inches, photographically recorded at Glasgow at 9 a.m. on the 9th. The barometric pressure then gave way, and the region of highest readings moved southwards along our west coast, and finally left the south of Ireland on the 15th. Weather throughout the period was mild, an unusual thing with a very high barometer. At the end of the month a second anticyclone spread over the country, when the barometer rose to 30·96 inches at Cork. Reference was made to previous excessively high barometer readings in England and in Siberia, and it was stated that a reading of 31·62 inches at Barnaoul in Siberia, in 1877, was probably the highest ever observed.—Mr. R. Inwards read a paper on Turner's representations of lightning, which he considered to be true to nature, and demonstrated the same by placing an actual example of Turner's work side by side with a photograph of a real flash of lightning.

Linnean Society, February 20.—Mr. C. B. Clarke, F.R.S., President, in the chair.—Mr. Clement Reid exhibited a collection of acorns planted by rooks, and made remarks upon the agency of these and other birds in the dispersal of seeds. A discussion followed, in which the President and Messrs. Cole, Druery, Harting, and Kirby took part.—Mr. Bernard Arnold exhibited and made remarks upon an abnormal growth of *Dactylis glomerata*, Linn., gathered at Shorne, near Gravesend, criticisms being offered by Messrs. B. Daydon Jackson and H. Groves.—Mr. W. H. Lang exhibited under the microscope some prothalli of several varieties of *Nephrodium Filix-mas*. These illustrated the apogamous production of the sporophyte which has been described in this species by De Bary and Kny. Dr. D. H. Scott and Mr. C. T. Druery took part in the discussion which followed.—On behalf of Mr. John Young there was exhibited an unprecedented case of hybridism between *Carduelis spinus* and *Linota cannabina*, the formerbeing the male parent. Some remarks were made on the subject by Mr. Harting, who took occasion to exhibit, on behalf of Captain M. Murphy, another hybrid, viz. one between black grouse and pheasant, which had been shot near Bunessan, Mull, in the month of January last.—On behalf of Mr. E. J. Lowe, F.R.S., a paper was read by Mr. Druery in which details were given regarding the culture of divided and redivided prothalli of *Scolopendrium vulgare*. Apart from the fact that by such subdivision and the consequent separation of parts bearing archegonia and antheridia, the oophoric stage of fern life was maintained for a number of years without the sporophoric generation appearing; the ultimate results, when fertilisation eventually took place, were very remarkable. In numerous instances several marginal plants appeared on the same prothallus of presumably the parental type; but single plants originating from the centre of each prothallus were, though of varying character, all distinguished by bearing prothalli upon their edges or terminal points, such prothalli developing root-hairs, archegonia and antheridiæ, although the young plants had formed a distinct axis of growth and thrown up a circle of such aposporous fronds. The paper embodied also the observations of Mr. C. T. Druery, Prof. F. O. Bower, Prof. Farmer, Dr. Scott, and Mr. Lang on material sent to them, and one of the plants in question, clearly showing the aposporous growths, was exhibited by Mr. Druery in illustration. A discussion followed, in which Dr. Scott, Mr. Lang, and Mr. Druery remarked upon the interesting nature of these and similar breaches of the law of alternation of generations in the Archegoniatæ.

Chemical Society, February 20.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read:—The origin of colour, No. XI. The yellow colour of 2:3-hydroxynaphthoic acid, by H. E. Armstrong. The yellow colour possessed by this naphthoic acid and its salts may be readily explained by assigning to it an orthoquinonoid structure of the following kind.



—Note on etherification, by H. E. Armstrong. 2:3-hydroxynaphthoic acid is converted into its ethylic salt more readily than the isomeric α-hydroxynaphthoic acid; an acid having the constitution indicated above should readily combine with alcohol yielding a substance which could easily give the ethylic salt by losing water, thus:—



—The relation of pinene to citrene, by H. E. Armstrong.—The conditions involved in the occurrence of inversion in the case of asymmetric (optically active) compounds, by H. E. Armstrong. The remarkable conversion of dextro- or lævo-malic acid into its optical antipodes is possibly due to the formation of a chlorophosphonium compound, which is then acted on by hydrogen chloride giving chlorosuccinic acid and phosphorus oxychloride. The production of naphthalene and of isoquinoline derivatives from dehydracetic acid, by J. N. Collie and N. T. M. Wilsmore. The yellow condensation product obtained from diacetylacetone is a benzene derivative, and condenses with ammonia, giving two isoquinoline bases.—Note on a difficulty encountered in the determination of nitrogen by the absolute method, by W. R. Dunstan and F. H. Carr. Very high values are obtained on determining the nitrogen in aconitine by the absolute method; this is shown to be due to the formation of methane during the combustion. Experiments with mixtures of methane and nitrogen show that the hydrocarbon in the diluted state is only burnt with great difficulty by red-hot copper oxide. —Mixed diazoamides containing an orthonitro-group, by R. Meldola and F. W. Streatfeild.—Allyl-p-dinitrodiazoamidobenzene: a study of the relations between melting-point and constitution, by R. Meldola and F. W. Streatfeild.

Edinburgh.

Royal Society, February 17.—Prof. Copeland in the chair. —Prof. John G. M'Kendrick made five communications. He first described the case of a boy, four and a half years old, who showed a remarkable appreciation of pitch, being able at once to

name any note struck on a piano. Then followed a demonstration of the acoustic turbine of Dvoràk and Mayer, and of a flame so sensitive that it was affected by the ticking of a watch. Next, Prof. M'Kendrick exhibited Graham's method of producing a musical tone in a circuit containing a variable resistance apparatus and a telephone. The sound emitted was like that of a cornet or flute. Finally, Prof. M'Kendrick made some further observations on the phonograph. He described apparatus by which the sounds could be magnified, and detailed his methods of studying the curves on the wax cylinder, of which he exhibited photographs. He showed that each note and sound had its characteristic curve, and, to show it, spoke the words "Arrubnidē fo Eetisrevenū" into a machine moving backwards, and the meeting was considerably startled to hear, on the instrument being turned in the proper direction, the words coming out "University of Edinburgh."

Cambridge.

Philosophical Society, February 10.—Prof. J. J. Thomson, President, in the chair.—Exhibition of a method of measuring osmosis at atmospheric pressure, by Dr. Lazarus-Barlow.—Exhibition of specimens showing the communication between the peritoneal cavity and renal veins through the nephrostomial tubules in the frog, by E. J. Bles.—On the effect of currents on the assimilation of water-plants, by F. Darwin and D. F. M. Pertz. The amount of gas given off by water-plants under the influence of light is markedly increased by continuously stirring the water. This holds good in the case of Elodea, but only under certain circumstances with Potamogeton. That form of gas-evolution which continues in darkness, owing to the gas-pressure in the water, is also increased by disturbing the water. The authors described simple methods of showing the effect of barometric pressure and of surface tension on the yield of gas.—On a collection of plants from New Britain (*Neu Pommern*), by I. H. Burkill. This collection was brought home by Baron A. von Hügel, having been made in the neighbourhood of Blanche Bay. There are in it a number of species not hitherto known as natives of New Britain; among them a new *Eranthemum* described as *E. Huegelii*. The name *Alpinia oceanica* is suggested for a plant described by Prof. K. Schumann as *A. nutans*: this being also held as possibly not identical with Rumphius' *Globba sylvestris minor*. The total number of species known from New Britain is still small, two-thirds of them having been found in German New Guinea, and about one-half in the Fiji Isles.

Paris.

Academy of Sciences, March 2.—M. A Cornu in the chair.—On the divergence of the series used in astronomy, by M. H. Poincaré. The results obtained by M. Hill are shown to be in agreement with those previously obtained by the author, the contradiction being only apparent.—Observations on the subject of photography through opaque bodies, by M. A. d'Arsonval. In reviewing the work of M. G. Le Bon and his critics, it is shown that their results are not necessarily contradictory. The solar rays do not appear to penetrate a thin plate of metal, even of aluminium; if a plate of glass, however, especially a fluorescent glass, be placed above the metal screen, the photographic plate is affected.—On the invisible radiations emitted by phosphorescent bodies, by M. Henri Becquerel. The light emitted by crystals of uranyl-potassium sulphate, $K(UO).SO_4 + H_2O$, can pass both through thin sheets of metal and also through black paper. This effect was first shown by covering a sensitive film with a metal screen, placing some crystals of the double sulphate on this, and then exposing to sunlight. But it was afterwards found that the crystals exerted the same photographic effect in the dark, a phenomenon which can hardly be attributed to phosphorescence, since $\frac{1}{100}$th of a second after exposure to light, these radiations are no longer visible (see p. 445).—The relation between the energy of muscular work and albuminoids in food, by MM. A. Chauveau and C. Contejean. The albuminoids in food are not directly concerned with the production of muscular energy, since the amount of nitrogen excreted in the urine is independent of the work done by the animal.—Observations on the Comet Perrine (1895 *c*), made at the Observatory of Toulouse with the Brunner equatorial, by M. F. Rossard.—On a means of recognising small variations in the rate of astronomical clocks, by M. G. Bigourdan. The use of a free pendulum, working in a vacuum at a constant temperature, is suggested.—On groups of operations, by M. Levavasseur.—Reply to the observations of M. H. Poincaré on the theory of the kathode rays, by M. G. Jaumann.—Observations on the subject of the preceding communication, by M. H. Poincaré. Presentation of prints obtained by M. Röntgen's method, by M. Londe.—Dark light, a reply to some criticisms, by M. Gustave Le Bon.—Diffusion of the Röntgen rays, by MM. A. Imbert and H. Bertin Sans. The experiments show that if the rays are regularly reflected, it must be only to a very small extent; they can, however, be readily diffused, and the diffusion appears to depend rather on the nature than on the condition of the surface of the diffusing body.—On the photographic representation of a medal obtained by the Röntgen rays, by M. J. Carpentier.—On the passage of the Röntgen rays through liquids, by MM. Bleunard and Labesse. Water, either coloured or not, and solutions of borax and potassium permanganate are transparent to the rays. Solutions of potassium bromide, antimony chloride, and potassium bichromate, on the other hand, are not so transparent.—Discovery and extraction of a needle embedded in the hand by means of the Röntgen rays, by M. P. Delbet.—Applications of the method of Röntgen, by MM. C. Girard and F. Bordas.—Extraction of rhodinol from the essence of pelargonium and from essence of roses; identity of these two alcohols, by MM. P. Barbier and L. Bouveault.—On the preparation of silicochloroform, silicobromoform, and on some derivatives of triphenyl-silicoprotane, by M. C. Combes. Silicide of copper, prepared in the electric furnace, and containing 20 per cent. of silicon, is heated in a current of dry HCl to the boiling point of diphenylamine. The liquid obtained consists of silicochloroform (80 per cent.) and silicon tetrachloride (20 per cent.), readily separated by fractional distillation. In this way there is no difficulty in preparing 1 kilo. of silicochloroform at one operation.—Oxidation of crotonic aldehyde, by M. E. Charon. By careful oxidation with silver oxide only one crotonic acid is produced.—The elements of the retina vibrate transversely, by M. A. Charpentier.—On functional assimilation, by M. F. Le Dantec.—A new function of the tubes of Malpighi, by M. V. Mayet.—Some diseases of the potato, by M. E. Roze.—The Hypostomaceæ, a new family of parasitic fungi, by M. Paul Vuillemin. A description of two new parasitic fungi discovered in the needles of Conifers.—On the inversion of the folds on the two sides of the Atlas of Blida (Algeria), by M. E. Ficheur.—On the secondary layers of the provinces of Murcie, Almeria, Grenada, and Alicante (Spain), by M. R. Nicklès.—The Observatory of Mount Argoual (Gard), by M. G. Fabre.

Philadelphia.

Academy of Natural Sciences, February 18.—A paper entitled as follows was presented for publication, "Contributions to the Life-history of Plants, No xii.," by Thomas Meehan. (1) Fecundity of Heliophytum Indicum; (2) origin of the forms of flowers; (3) spines on the Citrus family; (4) flowers and flowering of *Lanium purpureum*; (5) cleistogamy in Umbelliferæ; (6) rhythmic growth in plants; (7) pellucid dots on some species of Hypericum; (8) honey glands of flowers; (9) varying phyllotaxis in the elm; (10) special features in a study of *Cornus stolonifera*; (11) Folial origin of cauline structures; (12) polarity in the leaves of the Compass and other plants; (13) hybrids in nature; (14) origin and nature of plant glands; (15) nutrition as affecting the forms of plants and their floral organs; (16) some neglected studies.—Mr. D. S. Holman exhibited a new stage for the microscope devised for the purpose of studying large objects and widely-spread preparations. It can be adapted to all instruments provided with square stages, and has a motion of two inches each way.—Preparations of minerals containing diatoms in transverse section, and other microscopic arrangements of diatoms prepared by Mr. John A. Schulze, were exhibited by Mr. F. J. Keeley.—Prof. Edw. D. Cope described specimens of fossil reptilia from the Permian and Trias. They belonged to the order Cotylosauria, which had been described by him in 1879, and was afterwards characterised by Seeley from African types. The order embraces the families Elginiidæ, Pariasauridæ, Pariotichidæ, the distribution and characters of which were dwelt on. New genera of Diadectidæ were described under the names Bolbodon and Diatomodon, the teeth of which, as well as of the other genera of the family, were illustrated. The Platodontia may have been derived from the Diadectidæ. The roof over the temporal fossa and the foramen for the temporal eye were illustrated by specimens. The molar teeth of a species of Empedias, the cranium of *Bolbodon tenuitectis*, and the lower jaw of Diatomodon were

exhibited. Another form, described under the name *Conodectes favosus*, may belong to the Diadectidæ, but its relationships are at present uncertain.

Göttingen.

Royal Society of Sciences.—In the *Nachrichten*, No. 4, 1895 (mathematico-physical section) the following memoirs communicated to the Society are published.

October 19.—J. Orth: Report on the work done in the Göttingen Pathological Institute in the summer half-year 1895.

November 16.—W. Schur: Further communications on the results of pendulum-observations in or near Göttingen.

November 30.—Georg Landsberg: Foundations of the arithmetical theory of the algebraic functions of one variable.—Eduard Riecke: The quantities of electricity concerned in a lightning-flash (43 to 98 coulombs).

DIARY OF SOCIETIES.

London.

THURSDAY, March 12.

Royal Society, at 4.30.—The Croonian Lecture: Observations upon Isolated Nerve: Electrical Changes a Measure of Physico-chemical Change: Dr. A. D. Waller, F.R.S.

Mathematical Society, at 8.—On the Enumeration of Groups of Totitives: Prof. Lloyd Tanner.—(1) The Catenary on the Paraboloid and Cone; (2) The Motion of the Top: Prof. Greenhill, F.R.S.

Institution of Electrical Engineers, at 8.—High-Voltage Lamps and their Influence on Central Station Practice: G. L. Addenbrooke.

Society of Antiquaries, at 8.30.

Camera Club, at 8.15.—Lord Armstrong's Experiments in Electric Discharge: Dr. Bowles.

FRIDAY, March 13.

Royal Astronomical Society, at 8.—Observations of the Variable Star R Carinæ, December 1890 to August 1895: J. Tebbutt.—Discovery and Observations of Comet Brooks (*d* 1895); W. R. Brooks.—Observations of the Variable Stars W. X, and Y Sagittarii: Lieut.-Colonel Markwick.—Elliptical Orbit Elements of Comet 1894 *b* (Gale): Rev. T. THE PHYSIOLOGY OF THE EXCITABLE TISSUES.

Elektro-physiologie. Von W. Biedermann, Professor der Physiologie in Jena. Zweite Abtheilung. Mit 285 Abbildungen. Pp. 441 to 857. (Jena: Fischer, 1895.)

THE second volume of Prof. Biedermann's work, now before us, fully maintains the reputation of its author, and is, if anything, still more interesting than the preceding volume dealing with muscle.

This additional interest, though due in some measure to the subject-matter, embracing, as this does, the fundamental excitatory phenomena of nerve, the functional activity of electrical organs of fishes, and the electromotive phenomena of plant and glandular structures, is aroused and maintained by the evident drift of the writer towards a full expression of those views which he is known to share with Prof. Hering, and which the present volume affords him an opportunity of enunciating.

Such an exposition of the mental attitude of the present occupant of the Leipzig chair of Physiology (Prof. Hering), in regard to the play of those vital processes whose physical manifestations are the objects of the physiologist's investigation, is of the highest importance, since it is well known that the influence of this conception upon the physiological science of to-day is as great as was that of Hering's distinguished predecessor, Prof. Ludwig, on the science of a few years back.

The clear account here given of the two aspects of physiological change, association and dissociation, and their relation to the physical aspects of vital phenomena, is further increased in value by its setting. Placed at the end of the chapters on nerve, in that devoted to the theoretic views as to the electromotive phenomena of this structure, the author, adopting the historical method, leads up to Hering's theory through the earlier molecular theory of Du Bois Reymond and the very differently conceived theory of Pfluger, both of which rest upon a mechanical scheme as their basis, and the author then shows to what an extent the views of these two writers paved the way for that which he proceeds to present in Hering's words. Perhaps no more striking testimony to the universal character of the present acceptance of this latter view, could have been brought forward than the theory of Bernstein, the exposition of which follows that of Hering, since it brings into prominence the modifications in Hering's sense, which even such a staunch adherent of the molecular theory as the Hallé Professor has felt it necessary to elaborate.

The position here taken up by Prof. Biedermann is held by him to be the only one at present capable of embracing within its scope all the various phases of excitatory change, and its tenability is supported by an array of fundamental reaction phenomena, many of which have been ascertained by his own researches.

An interest of a very special kind is thus given to the description of the characters of the excitatory effects in nerves.

Such, for instance, is the experimental comparison between the circumstances which condition the excitatory effects produced on the opening of a galvanic current which has been led through a nerve. The initial, suddenly-developed, and comparatively short-lived muscular response to the opening nerve excitation (opening twitch) is shown to be essentially dependent upon a preceding constrained state of greater inexcitability (theoretically, *association*), and, as it is brought about by the removal of the constraining agent (the galvanic current), may be considered as a *dissociation* rebound from this condition. It is contrasted with a second more slowly developed and more lasting excitation, evoking in the muscle an opening tetanus, the essential productive factor of which is a preceding state of greater excitability (*dissociation*), a latent excitation now rendered kinetic in consequence of the slight additional dissociation effected by such a rebound. The play of different conditions upon the two effects is brought into prominence by the description of some most striking experiments, in which one is affected to the exclusion of the other by means of a special environment.

Such, again, is the description of the response evoked by nerve excitation in the muscles which respectively open and close the claw of the crayfish, a response which may be either the well-known contraction or a less familiar muscular relaxation (inhibition); experimental results which probably find their parallel in the well-known effects produced in cardiac muscle by excitation of the vagus nerve.

The excitatory electromotive changes localised to the neighbourhood of the poles when a galvanic current commences or ceases to flow through a nerve, the distinction between the vital reaction phenomena and the physical polarisation phenomena in special relation to the production of the extrapolar electrotonic currents, the specific reactions of etherised and of cooled nerves, the effect of different saline substances upon these reactions, are but a few of the many pertinent examples brought forward, the concise, clear statement of which renders the present volume such a valuable contribution to physiology.

It is perhaps to be regretted that the arrangement of subject-matter adopted by the author has involved the necessity of grouping such a large number of phenomena under the heading "Die elektrische Erregung der Nerven," with the result that this enormous chapter is 100 pages long. We venture to think that this portion might with advantage have been split into several subsidiary sections. A very large part of the present knowledge of nerve activity has been obtained by the use of electrical methods of excitation, and a vast amount of work has, in consequence, been carried out upon this aspect of the question. It is, therefore, an almost herculean task to set forth in unbroken continuity all the phenomena which fall within the scope of this title, and to do so without running the risk of making such narration wearisome to the reader, and annoying to the reference student who seeks information on one particular group of such phenomena. Prof. Biedermann has run this risk, and it cannot honestly be said that he has succeeded in avoiding the danger. As it stands at present, this chapter, although teeming with interesting details, because of this very fecundity, may not impossibly cause the reader to agree, during its perusal, with the remark

of Shakespeare's tinker listening to the play of *The Taming of the Shrew*:

> "'Tis a very excellent piece of work, madam lady,
> Would 't were done!"

We also venture to criticise the position which has been assigned by the author to the electromotive phenomena of plants. As a concise account of the present state of knowledge on the subject, this chapter is excellent; but we doubt if it is wise to place this apparently simple but really difficult branch of Electrophysiologie at the commencement of the volume. It is calculated to raise false hopes, and give the reader the impression that the phenomena in question form an easy prelude to those of nerve, which form the staple material of the work; and this, it need hardly be said, is by no means the case. The section on the electrical organ fitly follows that on the electromotive changes in nerve, and is an admirable one. If we are not mistaken, this portion occupies a unique position, since it is the first attempt to give a complete scientific account of the special functions of all known electrical organs. The excellence of the treatment is undoubtedly due to the evident necessity felt by the author to treat the subject *ab initio* from many points of view, yet to always tend towards one goal—that of explaining the nature of the specific electrical activity involved. To secure this, the section is far more amply illustrated than the others, and the illustrations themselves are extremely well chosen, whilst the hold upon the reader is strengthened by the description of the structure of the organ and of its nervous connections in the different fishes, and by the excellent woodcuts which portray the chief histological features.

It may be confidently asserted that no book has yet appeared, dealing with the fundamental phenomena of the excitable tissues, which can be compared with the volumes of Prof. Biedermann. The wealth of experimental data alone must stamp the work as one which for many years will be not merely read by advanced students, but consulted as a reference book, and it thus worthily takes its place in this highest rank of scientific treatises. It is with pleasure, therefore, that we anticipate its translation, in the belief that its appearance in an English dress will, by making it more accessible, confer a boon on all those in this country who take a special interest in physiology.

F. Gotch.

TAXATION.

Essays in Taxation. By E. R. A. Seligman, Columbia College, New York. Pp. 424. (London: Macmillan and Co., 1895.)

PROFESSOR SELIGMAN is one of the few economists that have influenced the politicians. The Tax Commission of Ohio made use of his book on "Shifting and Incidence of Taxation" (1892), and confessed they were not able to make full acknowledgment of the debt lest they should give their report too academic an appearance! ("Essays," p. 415.) Every one who reads Mr. Seligman's books will feel the reason of their influence; there is a firm grasp of principles; there is a close contact with facts; there is a constant testing of the one by the other.

The "Essays" were written in the first instance for Americans, and the illustrations are largely drawn from America. But the reasonings are of general application, and are more or less fully so applied. We need not dwell on the earlier part of Mr. Seligman's historical survey. Logic and experience, he thinks, conspire to show that not property, or even expenditure, but "income or revenue" is the best measure of ability to bear taxes (p. 18, *cf.* 21), and the world at large is slowly coming round to this conclusion.

> "To arrange a system of taxation which shall, on the whole, correspond as closely as possible to the net revenues of individuals and social classes, and which shall take into account the variations in tax-paying ability, has thus become the demand of modern civilisation" (pp. 21, 22).

It has taken a long time to sift out and reject the wrong systems, and, as we might expect, there is a singular correspondence between one nation and another in the progress through blunders. For example, the General Property Tax, condemned by theorists and confessedly unsuccessful on the other side of the Atlantic, is by no means peculiar to the United States. It was not a blunder at first, and only becomes so when perpetuated. It is that form of taxation which is suited to a society

> "where the only property is the collective indivisible property, where the landowner and capitalist are one. There is one kind of property, and therefore only one kind of property tax. But, as soon as property is split up into different parts, as soon as there are various kinds of property, just so soon does the single property tax become antiquated and useless. It is not only useless, but it is now absolutely iniquitous. For the attempt to include under one head the gains flowing from widely different pursuits . . . can end only in the virtual exemption of the new forms, and a consequent overburdening of the old" (p. 38).

In the Middle Ages it was for some time the prevailing tax, and was then quite fair because there was little differentiation of property (p. 46).

> "History everywhere teaches the same lesson. As soon as the idea of direct taxation has forced itself into recognition, it assumes the practical shape of the land tax. This soon develops into the general property tax which long remains the index of ability to pay. But, as soon as the mass of property splits up, the property tax becomes an anachronism" (p. 53),

and the property tax reverts to real estate. The property tax in the United States is therefore "not an American invention, but a relic of mediævalism." In our times all kinds of property are not equally productive; property is not a sure criterion of individual gains; and there remains the consideration of the individual's indebtedness, suggesting the need of taxing him not on his property, but on his clear assets (p. 60). The General Property Tax can be evaded by every one except a bank shareholder (pp. 147, 148). Practically, as now levied in the States, "it is one of the worst taxes known in the civilised world" (p. 61). Mr. Seligman has an English frankness in dealing with the faults of his native country.

The Single Tax (chap. iii.) on the land escapes no better. Our author rejects it both on theoretical and practical grounds; and he says all that needs to be said on the

matter, though this field has been often traversed, and there is less scope for his originality. He shows us

"that it would be inelastic, and that it would intensify the inequalities resulting from unjust assessments; that, although proposed chiefly from social considerations, it would prevent the Government from utilising the taxing power for other social purposes, and that it would divorce the interests of the people from those of the Government; that it would offend against the canons of universality and equality of taxation, and would seriously exaggerate the difference between profits from land and profits from other sources; and, finally, that it would be entirely inadequate in poor and new communities, that it would generally have an injurious influence on the farmer, and that even in the large urban centres it would exempt large sections of the population without bringing any substantial relief to the poorer classes" (p. 93).

We have in this book what the title of it leads us to expect—a series of detached essays, and not any connected series of arguments, growing one out of another like the chapters of a book. There is nothing but a play of words, for example, to make "Double Taxation" follow the "Single Tax," for single and double are not used in the same senses in the two cases described. Perhaps the most important discussion in the chapter on "Double Taxation" is that on the taxation of aliens. Seligman considers that the principle of economic interest should be the guide here. We should find out from what place an individual gets his income, and in what place he spends it. "Only in this way can his real economic interests be located" (p. 111). The question is even more difficult in the United States than here, for members of different States are financially foreigners, and even the relations of Scotch law to English law do not quite help us to understand the relations of (say) the laws of New York to those of California. In the case of the United States among themselves, seeing that there is no real political severance, it ought to be easy to accept "economic allegiance as against the antiquated political allegiance" (p. 110). But between the United States as one unit, and Canada as another, for example, a critic might observe that such a view will not so readily find acceptance.

After a short chapter on inheritance taxes, we come to the taxation of corporations, or, as we should say, companies. Mr. Seligman here, as elsewhere, makes very effective use of the Swiss Federation and its difficulties as a European parallel to the case of the United States (p. 248). On the subject generally, perhaps his most striking contention is that the bonds and loans of companies should be taxed as well as their stock and shares, since the bonds and stock together form the working capital of the company, from which the said company derives its income. He thinks that in the case of an individual, on the other hand, interest on debt must be deducted from income, or else there will be double taxation (pp. 214, 215, &c.). This is one of the few cases where he does not produce conviction. The conclusion would more naturally be that all money borrowed to carry on or extend business may be included in the borrower's capital, whether the said borrower be an individual or a company.

After these essays on particular taxes comes a "Classification of Public Revenues" (chapter ix.), which might have been better placed at the beginning of the book. It brings out the author's favourite distinction of fees from taxes. There is a good chapter on the "European literature" about taxation. The author's wide knowledge of it makes us surprised at his inacquaintance with Grote's remarks on Greek taxation (see p. 85, note).

English readers will find little to criticise in Prof. Seligman's account of the Betterment Tax (embodied in the Tower Bridge Act of 1895), and Sir William Harcourt's Finance Act of 1894. Surely, however, the Professor is wrong in supposing that we have no special assessments on landlords (p. 312). They are certainly under obligation to pay for the making of the roads in front of their property; and his description of "special assessments" fits their case exactly. Perhaps the distinction of these assessments from fees is less strongly marked than Mr. Seligman thinks; they are at least species of the same genus.

The language of the "Essays" is excellently suited to the subject, and there is no waste of it. It is just possible that love of antithesis is occasionally a snare to the writer.

"In the case of the private business the monopoly [monopolist?] seeks only the greatest possible profits; in the case of the public monopoly the Government seeks the greatest possible public utility" (p. 296).

If this were so, France would be proverbial for the excellence of her tobacco.

In a new edition perhaps the arrangement might be improved, and possibly the lesser book on "Shifting and Incidence" incorporated, so as to make the whole a connected treatise on taxation with more evident order and connection of parts. Till Mr. Seligman has done this for his book, it will not produce on the general public the impression to which its high merits entitle it.

OUR BOOK SHELF.

Handbuch der Mineralchemie. Von C. F. Rammelsberg. Zweites Ergänzungsheft zur Zweiten Auflage. Pp. 475. (Leipzig: Engelman, 1895.)

NO fewer than fifty-five years have passed since the author issued his "Dictionary of the Chemical Part of Mineralogy," and yet his energy is unabated. The present work is the second supplement to the second edition (1875) of his well-known "Handbuch der Mineralchemie," a treasury of condensed information relative to the results of the chemical analysis of minerals, and the supplement is a concise record of chemical work on minerals published during the last decade. As in the original treatise, the author restricts himself to the expression and criticism of observed facts, and avoids as far as is possible the discussion or even mention of constitutional formulæ. And for the purposes of the student it is doubtless convenient to have collected for him into a single treatise the observed solid facts upon which all speculation relative to the chemistry of minerals is to be based. Once more the mineralogical chemist is reminded how rarely the analysed material is truly pure, and how necessary it is to record its morphological and physical characters, the mode of its occurrence, and the nature of the accompanying minerals: it is only by regard to such records that the true composition of a mineral can in many cases be deduced. And the author points out how imperfect is our knowledge of the chemical composition of many of the commonest minerals notwith-

standing the number of analyses which have been recorded. In the case of the plagioclastic felspars, for example, though the results of many analyses are in close agreement with the hypothesis of the admixture of molecules of albite and anorthite, there are others which deviate considerably therefrom, and are as yet unexplained. The caution of our chemical Nestor is perhaps carried to an extreme. He declines, for instance, to recognise the interchangeability of F and HO, notwithstanding the results independently obtained of each other by Penfield and Sjögren in the case of the Humite group, and by the former in the case of Topaz, and attributes the variations of composition to alteration—to loss of fluorine and gain of water. But in the case of Topaz the angle of the optic axes has been shown to be related to the percentage of the fluorine, and it is difficult to regard the variation of chemical and optical characters to be a result of mere hydration. Every one will hope that the Berlin professor will be spared to issue a third supplement of this standard work of reference. L. F.

Elements of Botany. By J. Y. Bergen, A.M., Instructor in Biology, English High School, Boston. Pp. vi + 275 + 57. (Boston, U.S.A., and London: Ginn and Co., 1896.)

IT is very seldom that we have come across an elementary book on botany which has impressed us so favourably as the one now under review. It is intended primarily for school use, but the admirable method which is maintained throughout its pages ought to be practised in all grades of class work. A general account is given of the simple morphological and physiological phenomena of plant-life, and the student is encouraged to put the knowledge thus acquired in each section to a practical test. A selected object or experiment is indicated to him, and he is shown how to put his own questions. He is *not*, however, told the answer—that he has to find out for himself as the result of independent observation.

The work is well illustrated with more than 200 figures, and contains, besides, appendices on material and methods, a useful chapter of about fifty pages on the commoner orders and species of flowering plants inhabiting the northern and middle States.

Although the author has naturally paid special attention to the needs and opportunities of American students, his book ought to be well received in this country also, for most of the plants mentioned are readily obtainable here, and from an educational standpoint the book is quite one of the very best we have met with.

Geology. By C. L. Barnes, M.A., F.G.S. Pp. viii + 181. (London: Rivington, Percival, and Co.)

THIS is not a very remarkable addition to the already large number of easy books on geology. When we have said that the volume is readable, and a suitable one to put into the hands of beginners, we have uttered all that is demanded by the text. The illustrations are the least attractive features of the book; none of them are striking, and few, if any, of them are new. A fact to which attention may well be directed, is that the book does not follow any examination scheme.

The New Photography. By A. B. Chatwood. Pp. 128. (London: Downey and Co., 1896.)

THE "new photography" described in this book is not confined to work with Röntgen rays, but includes also accounts of colour photography, psychic photography (retinal impressions) spirit photography, and anaglyphs. The book is, to say the least, a trifle premature as regards work with Röntgen rays; and the title, as well as the shadow of the bones of a hand, printed upon the title-page, is misleading as to the contents.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Dr. Ball's Two Letters on the Ice Age.

SIR R. BALL'S last letter is a little embarrassing for those who have accepted his teaching. In it he claims that however faithless his other supporters may have proved, he can still rely on the countenance of Dr. Wallace. What does it all mean? Dr. Wallace is responsible for a theory of the Glacial period which has been before the world for many years, and which is entirely different both in essence and in its consequences from that proclaimed in "A Cause of the Ice Age." Are we to understand that Sir R. Ball has adopted Dr. Wallace's theory, or is it Dr. Wallace who has adopted Dr. Ball's? The differences between us are so important in view of modern geological conclusions, that I may be perhaps permitted to condense a few simple issues in a few questions. I could add more if necessary.

Sir R. Ball says he has not changed his views. Does he still then hold, as he once did, that astronomical causes alone will suffice to produce an Ice Age, or does he now hold with Croll and J. Geikie and Dr. Wallace that they will not, and must be supplemented by other causes?

Does he still maintain, as he maintained in the new edition of his book, the old-fashioned theory as to the laws of radiation, or does he believe in Stefan's law, which entirely alters the whole basis of the case, both as taught by himself and by Croll?

Does he still maintain that the Kabbalistic figures 63 and 37, which represent a constant and invariable factor, whatever variations there may be in the eccentricity of the earth's orbit, and which therefore cannot induce variability of climate, are not only the efficient element in producing an Ice Age, but represent, as he states in his work, the proportions of summer and winter heat received in the latitude of Britain either now, or at any time?

On page 27 of the same edition Dr. Ball says: *Our hemisphere was once covered with ice.* Does he still maintain this, the most extravagant doctrine ever propounded by a Glacialist?

In his first letter to you, Dr. Ball admitted that Mr. Culverwell's calculation of the distribution of the sun's heat over different zones of the earth at present, and during the period of extreme eccentricity, is unassailable, but that the result is affected by convection of heat from other places. How does he reconcile this view, which was Croll's, and is also Mr. Culverwell's, with any part of the argument in his book, which was written, as he says, to enable us to dispense with other than astronomical causes?

Lastly, Sir R. Ball professes to account for *the* Ice Age—that is, the Glacial period of the geologists. In doing this he contrasts the effects of present eccentricity with the effects of the limit of *extreme eccentricity* as calculated by Leverrier and Stockwell. Does he seriously argue that the great Ice Age took place 850,000 years ago? As he well knows, we must go back to that period before we get a disparity of the seasons amounting to thirty-three days, and any time during the last 300,000 years, this disparity has been always very much less. Is it either ingenuous or right to treat this extreme variation as a factor in any possible range of speculation on the Ice Age?

As I said, I could add largely to these issues; but they will suffice. The matter is not a private difference of opinion. It is one upon which the basis of a great deal of geological reasoning must be founded. HENRY H. HOWORTH.

March 11.

The Röntgen Rays.

So many people are buying tubes for the "new photography," that I think it ought to be made known that the best results can be obtained with the original spherical tube used by Prof. Crookes in 1879, to show the incandescence of platinum under impact of the projected molecules which were focussed on it by a concave kathode. I have been using such a tube for my best work up to now. On January 29 last, I put in hand a larger tube of the same kind, with the same large concave kathode at the top and small disc anode at the bottom, but without the platinum in the middle. This tube is six inches in diameter. But the tube-makers have been so occupied with smaller tubes,

which are far less trouble to make, that it was only sent me yesterday. I at once used it to photograph a man's hand on an inverted celluloid film, the whole enclosed in a black bag in the usual way. With five inches of spark, and an exposure of three minutes at eight inches distance from the film, I obtained fine definition of the bones as far as the film went, including the junction of the two bones of the arm with the wrist. No Tesla apparatus was used. Had it been, doubtless the exposure could have been considerably shortened. An area of twelve inches by ten inches was covered perfectly. The tube was then set on for thirty minutes without stopping with a ten-inch spark coil, and showed no perceptible heating.

Although the definition was even better, the original tube with the platinum required an exposure of ten minutes under the same conditions.

I should like to draw attention to a curious dark shadow, which appears to be hanging in mid-air just above the anode, when the six-inch tube is set in action, and persists for some time afterwards. This shadow has the appearance of an ovoid dark space surrounded by a halo, and is probably the shadow of the kathode. Is it possible that rays proceed from a spot coincident with this shadow? A few rough experiments I have made, seem to lend colour to this view.

Chard, March 8. J. WILLIAM GIFFORD.

I SEE from a note in last week's NATURE, that some little doubt has been thrown upon the practical value of Röntgen's discovery in surgery. The following notes may therefore be of some interest.

With regard to the cryptoscope—after trying a number of substances, I have fallen back upon potassium or barium platinocyanide for the screen; the potassium salt was suggested to me, and I find the shadows show up in some respects better. The special form of cryptoscope which I have made is binocular, and with a good Crookes' tube I have had excellent results. I have been able to see distinctly shadows of the whole of the bones of the upper extremities, and a good portion of the lower; but what is most interesting, I have been able to look straight through a skull into which I had placed two or three bullets, and had no difficulty whatever in seeing shadows of them, although somewhat enlarged.

With regard to the photography—I have photographed the inner table of the cranium, the upper part of the spine in the neck, and half the spine and vertebræ in an adult. Not only have I got shadows, but distinct images of the surface of the bones of the spinous and transverse processes of the vertebræ; the ribs being particularly well defined. I have also photographed all the joints in the body with two exceptions, and this for the simple reason that I had not time to do them.

For practical purposes exposure is of importance. Fortunately the movable parts, such as the extremities, are more easily photographed than the denser and thicker tissues of the trunk. In other words, where we require quick exposures the conditions are more favourable.

I believe the Röntgen photography, and the cryptoscope, will prove to be one of the most valuable discoveries ever placed before us. JOHN MACINTYRE.

179 Bath Street, Glasgow, March 16.

WHILE a Crookes' tube discharges an electroscope charged with positive or negative electricity, when negative most rapidly, I have found with several of the ordinary spectrum tubes, particularly one containing oxygen, and another hydrogen, that these tubes produce the Röntgen rays, but act differently upon a charged electroscope. When the charge is positive, the leaves collapse immediately; when negative, they open out still further.

With the spectrum tube containing oxygen, good impressions have been obtained upon a photographic plate in four minutes.

London, March 16. F. J. REID.

The Huxley Memorial.

SINCE last a public announcement was made, the names of Sir H. H. Johnston, K.C.B., H.M. Commissioner and Consul-General in British Central Africa, and of Mr. Charles Hose, resident magistrate at Sarawak, have been added to the General Memorial Committee, which now numbers considerably over 700 persons, representative of science, literature and art, in all parts of the world.

The amount promised and received now exceeds £2300, and as a sufficient sum is thus guaranteed for the statue at the British Museum of Natural History and the medal at the Royal College of Science, London, the first two objects of the Committee definitely decided upon, Sub-Committees have been appointed to carry these objects through, and designs for the statue are now being prepared by Mr. Onslow Ford, R.A.

Appeal is now being made for the third object of the Committee, viz. "the furtherance of biological science in some manner to be hereafter determined, dependent upon the amount collected." The foundation of exhibitions, scholarships, or lectureships has been proposed, and for this purpose a considerable sum will be required. The efforts of the Committee to raise this are being promoted by the organisation of Local Committees in all parts of the world. Conspicuous among the results already obtained by this means is the receipt of £25 from the town of Leicester, through the mediation of its Literary and Philosophical Society; and it is hoped that this may be taken as a criterion of expectation from other localities. Donations of any amount will be gladly received by the Hon. Treasurer, Sir J. Lubbock, Bart., or by the Bankers, Messrs. Robarts, Lubbock, and Co. (15 Lombard Street, E.C.), or by myself.

A circular is now printed for distribution in lecture-rooms and elsewhere, and I should be very glad to communicate with friends or admirers of the late Prof. Huxley, or with persons connected with societies or institutions, who may be willing to aid the Memorial Committee by distributing copies of this letter or in any other manner. G. B. HOWES,

Hon. Sec. Huxley Memorial Committee.

Royal College of Science, South Kensington, March 17.

Natural History Museum.—Bird Gallery.

MAY I ask when the "common people" Mr. R. B. Sharpe speaks of in your issue of February 20, will "have the opportunity to read, mark, learn, and inwardly digest what the Museum is trying to teach"? As regards the Bird Gallery, the "opportunity" seems to be no nearer than it was fourteen years ago. Surely there has been time during that period for the preparation of a "guide" for the Bird Gallery, equally with the Shell and various other departments. *All* the "common people" can learn at present, is the scientific and, in some cases, the popular name of the bird, and its habitat. Among the thousands of species exhibited, there must be many whose history, written in a few lines, as is done with the British specimens in the table-cases, would be both interesting and instructive. I may add that there is no "guide" to the Department of British Zoology.

E. S.

The Aurora of March 4.

THE fine auroral display, noticed in NATURE, March 12, pp. 437 and 444, was brilliantly visible from the streets of Dublin at 8 p.m. on March 4. The great beam, rising from the characteristic bank of cloud into a starry sky, originated due west, and, if continued, would have passed to the south of the zenith. At 8.5 three or four short parallel rays, resembling a gridiron, appeared in a patchy way some 20° to the north, in a similarly clear sky; they disappeared rapidly, and five similar parallel bars arose close to the north side of the main ray at 8.10. At 9.30 the display had faded, as far as the city was concerned. GRENVILLE A. J. COLE.

Royal College of Science for Ireland.

Inverted Images.

MANY years ago I tried the method of reading a book upside-down on people who had never consciously attempted it before. I was surprised at the very great difference of aptitude. Generally individuals who had clear recollections of form, and could reproduce sketches of what they had seen more or less correctly, read easily and at once; but the greater number read slowly, frequently spelling as they went along. A boy of nine years of age, who was in the habit of reproducing on paper, with scissors, horses, dogs, cats, coaches, &c., read upside-down at once. I noticed that in cutting his patterns he sometimes cut his horse upside down, but more frequently the normal way. The same

boy, in demonstrating geometrical propositions, was not the least put about with the reversal of the diagram. He afterwards turned out a clever pattern-designer. JAMES SHAW.

The Age of the Wealden.

IN a letter in NATURE for March 12, Prof. Marsh calls attention to the evidence of the vertebrate fauna of the Wealden rocks as being in favour of including that series in the Jurassic system.

It may be of interest to add that a recent examination of an exceedingly rich collection of fossil plants obtained by Mr. Rufford from the Wealden rocks near Hastings, and now in the British Museum, leads very decidedly to the same conclusion. Between the Wealden flora of the South of England, in which no traces of undoubted Angiosperms have so far been found, and the typical Jurassic plants from the Yorkshire coast, there is a very close resemblance. A. C. SEWARD.

Cambridge, March 16.

The Stress in Magnetised Iron.

DR. CHREE will meet, I think, with general support in his opposition to the view that there is of necessity, or even usually, an actual stress in a magnetised rod tending to shorten it; but in maintaining, as I understand him to do, the opposite view that the magnetic tension along the lines of force is necessarily accompanied by a mechanical stress of pull and the associated extension, he appears to me to be on more disputable ground. Dr. Chree's conception of the Maxwell distribution of stress seems, if I may venture to say so, to be too materialistic. What Maxwell really showed, of course, was that such a distribution would produce on every element of matter in the field the mechanical force which it was known actually to experience. It was not suggested, however, that these stresses were to be considered as transmitted by the matter by virtue of its mechanical properties, indeed this could clearly not be the case where the matter was liquid or gaseous; and so there are no grounds for supposing that the matter would exhibit strains directly associated with these stresses. The stresses, in fact, must be considered as transmitted by the ether which pervades the field, and it is in the ether that the associated strains are to be looked for.

If, however, we turn our attention from the ether to the matter in the field, and remember that certain portions of this matter will in general be experiencing mechanical forces, we see that if its equilibrium is to be maintained a suitable system of mechanical stresses and the associated strains must be set up in it.

In the case considered by Dr. Chree in his letter to NATURE, published on January 23, it is plain that if AA′ and BB′ are air-gaps, and are not filled up with a material capable of offering resistance to longitudinal compression, the portions A′ and B′ of the bar must be held or fixed in some way if there is to be equilibrium. This was pointed out by Prof. Ewing, but Dr. Chree does not seem to have appreciated its significance, and his disregard of the external forces required for this purpose is responsible for the apparent discontinuity to which he refers in his second letter. If A′ and B′, with these forces applied to them, are allowed to move up to A and B so as to close up the air-gaps, we pass without discontinuity to the case of a magnetised rod under external pull, and thus in a state of mechanical tensile stress and elongation. If now we consider these external forces to be gradually diminished to zero, and suppose that the question is not complicated by end effects at the outer ends of A′ and B′ (as it will be in the case of a straight rod unless external forces are kept applied at these ends), the mechanical tensile stress and elongation will diminish to zero also, and we have passed without discontinuity from Dr. Chree's result to Prof. Ewing's.

That Dr. Chree has obtained the correct result for the special case which he investigates, appears from the following considerations. Assuming that AA′ and BB′ are equal air-gaps, and that A′ and B′ are fixed, AB will be in equilibrium. The Maxwell distribution of stress gives equal mechanical forces on the surfaces A and B directed outwards, and consequently there will be tensile mechanical stress in AB with its associated extension. In this case, therefore, there is actual elongation of the metal in the direction of the lines of force. In the case of an endless ring, however, the Maxwell distribution of stress gives no mechanical force, and no mechanical stresses with associated strains will be set up. This is the case considered by Prof. Ewing, who obtained the same result. I must confess that I do not follow Dr. Chree's objections to Prof. Ewing's reasoning on this point. The mechanical stresses must be such that every portion of the ring is in equilibrium. Prof. Ewing does not complain that tensile stress in a ring is unimaginable, but that it does not comply with this condition. If Dr. Chree will reconsider his reference to the case of a rotating anchor ring, he will admit, I think, that as every element of such a body is not in equilibrium, but in accelerated motion, the fact that tensile stress can and does exist in it is not relevant.

As a further illustration of the variety of the mechanical actions which may accompany the Maxwell distribution of stress, we may consider the case of two sheets of tinfoil placed against opposite faces of a plate of glass and maintained at different potentials. It is readily seen that in this case the glass undergoes a mechanical stress of compression and the associated strain of shortening in the direction of the lines of electrostatic force, though the Maxwell stress in this direction is a tension. L. R. WILBERFORCE.

Cavendish Laboratory, Cambridge, February 26.

RECENT WORK OF THE GEOLOGICAL SURVEY OF THE UNITED STATES.[1]

II.

SINCE Gilbert (in 1887) published his classical monograph on the geology of the Henry Mountains, in which he gave to the world for the first time a clear and connected account of the nature and occurrence of Laccolites, we have waited many years for further original work on this type of physical structure in America. A study of the writings of Peale, and of the exquisite panoramic drawings of Holmes, made it abundantly clear that laccolitic masses must be frequent in the United States. Mr. Whitman Cross has now collected a number of instances from Colorado, Arizona, and Utah.[2] He has remarked on their structure so far as it has been made out by these observers, by Emmons, and by himself, given a description of the characters of the rock of which the laccolites consist, and offered some remarks on the general theory of laccolitic structure.

The theory has not been quite so fertile in results as might have been expected from the clear-cut nature of Gilbert's brilliant piece of work; nevertheless the author is able to show that, although Reyer refuses to accept the facts on which the theory is based, Suess, on the other hand, reproduced the illustrations, summarised the results of Gilbert, Peale, and Holmes, and applied them to European and other examples, while Neumayr added further arguments in favour of the intrusive nature of the Henry Mountain rocks themselves. It may be pointed out here that the existence of laccolites has been taken almost for granted by many British authors (not referred to by Cross), such as Kinahan, Geikie, Harker, Marr, and others, and that in one case at least a numerous group of laccolites has been described, and proof given that the igneous masses are conformably underlain and overlain by sediments.[3] The abstract of this paper, all that was published for many years, also anticipates some of the conclusions independently reached by Mr. Cross.

The familiar Henry Mountains are first described, then the West Elk Mountains to which attention was drawn by Peale, and in succession the San Miguel, La Plata, Carriso, El Late, Abago, and La Sal Mountains. All these are either on the verge of the great plateau, being thus geographically outliers of the Colorado Mountains, or they are isolated groups on the plateau itself. They are groups of laccolites intruded into nearly horizontal strata probably at about the same period—in Tertiary

[1] Continued from page 441.
[2] "Fourteenth Annual Report of the Geological Survey of the United States," 1892-93. (1894.)
[3] "Report of the British Association," 1886.

time, as they pierce rocks of Cretaceous age. The Mosquito Range of central Colorado, and the Ten-Mile district to the west of it, were studied by Jacob and Emmons, and in these areas intrusive rocks of the same composition occur as laccolites, sills, and dykes in more ancient rocks, and even in the fundamental Archæan complex. A few other cases are referred to.

The study of these examples reveals the fact that the theory has received several important accessions, and even some modifications. The laccolite is beginning to lose the familiar mushroom shape which, with its central stalk, has done much to cause incredulity; we find, instead, excentric dykes and pipes, complex groups of dykes, even sheets and dykes in suspicious proximity to important faults, indicated as the feeders of the lens-shaped masses of igneous material; this gives much more of structural verisimilitude to the type. Again the masses are shown to be more often irregular or unsymmetrical in outline, faults as well as folds give easement to the lifted cover, the so-called pine-tree laccolite, or group of anastomosing sheets is not infrequent; bunches of laccolities irregularly intruded into yielding shales take the place of the single "stone cistern," and the laccolite is sometimes shown to cross the strata both above and below. In addition to formal sections, many of the beautiful outline and panoramic sketches of Holmes are reproduced; these are drawn with such a wonderful feeling for the run of the country, that the igneous structure can often be made out from them alone. In fact, so much has been made out of what material has been already got together, that we feel bound to express a hope that selected examples of the group will shortly be mapped out in detail by the skilled stratigraphers of the Survey, in order to ascertain in such a favourably exposed region what is the precise relation of laccolitic groups to the folding of rocks, and the exact part played by them in tectonic history.

It is a remarkable fact that the rock in the laccolites is almost uniform in character. It is called a porphyrite, and contains phenocrysts of either hornblende, augite, hypersthene, biotite, quartz, and felspar, or several of these in a holocrystalline but compact matrix of quartz and orthoclase. The silica percentage, omitting one doubtful and exceptional type, varies from 69-55, but is generally about 63, and the proportion of potash to soda, 2·5-4, is fairly constant. The porphyritic crystals, chiefly intratelluric in origin, have increased in size after the intrusion of the rock, and it is thought that the phenocrysts of orthoclase, which occasionally occur, have been completely formed after intrusion. Gilbert's hypothesis, that the laccolitic structure is determined by conditions of density, is not accepted in its entirety, the author quoting with approval Dana's criticism that Gilbert's explanation "appears to be complete without reference to this difference of density. With so powerful a forced movement as the facts, if they are rightly interpreted, show to have existed, no other cause could be needed for a flow to the surface in the case of an open channel, or for a flow to any level in the strata at which a fissure might terminate; and this is true, whether the lava be light or heavy." Hints are given throughout the paper that orographic movements may often have had a determining effect in the localisation of laccolites, a result already reached by some observers in Britain.

An exceptionally interesting piece of experimental work is contained in Mr. B. Willis's "Mechanics of Appalachian Structure."[1] A long series of experiments was undertaken, and is here illustrated by twenty-one large plates, while a number of maps, sections, and photographs from the Appalachian ground are of use to compare with the experimental results. In addition to the usual types of folds defined by the opposed dips, we have a classification according to compression into open, closed, and carinate or isoclinal folds. In the Appalachians the following districts are recognised: the district of (1) open folding, (2) closed folding, (3) folding with faulting, (4) folding with schistosity. One of the great questions to which the observer is led is this: As the "conditions antecedent to deformation were the result of sedimentation, does the distribution of strata afford an answer to the questions raised?" To investigate this problem a mixture of beeswax with plaster of Paris and Venice turpentine of varying consistency was used, in thin, large sheets, resting on a plastic support, and covered by shot to act as a load. This was contorted by lateral pressure applied by means of a slow-motion screw. One of the first results to come out was that any slight dip in the layers of material was usually sufficient to initiate a fold. "In strata under load an anticline arises along the line of initial dip, when a thrust, sufficiently powerful to raise the load, is transmitted by a competent stratum. The resulting anticline supports the load as an arch, and, being adequate to that duty, it may be called a competent structure." From this it follows that the size of an anticline depends on the competency of the stratum and inversely on the load. Some evidence has been obtained in the field that the initial dips in the Appalachians have influenced the folding. An interesting by-product of the experiments is the fissuring of tissue-paper placed between the layers, along lines at right angles to the wrinkles. The work then goes on to consider the packing of folds and the formation of faults. The plates illustrate the successive steps of each experiment of which the details are thought worthy of publication.

Owing to the small scale of the maps and to the rapidity with which surveying is carried out, it is often necessary to generalise the geological as well as the topographical features expressed on the maps, when it is desired to bring out important tectonic characters. This is pointed out by Prof. Iddings, and atoned for by the conscientious completeness with which he has worked out the petrological affinities of the intrusive and eruptive rocks of Electric Peak and Sepulchre Mountain.[1] Separated now by a great fault, with a downthrow to the north-east, along which a valley has been excavated, one of these masses—Sepulchre Mountain—was once situated almost directly over the other. Sepulchre Mountain is made up of volcanic accumulations, andesitic and rhyolitic breccias and lava-flows, with dykes and other eruptive volcanic products; Electric Peak consists of intrusive sheets, dykes, and "stocks" of porphyrite and diorite corresponding in a general way in composition with the rocks first mentioned, but differing in their coarser texture and more plutonic aspect. The relative date of the members of the intrusive series can be made out and paralleled stage by stage with the volcanic products, so as to make it clear that we have here side by side the surface and the deep-seated products of one volcano. This is expressed in tabular form, as follows:—

Electric Peak.	Sepulchre Mountain.
(*a*) Intrusive sheets of porphyrite.	(*a*) Andesitic breccias.
(*b*) Intrusion of dyke and stock rocks in the following order:—	(*b*) Andesitic breccias and dykes in the following order:—
Pyroxene-porphyrite to pyroxene- and hornblende-diorites.	Pyroxene-andesites to pyroxene-hornblende-andesites.
Hornblende-biotite-diorites and porphyrites.	Hornblende-biotites-andesites.
Quartz-biotite-diorite-porphyrite.	Dacites.

Such a parallelism cannot be the result of an accident, and it affords a most useful opportunity for the study of the relations of deep-seated and surface products; of this

[1] Thirteenth Annual Report of the Geological Survey of the United States, 1891-92. (1893.)

[1] Twelfth Annual Report of the Geological Survey of the United States, 1890-91. (1892.)

chance Prof. Iddings has not been slow to take the fullest advantage. The author does not use the word porphyrite in the sense of an altered or ancient andesite, but applies it to "medium-grained porphyritic rocks that occupy an intermediate position between the coarsely granular diorites and gabbros and the microlitic or glassy andesites." In describing the diorites, he gives a plate of examples of the intergrowth of such minerals as hornblende, biotite, augite, and hypersthene. The whole of the plutonic rocks are compared together as to structure and chemical composition, and shown to form a connected and overlapping series. Similar comparisons are effected between the volcanic products of Sepulchre Mountain. Mr. Iddings points out that it is impossible to trace any actual transition through stock and dyke rocks into the corresponding eruptive rocks, for the reason that they are often cut asunder while the volcano is in activity, and because the pipe is invaded by each magma in turn, the last alone remaining there to solidify, unless little patches of necessarily altered previous types happen by accident to survive.

In the nineteenth monograph, Messrs. Irving and Van Hise treat of the Penokee iron-bearing series of Michigan and Wisconsin. This is a monoclinal series of rocks dipping northwards off a mass of crystalline rocks which lie to the south, and extending a distance of eighty miles along their strike. The "Southern Complex" is a mass of schists of eruptive origin, with masses of granite intruding into them. Resting unconformably on this complex, comes a thin series of cherty limestones (300 feet) of aqueous origin, but whether chemical or organic is not known, and unconformably again on that, the quartz-slate (500 feet). The iron-bearing member (800 feet) in its least altered state is a water-deposited cherty iron carbonate, which can be seen to grade into ferruginous slates, these into ferruginous cherts with concretionary and brecciated structures, and these again into actinolitic slates containing much magnetite. This rock is penetrated by diabase dykes which, when intruded, appear to have been vertical, while the beds were horizontal. It results from this that, now both are tilted, V-shaped areas occur defined by the upper quartzite of the quartz-slate on the one hand, and the dykes on the other. It is in the apices of these V's, that the iron ore is now concentrated, the original rock being rendered very poor in ferruginous constituents, which have been re-deposited in the ore masses as hæmatite. In the area east of Gogebic Lake, the regular succession is disturbed by volcanic accumulations and greenstone conglomerates. The Upper Slate member (12,000 feet) rests on the iron-bearing rocks, but it does not extend quite so far as they do. The southern complex is placed in the Archæan system, the overlying beds into the Algonkian; these are covered by the Keweenawan series, after which the rocks received their monoclinal tilting; finally, the Eastern Sandstone was unconformably deposited on them all. The work is illustrated by a large series of illustrations of the microscopic structure of igneous and sedimentary rocks, and by maps and sections.

Mr. Walcott[1] gives an admirably illustrated account of the igneous rocks of the Unkar terrane, a group which underlies the Tonto Sandstone in the district of the Grand Cañon of the Colorado, and has been variously referred to the Algonkian, the Cambrian, and the Silurian by himself and other authors. The presence of a well-marked Middle Cambrian fauna in the upper part, and a strong unconformity at the base of the Tonto Sandstone, are sufficient in the opinion of the author to warrant our considering the Unkar beds as Pre-Cambrian, and correlating them with part of the Algonkian succession. The upper part of the Chuar terrane, which immediately underlies the Cambrian rocks, consists of 1700 feet of shales and sandstone, with 138 feet of limestone; the lower division of this terrane has 3420 feet of similar rocks, with 147 feet of limestone of a rather different type. Two of the limestones are spoken of as *Stromatopora* limestones, and they contain an organism which is probably a species of Cryptozoon.

The Unkar terrane which underlies that last described, is 6830 feet thick; there are magnesian limestones at the top, followed by lava beds 800 to 1000 feet thick, then sandstones and another lava bed from 80 to 180 feet thick on a limestone and conglomerate, which rest unconformably on the Vishnu schist, and the gneisses and schists of the Archæan System. The igneous rocks were probably submarine flows poured out from fissure eruptions, the dykes of which are still visible in the walls of the cañon, during a slow subsidence when beds of sandstone and shale were interleaved with the volcanic products.

Mr. Iddings, who contributes an appendix, describes the lavas as olivine-basalts sometimes fresh but more usually altered, the felspar passing into saussurite, the pyroxene to chlorite, and the olivine to serpentine and other products. When the original structure is well preserved, it does not differ much from that of the Tertiary lavas of the same area. The ground-mass of the basalts is usually microcrystalline, but in the middle of thick sheets it becomes ophitic, while the upper and under parts are scoriaceous and amygdaloidal.

In that lucid style for which his work is well known, Mr. Walcott[1] sketches out the physical history of the North American continent during Cambrian time. He shows that Dana's idea of the existence of a V-shaped skeleton, about which Palæozoic sediments accreted, is in the main correct, but he is able to fill in a number of details which were of necessity left blank by that author. The underlying massif is composed of Algonkian rocks resting unconformably on those of Archæan age; its rocks were tilted and uplifted into a land area, which Walcott proposes to call the Algonkian continent, and which was of wider extent than any land in this position until Mesozoic time. This continent consisted of four chief parts: (1) the V-shaped mass running parallel to the outlines of Hudson Bay, and possibly extending in a shield-like area to Texas and the Colorado River; (2) a Palæo-Appalachian range, with sub-parallel chains and spurs; (3) a Palæo-Rocky Mountain mass; and (4) a Palæo-Sierra Nevada mass. Sedimentation took place in all the seas defined by these land areas in early Cambrian (*Olenellus*) times; that is to say, in (1) the Atlantic Coast Province east of the Palæo-Appalachians; (2) the narrow sea extending from Labrador to Alabama; and (3) on the west side of the great V-shaped mass.

In Middle Cambrian times there was little change in the areas of deposition, except that partial barriers erected along the line of the Appalachians only allowed a small part of the typical (*Paradoxides*) fauna to penetrate westwards from the Atlantic basin. Strongly defined zoological provinces evidently existed in Middle Cambrian time, as proved by the study of the fauna of this period to the west.

Steadfast depression then began, and the Upper Cambrian Sea carried its sediments over the whole of the great south central region, including almost the whole of the United States as far north as Chicago, and from the Sierra Nevada to the Appalachians. The Appalachian barrier was, however, strengthened so that the fauna of the Atlantic coast in Upper Cambrian times was related to that of Europe, and quite distinct from that of the Central States. This great depression brought on the limestone deposits of the Ordovician system. The memoir is illustrated by several important geological and palæo-geographical maps.

[1] Fourteenth Annual Report of the Geological Survey of the United States, 1892-93. (1894.)

[1] Twelfth Annual Report of the Geological Survey of the United States, 1890-91. (1891.)

Volume xxiii. (1894) of the Monographs of the Survey is devoted to the geology of the Green Mountains in Massachusetts, by Messrs. Pumpelly, Wolff, and Dale. This district of Palæozoic rocks is complicated by two circumstances; in the first place, the limestones of Greylock Mountain appear to pass shoreward into the sandy and shaly beds of Hoosac Mountain to the west, and in the second place, metamorphism has proceeded much further at the western end of the series. Resting on the Stamford gneiss of Pre-Cambrian age comes the coarse gneiss of the east side of Hoosac Mountain, which is traceable into coarse conglomerate, "white gneiss," and quartzite as we pass towards the north and west. The lower part of the Hoosac schist passes similarly through the calcareous schist of the Hoosac Tunnel into the Stockbridge limestone. The upper part of this schist is perhaps to be correlated with the Berkshire and Greylock schist series, which are separated by the Bellowspipe limestone. The rocks are over-folded and faulted as well as metamorphosed, but patient mapping has unravelled the complex structure, and enabled the writers to assign the Stamford gneiss to the Pre-Cambrian System, the Vermont Formation and the Lower Stockbridge limestone to the Cambrian, and other rocks mentioned to the Silurian System. Much credit is due to the authors, and their assistants in the field, for such a careful and detailed piece of work, in which everything has been subordinated to the elucidation and presentation of the facts.

Mr. T. Nelson Dale,[1] in his account of the Renselaer Grit Plateau of New York, thinks that the grit occupies a place (probably unconformably) above the Hudson River shales, which are themselves equivalent to the Berkshire schists, but in a less altered condition, and in their turn rest on the Stockbridge limestone. The upper part of this last rock, which is crystalline and contains clastic grains of quartz and felspar, yields fossils of Trenton, Chazy, and Calciferous age, but its lower part represents much more ancient time, as it contains Cambrian fossils. and is thought to be the equivalent of the *Olenellus* limestone, which, further east, rests on Archæan rocks.

The grit itself is a coarse graywacké containing some secondary minerals, and interbedded with red slates and phyllites. On the west side of the syncline it is underlain by shales and phyllites of the Hudson River group, which pass towards the east into muscovite and chlorite schists which contain ottrelite, tourmaline, and more rarely albite. A map, coloured sections, some admirable photographs, and figures of rock-structure, illustrate the paper, which appears to be an excellent piece of minute stratigraphical and petrological work.

To the same author we owe an account of the structure of the ridge between the Taconic and Green Mountains in Vermont.[2] This consists of an anticline of lower Cambrian rocks overlain by Stockbridge limestone and Berkshire schist. The anticline is broken by a "keystone" fault, a thrust-plane, and one or two minor disturbances. Mr. Dale also gives another interpretation to the structure of Monument Mountain[3] differing from those advanced by Dana. He regards it as a synclinorium somewhat disturbed by faulting. The rocks involved are the Stockbridge limestone, the Berkshire schist, quartzite, and Silurian rocks.

Mr. A. Keith[4] gives an account of the Catoctin Belt, a region which is roughly the mountain tract of Maryland and Virginia, a geological continuation to the north-east of the Appalachian flexure system. The lowest rocks are relegated to the Algonkian System, and consist of a flow of diabase lava, followed by others of quartz-porphyry and andesite, and by intrusions of granite; these, again, are succeeded by other diabase flows: the diabases are now converted into the Catoctin schists. The overlying Cambrian rocks are divided into four, and the Silurian into three, divisions. A map of the whole area is given, and, in describing both igneous and sedimentary rocks, smaller scale maps are used to show variations in composition and structure. Lines are drawn on these maps through those points where a given band of rock has the same thickness (isometric or isodiametric lines, as they have been called), and by this means a very good idea of variation in thickness is given. Fossils found in the Cambrian rocks have been of the utmost use, not only in indicating the general age of the rocks, but also in making out the general succession, and in unravelling difficult bits of stratigraphy. The upper part of the Shenandoah limestone contains Silurian (? Ordovician) fossils, but its lower part yields lower Cambrian with some middle Cambrian forms. Above the representative of the Hudson River shales comes the Newark formation, of Jura-Trias age, which contains dykes and sills of diabase. The region underwent folding, thrusting, and metamorphism of Appalachian type before the Newark time, and subsequently was tilted and faulted on the monoclinal plan. It was planed down in Cretaceous times, and reduced to a base-level before the Lafayette period; certain portions which survived this second planing are delineated in a map. An interesting comparison is appended in which the amount of area planed down, and the amount of rock removed by different phases of denudation are used to obtain a rough estimate of the time elapsing during different parts of the Tertiary Period. This gives the following relative figures:—Tertiary, 134; Early Pleistocene, 1; Late Pleistocene, $\frac{3}{8}$; Recent, a small fraction.

Mr. C. S. Prosser's *Bulletin* on the Devonian Rocks of East Pennsylvania and New York[1] is an admirable piece of detailed stratigraphy, in which the fossils have evidently been carefully collected and identified from each important horizon, so as to place on record a number of facts that enable detailed comparison to be made with the better-known sections of western and central New York. About 8000 feet of rock are shown, of which 500 belong to the lower, 2200 to the middle, and 5300 to the upper division of the system. The bulk of the fossils are of marine type, but some land plants were discovered.

In his paper on a Geological Reconnoissance in North-west Wyoming, Mr. G. H. Eldridge[2] gives a description of the great anticline of the Big Horn Mountains and the three basins lying east, west, and south of it respectively. The rocks belong to the Archæan, Cambrian, Silurian, Carboniferous, Triassic Cretaceous, and Eocene systems. The Palæozoic rocks appear to be conformable throughout, and there seems to be no break between them and those of Mesozoic age until the summit of the Laramie beds is reached; several breaks occur in the higher beds. Coal, a lignite of good quality, is found in the Laramie terrane, oil in the anticlines of Trias and Niobrara beds, building-stone everywhere, and gold in the north part of the Big Horn Mountains. The hot springs and agricultural qualities of the soils are described, and useful analyses of forty coals are appended.

An account of the economic geology of a portion of the main Appalachian coal-basin, and of an outlier called the Potomac field, is given by Mr. J. D. Weeks in the fourteenth annual report.[3] The chief coals are the Pittsburg seam of the Upper Productive Measures, the Upper Freeport and Lower Kitanning seams of the Lower Measures, and the New River and Flat Top seam of the Pottsville conglomerate. A description of the measures and their coals is given, but some of the vertical sections

are at first rather misleading, as one scale is employed for the measures; another and much larger one for the interbedded coal-seams. It is pointed out that in many cases it is not the only, nor indeed always the best, seam which is actually mined at any particular spot.

Passing to the west side of the continent, we have first to deal with the work of Mr. H. W. Turner on the rocks of the Sierra Nevada.[1] The older set of rocks, which contain auriferous veins, and are spoken of as the auriferous series, are much disturbed, and it is very difficult to make out their exact relations, particularly as they are bent into a series of isoclinal folds. Fortunately, however, many of the beds contain fossils, by the aid of which it may be possible eventually to unravel their structure. The following Systems appear to be represented: the Silurian, Carboniferous (three divisions), Jura-Trias (?), Trias (two divisions), and Upper Jurassic or Lower Cretaceous. The last, or Mariposa formation, appears to overlap the others, and sometimes to rest on Carboniferous beds; but the maps which express this fact are not easy to interpret. These older rocks contain beds of lava and ash at many horizons, with intrusive rocks of all types, from granulite and granodiorite (or quartz-mica-diorite) to peridotites and pyroxenites. The sediments are often highly metamorphosed, and, so far as we may judge by the nature of the minerals produced, such as andalusite and sillimanite, in all probability by thermal action.

The newer rocks include representatives of the Upper Cretaceous, Eocene, Miocene, Neocene, Pliocene, and Pleistocene Systems. The Neocene rocks are the auriferous river gravels, and the Pliocene beds are shore gravels, which sometimes contain gold. These are associated with flows of rhyolite, basalt, and andesite of various types, and with great sheets of breccia and tuff derived from them. The Sierra appears to have received its chief uplift after the deposit of the Mariposa slates, and then to have been planed down in both Cretaceous and Tertiary times to an almost flat surface, which is in places preserved under the Tertiary volcanic accumulations. Late in Tertiary time came another great uplift, accompanied by faulting.

A very useful piece of economic work is that by Mr. W. Lindgren on the gold-silver veins of Ophir, California.[2] The country-rock consists of an area of schistose amphibolites towards the north-east, into which a mass of granodiorite was intruded at some date subsequent to the formation of the Mariposa slates. The amphibolites contain lath-shaped felspars set in hornblende, chlorite, and felspar, and they have evidently been derived from the alteration of diabases; the grandiorite consists of quartz, potash and soda-lime felspar, biotite, and hornblende. Dykes of amphibolite and the auriferous veins traverse both rocks, and the latter group themselves into four systems: a north-west and south-east set parallel to the strike of the schists, another set running north and south, a third west 10° north, and a fourth east 20° north. To some extent all the quartz veins bear precious metal, but the ore is concentrated into pockets and chimneys. While the veins in the granodiorite are more extensive, of low grade and rich in silver, those in the amphibolite are of smaller extent in depth and width, but richer in gold, poorer in silver, and frequently reduced to mere pockets. The amphibolite is in places impregnated with pyrites, and it is well known that where the veins cross these "iron belts" they become especially rich in ore. The minerals include native gold, silver, and copper, electrum, horn-silver, and many sulphides. Both types of rock are much altered along the walls of the veins, the amphibolite passing into an aggregate of carbonates, white mica, and pyrites.

The geology of the Eureka district, Nevada, by Mr. A. Hague,[1] contains an appendix on the fossils by Mr. Walcott, and another on the igneous rocks by Prof. Iddings. The work begins with a general description of the physical geography and geology, from which we gather that the following is the succession of the chief rocks of the district. The Cambrian rocks are 7700 feet thick, and are divided into the Prospect Mountain quartzite, the Prospect Mountain limestone, which contains an *Olenellus* fauna, the Secret Cañon shale, the Hamburg limestone with a Potsdam fauna in its lower and upper parts, and the Hamburg shale. The Silurian rocks are 5000 feet in thickness, made up of the Pogonip limestone with a Potsdam fauna at the base, then Chazy forms, and in the higher portion some of Trenton facies; the Eureka quartzite; and the Lone Mountain limestone with Trenton and, possibly, some Niagara fossils. The Devonian system is 8000 feet thick, divided into the Nevada limestone and the White Pine shale. The Carboniferous Formation has four members, the Diamond Peak quartzite, the Lower Coal Measure limestone, the Weber conglomerate, and the Upper Coal Measure limestone. The chief feature about the Carboniferous rocks is the fact that there occurs a freshwater fauna at the base of the Lower Coal Measure limestone, and a mingling of Devonian, Lower Carboniferous, and Coal Measure species in a limestone overlying beds characterised by a pure Coal Measure fauna.

These sediments are penetrated by granites, granite-porphyries, and quartz-porphyry, and are overlain by immense quantities of Tertiary or later volcanic rocks. The great eruptions for the most part cover subsided regions; where a mountain block has been uplifted, they occur at its borders. The succession of eruptions seems to have been as follows: hornblende-andesite, hornblende-mica-andesite, dacite, rhyolite, pyroxene-andesite, basalt. It is suggested that the original magma split up into two—one felspathic, the other pyroxenic; the felspathic eruptions become steadily more acid until rhyolite is reached, the pyroxenic eruptions more basic from andesite to basalt. The ore deposits are mainly of lead and iron rich in gold and silver. Originally deposited as sulphides, they have been oxidised by air and surface water. They occur in cavities in all the Cambrian, Silurian, and Devonian rocks except the great shale masses. One analysis gave 27·5 ounces of silver and 1·5 of gold to the ton.

Mr. Walcott's appendix includes a long list of fossils from all the beds. Mr. Iddings calls the granite an amphibole-granitite containing quartz, orthoclase, plagioclase, hornblende, and mica; the granite-porphyry is the chilled-edge phase of the granite-magma, of which the quartz-porphyry is the final phase. In all the volcanic rocks "there is a marked similarity between the individual crystals of the same mineral species wherever they occur . . . which links the various kinds of rocks together and suggests the possibility of a common source." The work is admirably illustrated by figures and photographs.

Mr. J. S. Diller gives an impressive picture of Tertiary denudation in his "Tertiary Revolution in the Topography of the Pacific Coast."[2] After the beds of the Shasta-Chico (Cretaceous) series were laid down, the country was planed down to a base-level. At the present time this "pene-plain" has an average maximum slope of 2°, which rises to 5°, and then somewhat rapidly up to 17°, on the flanks of the Klamath Mountains, a name used to designate the group which occurs at the junction of the Cascade range with the Coast range and the Sierra Nevada. The plain stretches across the head waters of the Sacramento River to the Sierra Nevada, and probably comes out at the other side of it in the

[1] Fourteenth Annual Report of the Geological Survey of the United States, 1892-93. (1894.) [2] *Ibid.*

[1] Monographs of the Geological Survey of the United States, vol. xx. (1892.)

[2] Fourteenth Annual Report of the Geological Survey of the United States, 1892-93. (1894.)

interior of North-East California and the adjacent parts of Oregon, being covered in the interval by Tertiary volcanic products. The plain is cut on to the Chico series and older rocks, and there rest on it the Ione formation, probably equivalent to the auriferous gravels, the Tuscan tuff, and the Red Bluff Pleistocene beds. It is noteworthy that the plant remains in the oldest of these rocks are of low altitude and not mountain types. There was evidently much movement in post-Chico time, then came erosion during the Eocene, and finally new movement with some warping and deformation. As the Eocene base-level was perfected erosion became much slacker, and was chiefly effected by solution, so that there was left much insoluble and dense material, including quartz and gold, ready to be deposited in the auriferous gravel when the next movement supervened, making the slopes steeper and giving the streams fresh impetus.

Returning now to the east, we have a lengthy account, by Mr. W. J. McGee, of the Lafayette Formation.[1] This writer has shown a remarkable adaptability in suiting his style to his subject, as he expresses it in the following sentence: "The history of development of the eastern land is recorded in nature in characters so grand that but a small part of a single one may be seen at once, so that the direct reading is difficult." The Coastal Plain of the United States is based on Cretaceous rocks, which are covered by the following rocks in order, the first having an uncomformable base: the Lignitic beds, the Claiborne and Meridian deposits, the Vicksburg-Jackson or White Limestone, the Grand Gulf beds, the Lafayette formation, and the Columbia beds. From this succession the author makes out the chief oscillations and changes in physical geography undergone by the Atlantic slope and the Mississippi embayment. The age of the formation we are left to judge from the following enigmatical sentence. "If the Cenozoic be not made to include the Pleistocene, and if the age be then divided into equal portions called Eocene and Neocene, and if then the Neocene be divided into ten equal parts, the Lafayette period may be supposed to correspond with the eighth or, perhaps, with the seventh or the ninth of these parts." The work closes with an account of the material resources of the formation, soils, siliceous clays, gravel, and iron, followed by the history of events recorded in the rocks. Mr. McGee illustrates his paper with some excellent maps, and also contributes to the fourteenth Annual Report a geological map of the whole of the United States at present surveyed.

W. W. W.

THE GAME FIELDS OF THE EASTERN TRANSVAAL.[2]

IN proceeding into the interior of Africa from almost any point on the eastern coast, the traveller passes over a low coastal plain to the foot of the scarp of a high plateau. This plateau is succeeded to the west by a still higher one, which is gained either by a second steep ascent or by a gradual slope. The existing river valleys and former earth-movements have in places interrupted this arrangement; but, notwithstanding a few such exceptions, it persists with remarkable uniformity from Abyssinia to Natal, where the dominant meridional geographical lines bend round into the east and west series that rules in Cape Colony. In the eastern Transvaal, this zonal arrangement of the country is well developed. Inland from Delagoa Bay is a tract of undulating lowland, ending at the foot of the Libombo Mountains, which separate Swaziland and the Transvaal from Portuguese East Africa. Seventy miles further to the west is the parallel range of the Drakensberg or Kahlamba (to adopt the author's spelling of the name, which is usually written Quahlamba). Between these mountain ranges is a belt of bush-covered veldt. The Crocodile River (a tributary of the Komati) and the Olifants River flow from west to east across this belt, at a distance of about 100 miles from one another. These, with the mountains, enclose a roughly quadrangular area, some 7000 square miles in extent, which is the favourite hunting-ground of Mr. F. V. Kirby. Small though this area is, it includes very varied types of country. To the west are the densely wooded eastern slopes of the Drakensberg, and part of the turf-clad plateaus or terraces beyond; to the east lies low country with sub-tropical vegetation, intervening between the Libombo Mountains and the Limpopo River.

FIG. 1.—A Head of the Great Kudu.

Most of the area consists of barren, scrub-covered plains known in this part of Africa as Bush-veldt, and near the equator as the Nyika. Most of this area was once rich in game. In the Bush-veldt lived the rhinoceros and buffalo, the sable and roan antelopes, the gnu, waterbuck, zebra and mpalla. The wooded foothills of the Drakensberg, or the "Kloof Country," was the home of the koodoo, the hill-leopard, the bush-buck, and the reed-buck. On the western plateau, or the "Krantz Country," in addition to some of the animals mentioned, lived the oribi and the mountain reed-buck.

This book relates the experience of nearly twenty years of hunting in this rich game country. The author tells his story in much better English than we are used to in books of sporting adventure. He is obviously not only a skilled sportsman, but a man with a keen eye for fine scenery, of literary tastes, and a careful and patient

[1] Twelfth Annual Report of the Geological Survey of the United States, 1890-91. (1891.)

[2] "In Haunts of Wild Game. A Hunter-Naturalist's Wanderings from Kahlamba to Libombo." By Frederick Vaughan Kirby, F.Z.S. 8vo. Pp. xvi + 567. With map, portrait, 16 full-page and 24 smaller illustrations. (Edinburgh and London: Wm. Blackwood and Sons, 1896.)

observer. His book is somewhat lengthy, and consists in the main of descriptions of successful stalks, night-watches, and exciting encounters in the chase of the various classes of game. Every page will be of interest to sportsmen; while the notes on the habits of the game, and the descriptions of variations from the normal forms, render it of importance to naturalists.

The book is divided into two parts. The first describes shooting in the "Krantz" and the "Kloof" countries; the second, that of the Bush-veldt. As the district is settled, and the natives friendly, and as the railway to Pretoria passes along the southern border of the country, the conditions of life are very comfortable. The author shot with dogs, generally on horseback, and in the case of smaller game, had the help of large parties of beaters. But the sport was not always by any means of the battue type. Five chapters out of the thirteen in the first part of the book are devoted to leopard hunting, which is always arduous, and one to buffalo hunting, which is generally dangerous. The author has great respect for the leopard, and protests against its being described, as he says it generally is, as "a contemptible sneak" and "utter coward." He describes it, on the contrary, as "an incredibly daring brute," and says it "will usually show fight where a far larger and more powerful animal would try to back out of it." But we thought that this estimate of the courage of the leopard was generally accepted, although the author describes the other as that which is invariably held. The five chapters on lions and lion-hunting, in the second part, will probably be the most generally attractive in the work. The author scorns the idea that the lion is not the king of beasts, and his experiences certainly show that its courage is sometimes superb. His remark, however, that in the case of lions, "if not interfered with or actually in a starving state, there is absolutely nothing to fear from them if met in the day-time," is not supported by recent accounts from Equatorial Africa. Some lions there recently, in broad daylight, attacked and routed a hundred men belonging to a Uganda caravan. The last chapter in the book is a discussion of the respective merit of rifles, in which the author takes the side of heavy weapons. He declares the ·303 to be a very over-rated gun, and most of his arguments seem to me quite sound, at least as far as concerns the professional sportsman. The author, however, perhaps does not sufficiently consider the case of those with whom sport is only secondary to other work. He says that the advantages claimed for the ·303, owing to its lightness and absence of recoil, are fictitious; for sportsmen must be so strong, that the few extra pounds make no difference, and that they do not feel the recoil of a ·577. This is no doubt true, if potting game is a man's sole occupation; but if in addition to a rifle he has to carry a butterfly-net and a satchel of collecting-bottles, every pound saved is of great importance. It is no doubt true, that during the excitement of the chase, a sportsman does not feel any inconvenience from half-a-dozen blows from a ·577; but if, during the next few hours, the traveller tries to take an altitude, or read a round of angles with a theodolite, he will find that he *has* felt the recoil, and has to pay for his sport by less accurate observations than he might otherwise have taken.

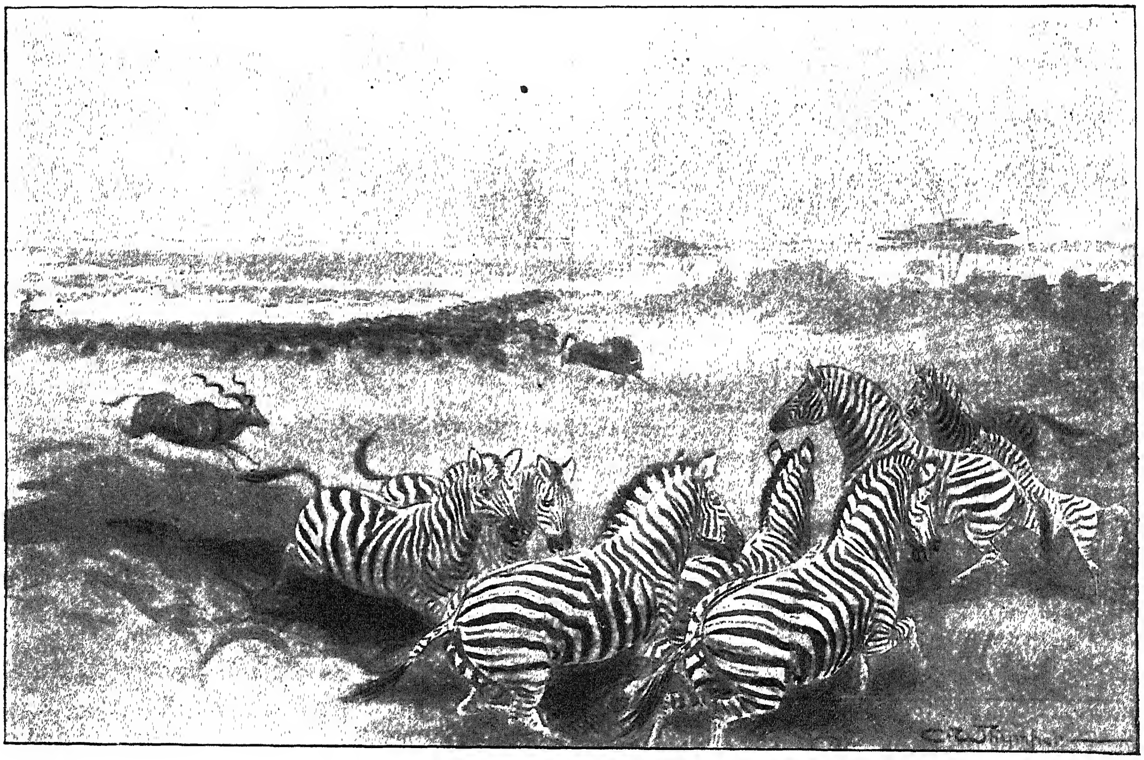

FIG. 2.—A Scene on the Game Fields.

The interest of the book is greatly enhanced by Mr. Charles Whymper's illustrations, which are a valuable addition to that artist's series of studies of wild animal life. By the courtesy of the publishers two are here reproduced as examples. In the picture of the game-fields, the artist has well illustrated the inquisitive zebras' stupid habit of swinging round occasionally to satisfy their curiosity as to danger, from which they might otherwise escape.

The most regrettable feature in the book is the author's habit of using native or local names for animals without giving the zoological name. Comparatively few of his readers are likely to recognise the *hyrax* or coney in the "dassie," especially as this term is not mentioned as a synonym in the notes on the fauna in the last chapter. The author's interesting remarks on some snakes lose much of their value, owing to the uncertainty of knowing which species he is describing.

The author's account of life on the game-fields shows that these are not Edens. His realistic account of a fight between a lion and a sable antelope, which resulted in the death of both combatants, and of a zebra which he shot, only to find that it had been so wounded by lions, that much of its flesh was putrid, and that it was full of maggots, help one to realise the tragedy of the struggle for existence. The author blames the Boer Government for allowing the destruction of the game; but the case of South America shows how a fauna, much richer than that of Africa, has become extinct in comparatively recent times, and without human intervention. The extermination of some species in regions of Africa where the game has not been seriously hunted, shows that natural agencies help in that destruction of the game, for which man generally bears the whole of the blame.

J. W. G.

GENERAL J. T. WALKER, R.E., C.B., F.R.S.

By the death of General James T. Walker, on February 16, the Indian Army, all scientific bodies, and geographical societies, at home and abroad, have to deplore the loss of a gallant and accomplished officer. It is a loss which will be felt most by past and present members of the Indian Survey Department who survive him, who are better cognisant of and can appreciate the many years of service he rendered that Department from first to last, and the talents he devoted to its accurate execution.

Following in the footsteps of previous Superintendents of the Trigonometrical Survey, Colonel Lambton, Sir George Everest, and Sir Andrew Waugh, his principal aim, in guiding the trigonometrical work they had performed, was to carry it to a successful issue, and with the greatest accuracy, more modern instruments, and all that mathematical and geodetical knowledge could achieve. These operations could not have fallen into more zealous, able hands, for it may be said, for the information of those who hear and read little of such work (often insufficiently rewarded), that as a survey of a very large area of the earth's surface, no other area has been so laboriously measured, the observed angles so rigorously computed, and dealt with, and with so little resultant error. Many accomplished brave officers, assistants, and men have also fallen victims to the climate in which the operations were carried on, ranging as it did from the plains of India to the often deadly Terai up to the highest peaks of the Himalayas. In achieving this result, to General Walker, and the officers he directed, is due the greatest measure of praise for its perfectness. All that it entailed from the very commencement in 1800, is to be found in the "Account of the Operations of the Great Trigonometrical Survey of India," twenty volumes, the first nine of which were compiled by General Walker. My first knowledge of his name and work was as far back as 1855, when serving with my regiment at Peshawur I drew for the Quarter-Master General's Department, under the direction of Dr. P. Lumsden, the first map of the Kooram Valley, on which were laid down the peaks on the Sufaidkoh Range, of which Walker had been the first to fix the position. Lieut. Walker's name was well known then in the Panjab, for up to 1853 he had been working single-handed with his usual zeal at the military survey of the Trans-Indus territory. This was dangerous service in those days on that disturbed wild frontier of the north-west of India, which the East India Company had very lately acquired, where the tribesmen might be seen following their bullocks at the plough, *jezail* slung on back. On this survey it may be said Walker carried his life in his hand, he and his party often being the target for these same *jezails*. The ascent of Turturrah Peak in the Khyber Hills is only one instance of a very hazardous piece of work, but the dash and rapidity with which his plans were made and the distance done, surmounted the difficulties, and brought him safe out of the expedition with the coveted angles secured. Similar risky exploration was effected by him on the borders of Eusofzai and along the base of the hills, near where our troops have been lately employed at the Malakand Pass, and in the neighbourhood of Umbeyla. In fact, all we knew of that border topography for many years, and up to very recently, was the outcome of the young engineer's reconnaissance. Very little was said about this work at the time. In those days it was not the fashion to write up, and make so much of such travel, as is now the case. It took place far off in time and distance from home and headquarters, and only those in the district—his immediate superiors and his brother officers—knew the value of it, and the pluck and endurance it demanded. Moreover, by his tact with some of the chiefs, he managed to penetrate even beyond the frontier; but on returning to Peshawur, and reporting his success in this way, and making certain of praise, he received a severe reprimand. It was perhaps feared that in risking his own life, and the men of his party, he also risked embroiling his Government. It was not until 1865, when I had been in the Survey Department some years, and knew more of his work, that I became personally associated with him and under his immediate orders. He was then engaged on the compilation of his first map of Central Asia. I shall never forget the great pleasure of meeting him daily, and how much I learned from him, discussing portions of that country, looking up books of travel, and the latest work of the Russian Survey, and getting that map completed with the Himalayan Range as far east as longitude 81°. It was the first large map turned out in India by the process of photozincography, then but lately introduced into the office at Deyrah Dhoon, and it went through many subsequent editions. It was when engaged on such researches that Walker's knowledge and his intense love for geographical study showed itself. There was at that period much new topography coming in. The work of the Kashmir Survey, under Captain T. G. Montgomerie, R.E., had filled up an immense blank in the northern frontier of India, from the confines of Gilgit and Hunza Nagar to the Chang Chingmo. Mr. W. H. Johnson had just returned from his trip over the Karakoram range to Ilchi in Khotan; his route survey and observations had to be brought into place, and affected the position of other places in that part of Asia.

It was never my good fortune to serve under General Walker in the field; but I can look back on a short spell of camp life with him, on the mountains north of Mussoorie, with those feelings of desire that the time might come over again. Walker had been working hard for months at his computations, and was overworked; I suggested his joining me in a collecting trip I had planned into the hills, and he fell in with the idea. How he enjoyed the complete rest, and entered with zest into my pursuits; how much there was to talk over that was interesting to both; how we revelled in the lovely scenery of the oak-crowned ranges, with the snows of Jumnutri in the distance, and enjoyed the splendid air of October in the Himalayas, which sent him back to duty again quite set-up. In those few days, however, I got to know Walker, and all the good traits in his character, better than per-

haps in a far longer interval of departmental work. Only as one of his many assistants do I now put on paper my own feelings on the loss we have all sustained. A full record of his service and life can only be written by some officer of the Survey who was closely and long associated with him in his geodetical labours.

General Walker passed out of Addiscombe into the Bombay Engineers in 1844, and landed in India in 1846; he retired in 1883. He was an officer of high training and ability, who worked zealously in his profession, and expected others to do the same, taking a keen interest in their work. He had a good record of hard military service during the Panjab campaign at the Siege of Multan and Battle of Gujerat, and during the Mutiny at the Siege of Delhi, where he was severely wounded; he also served in 1860 with the Mahsood Waziri Expedition. He was as good a field surveyor as a geodecist, with a reputation outside his own corps and country; for twenty-two years in charge of the Trigonometrical Survey, and five years Surveyor-General of India; and he was a constant writer on many subjects relating to geography, almost up to the time of his death. Fuller details of these services are to be found in an excellent obituary notice by Mr. Clements Markham, President of the Geographical Society, in the March number of the *Geographical Journal*. H. H. G.-A.

NOTES.

Lord Kelvin has communicated to us the following telegram which he has received from Edison: "Just found calcium tungstate properly crystallised gives splendid fluorescence with Röntgen rays far exceeding platino-cyanide rendering photographs unnecessary."

The Committee of the Athenæum Club, acting under the provisions of the rule of the Club which empowers the annual election by the Committee of nine persons "of distinguished eminence in science, literature, the arts, or for public service," have admitted to membership Prof. Arthur Schuster, F.R.S.

We regret to announce the death at Madras, on February 14, of Mr. Marmaduke Alexander Lawson, M.A., F.L.S., Government Botanist and Director of Cinchona Plantations to the Madras Government. Mr. Lawson held for many years the posts of Sherardian and Sibthorpian Professor at Oxford, which were separated on his resigning to take up a new position in India in 1882.

The French Government has decided to continue to M. Pasteur's widow the annual pension of 25,000 francs (£1000) granted to her regretted husband in 1883.

Prof. Arthur Auwers and Prof. Karl Weierstrass, both of Berlin, have been elected foreign members of the Royal Academy of Mathematical and Physical Sciences of Naples, in the place of the late Profs. Cayley and Hermann von Helmholtz.

The Royal Academy of Mathematical and Physical Sciences of Naples offers a prize of 1000 lire for the best essay (illustrated by specimens) on the geology of the quaternary lakes of the Basilicate. The essays have to be sent in on or before June 30, 1897.

Mr. W. L. Sclater has left England to take up his appaintment as Curator of the South African Museum, Capetown. His successor in the science-mastership at Eton College is Mr. M. D. Hill, of the University of Oxford.

Mr. Edwin Wheeler, of Clifton, Bristol, has presented to the Natural History Museum a valuable series of water-colour drawings of fungi—2449 in number—made by him in illustration of the British fungus flora. The drawings, which fill twelve bulky volumes, represent the result of assiduous labour and observation extending over many years, and the Museum authorities are fortunate in receiving so munificent a gift.

The "Coral-Reef Expedition," under the command of Prof. Sollas, F.R.S., will shortly leave England for the Pacific. Mr. J. S. Gardiner, of Cambridge, who has been selected as Assistant Naturalist, will devote himself to an examination of the fauna and flora of the Ellice Islands, while a deep hole is being bored into the coral-beds of Funa-fute, with the object of ascertaining the depth and exact structure of the formations.

Excellent accounts continue to be received of the progress made by Dr. Forsyth-Major in Madagascar, and several valuable collections made by him have already arrived at the British Museum. Amongst these are numerous remains of the extinct gigantic birds of the family *Æpyornithidæ*, the study of which will, it is expected, considerably increase our knowledge of the structure of this group. The specimens are being examined by the officers of the Geological Department.

Amongst the natural history collections from British Central Africa, last received from Sir Henry Johnston, is a small series of birds obtained, by Mr. Alexander Whyte, on the previously unexplored mountain of Chiradzulu, half-way between Blantyre and Zomba. With the specimens is an example of a new and very beautiful species of Oriole, which Captain Shelley will describe and figure in the next number of the *Ibis*, as *Oriolus chlorocephalus*.

Mr. J. E. S. Moore, who is gone on a mission from the Royal Society to explore the fresh-water fauna of Lake Tanganyika, arrived at Zomba, British Central Africa, on his way there in December last. He was obliged to stop there on account of the Stevenson Road being blocked by the Arabs; but the road having been since cleared by the Commissioner's forces, will now be open for Mr. Moore's further progress to Lake Tanganyika, where we have no doubt he will reap an abundant harvest.

The Zoological Society have lost the large male Indian elephant which was brought home by the Prince of Wales on his return from India in 1876, and presented by his Royal Highness to the collection. After carrying an innumerable number of children up and down the walks for the past twenty years, "Jung Pasha" died quite suddenly on the 8th inst. Although tuskless, he was pronounced by all those experienced in such matters to be one of the finest and largest of living Indian elephants. His skin has been presented to the British Museum of Natural History, and is being stuffed for exhibition in the Mammal Gallery.

As a direct outcome of Mr. Saville-Kent's book on "The Great Barrier Reef of Australia," Prof. Alexander Agassiz has, as already briefly announced, determined to undertake an expedition, having as its express object the investigation of the many subjects associated with this vast and specially interesting biological area. Soundings, and an examination of the ocean bottom and the study of the pelagic and surface faunæ, are subjects which will especially occupy Prof. Agassiz's personal attention. In order to utilise the opportunities that will be presented to their fullest extent, Prof. Agassiz takes with him a trained staff of artists and assistants, and has also engaged the services of the experienced American collector, Mr. W. Ward, to make typical collections of the Madreporarian corals characteristic of the Great Barrier region; and with the special purpose of securing extra large specimens, for exhibition at the Cambridge, Mass., and other of the United States museums.

Prof. Agassiz has been in communication with Mr. Saville-Kent for some months past with reference to the best season of the year and most favourable localities to adopt as the bases of operation for both himself and collectors, who will work independently. Mr. Saville-Kent has asked Mr. Ward to make a measurement of the selected coral growths at Thursday Island, of which he took photographs and constructed a diagrammatic chart six years since. He has also commissioned Mr. Ward to secure certain of the more appropriate of these types, with their registered accession of growth, as a supplementary addition to the extensive series of the Great Barrier reef and other Australian Madreporaria that he has already contributed to the Natural History Museum.

OUR American correspondent writes, under date March 6:—Mr. Daniel G. Elliot is on his way to Africa, where he will hunt large game for the Field Columbian Museum of Chicago. He will have charge of 150 men. At a meeting of the Board of Managers of the New York Botanical Garden, held on March 4, it was announced that the following persons had become patrons: J. Pierpont Morgan, Andrew Carnegie, Cornelius Vanderbilt, J. D. Rockefeller, Darius O. Mills, Addison Brown, James A. Scrymser, William C. Schermerhorn, Charles P. Daly, Oswald Ottendorfer, Samuel Sloan, George J. Gould, Miss Helen M. Gould, J. S. Kennedy, William Rockefeller, James S. Constable, Mrs. Esther Herrman (who contributed 10,000 dols., instead of 5000 dols., which was her first intention, as announced in NATURE of February 6), and James R. Pigeon. The Committee on plans and buildings submitted plans for the greenhouse. An acre is to be covered by glass, and a tower sixty feet high is to be erected in the middle. The Committee was authorised to obtain final plans from architects for the large museum which is to be erected. The scientific directors were authorised to purchase for the garden museum the herbarium of Mr. J. B. Ellis, of Newfield, N.J., consisting of 75,000 specimens of fungi.—The storm of March 2–5 was unparalleled at New York City for the protracted severity of the winds, which at one time reached the velocity of eighty-two miles an hour, being two miles faster than any previous record here. Great difficulty was experienced in navigation in the harbour on account of ice, and travel ashore was more interrupted by snow than at any time since the memorable blizzard of March 1888.

IN connection with the affiliation of Photographic Societies with the Royal Photographic Society, six experimentally-illustrated lectures will be delivered upon the subject of "Photography with the Bichromate Salts," beginning on Friday, April 10, and ending on Tuesday, April 28.

A MEETING of the Institution of Naval Architects will be opened in the hall of the Society of Arts, on Wednesday, March 25, and will be continued on the two following days. The Earl of Hopetoun, President of the Institution, will occupy the chair.

THE anniversary meeting of the British Ornithologists' Union has been fixed this year for Wednesday, April 22, when a large attendance is expected. The Union now numbers nearly three hundred members.

THE next Annual Meeting of the American Microscopical Society will be held at Pittsburg, Pennsylvania, from August 18 to 20. The President for the year is Dr. A. Clifford Mercer, of Syracuse, New York.

AMONG the lecturers and their subjects at the Royal Institution after Easter are:—Prof. James Sully, on child-study and education; Mr. C. Vernon Boys, on ripples in air and on water; Prof. T. G. Bonney, on the building and sculpture of Western Europe (the Tyndall Lectures); Prof. Dewar, on recent chemical progress; Mr. W. Gowland, on the art of working metals in Japan; Dr. Robert Munro, on lake dwellings; and Dr. E. A. Wallis Budge, on the moral and religious literature of Ancient Egypt. The Friday evening meetings will be resumed on April 17, when a discourse will be given by M. G. Lippmann, on colour photography; succeeding discourses will probably be given by Prof. G. V. Poore, Colonel H. Watkin, C.B., Prof. Silvanus P. Thompson, Prof. J. A. Ewing, and Prof. J. A. Fleming, among others.

WE regret to announce the discontinuance of the *American Meteorological Journal* after the forthcoming April number, which ends the twelfth volume. Mr. Robert Ward informs us that the journal has been carried on at a financial loss on the part of the editors ever since its foundation in 1864, and the present step has been decided upon because there seems no hope that it will become self-supporting. Arrangements have been made with the editor of *Science*, whereby Mr. Ward will contribute short notes on, and reviews of, current meteorological publications to that periodical. He therefore hopes authors will send their publications to him in the future as they have done in the past.

THE St. Louis Observatory, at St. Helier, Jersey, is being developed under the able direction of Père Dechevrens, formerly of Zi-ka-wei, in China, well known for his researches on wind, and other subjects in meteorology. This observatory is situated on a small open plateau above the Jesuit College, and one feature of it is a tower, of Eiffel type, about 170 feet high, with spiral staircase, and a number of instruments at the top, connected by a cable of twelve electric wires with recording apparatus in the house. Among these instruments is an anemometer of somewhat special design. A T-shaped support, with orienting arrangement, bears on one arm an anemometer with half cylinders instead of the usual cups, being thus made sensitive, it is claimed, to horizontal currents only; while a helical fan on the other arm gives the vertical component. The *Bulletin* for 1895 (the second year) contains very full information of the various weather elements, including hourly variation of pressure and temperature, and of the velocity of the wind. It is a curious fact, observed at this station, as at the Eiffel Tower in Paris, that the diurnal variation of wind velocity shows an opposite character near the ground and at the top of the tower; in the former case the velocity reaches its maximum about midday, and in the latter about midnight. The climate of the Channel Islands is interesting in many respects, and a well-equipped station like that of St. Louis may be expected to add largely to our knowledge of it.

THE Report of the Meteorological Council for the year ending March 31, 1895, has just been presented to Parliament. The Council have continued the practice of lending instruments to captains of merchant vessels for the purpose of obtaining observations made at sea, and of supplying instruments to the Royal Navy. A very large proportion of logs returned are classed as "excellent," and these observations have been largely supplemented by the Remark Books kept on H.M. ships, and by logs received from the Ocean Steamship Company of Liverpool and others. Among the works actually published, or in course of publication, are charts of the Red Sea, current charts for all oceans, and meteorological charts embracing the area from the Cape of Good Hope to New Zealand. It was for the purpose of collecting and publishing information of use to seamen that the Meteorological Department of the Board of Trade was first established in 1854, as the outcome of the Maritime Conference of Brussels in the previous year. But as time went on, the attention of Admiral FitzRoy was turned to the more practical branch of weather prediction, and this subject now forms an

entirely distinct and important department of the Office. Storm signals are supplied to all ports at which the local authorities will undertake their management. The report shows that the signals were hoisted at 180 stations, but more recently the number has been considerably augmented by their exhibition at exposed lighthouses, for the benefit of passing vessels. Weather forecasts are prepared three times daily, and are also sent to a selected number of agricultural districts during hay-making. A comparison of the results obtained for these forecasts gave a total percentage of 89, which is considered to be very satisfactory. The department dealing with climatology of the British Isles receives observations from 245 stations; the results are collated and published in various forms, available for present or future discussions. Much attention is also paid to the collection of rainfall values, the comparison of various kinds of anemometers, and other researches.

THE report of the Committee, appointed in May of last year, to inquire into the causes of the explosion, and the precautions required to ensure the safety, of cylinders of compressed gas, has now appeared. The Committee, in addition to examining manufacturers of the cylinders in which compressed gases and liquefied gases are sold, and some of the engineers who make and compress the gases, visited works where the manufacture is carried on, and conducted a series of experiments to determine the causes of the accidents to cylinders, and on the amount of damage such explosions are likely to produce. The information thus obtained has enabled them to draw up a detailed statement of the conditions which are necessary to secure safety in the transport and use of compressed gas cylinders, and as to the regulations which would be desirable to prevent risk. The risks of explosion fall into two classes, viz.: (1) risks due to negligence in the manufacture, annealing, and testing of the cylinders; (2) risks due to neglect of precautions in filling the cylinders. As the manufacture is carried on very extensively, and is likely to increase, the Committee think that the risks would be reduced if there were some control of the trade of making cylinders by official inspection. They suggest that there should be a general inspection of all factories manufacturing compressed or liquefied gases. If an inspector were satisfied that the arrangements at any factory were adequate, and that the precautions laid down in this report were being taken, a certificate would be granted authorising such factories to test and mark cylinders. It is suggested that a first thorough inspection, and an occasional inspection subsequently, at intervals of about six months, would be sufficient as a ground for granting and renewing certificates. The report is signed by Profs. W. C. Unwin, C. V. Boys, H. B. Dixon, Dr. A. Dupré, and the Rev. F. J. Smith.

HITHERTO most experiments with the Röntgen rays in this country have been made with the object of photographing living human hands and feet, in which only the bones are represented. On the continent, however, the "new photography" has been employed with remarkable success to delineate the arteries in a hand injected with a substance opaque to the Röntgen rays. Some experiments of this kind are described by Dr. Uberto Dutto, of Rome (*Att. R. Acc. Lincei*). Observing that the opacity of bones to the new rays is probably due to salts of calcium, of which they so largely consist, a human hand was injected with a paste of plaster of Paris sufficiently thin to penetrate the smaller arteries, and as soon as this had hardened, the hand was photographed in the usual way, the Crookes' tube being fixed at sufficient distance from the plate to produce sharp outlines. It would be interesting to try obtaining stereoscopic views of such specimens; this could, no doubt, be readily done by projecting the rays obliquely on the specimen and plate, first from one side and then from the other. Dr. Dutto points out the great value of this method in facilitating the study of anatomy.

IN one of a series of articles on the use of the Crompton Potentiometer, which he is communicating to *The Electrician*, Mr. Fisher gives some very interesting tests which have been applied to standard Clark cells. The form of cell used is that supplied by Messrs. Muirhead, in which the positive pole consists of a spiral of platinum wire amalgamated and filled with mercury. It is very generally believed that if by any chance a Clark cell becomes short-circuited, then the cell is either totally ruined or only recovers after a very long time. Mr. Fisher has shown that the Clark cell will stand very much rougher usage than one would think, and still recover even in a very short time. In one set of experiments a Muirhead pattern cell had for one minute a potential applied to the terminals of $\frac{1}{100}$ volt in excess of the electro-motive force of the cell. As a result, the electro-motive force rose about three parts in 14,000; but regained its normal value after ten minutes. After short-circuiting for one minute through 500 ohms the electro-motive force fell from 1·4323 volts to 1·431, but recovered its normal value after thirty minutes. Short-circuiting the cell through two inches of No. 18 copper wire for thirty seconds caused a drop from 1·4319 volts to below 1·431; but after thirty minutes it had almost recovered. A cell having been short-circuited through a few inches of copper wire (No. 20) for twenty hours, its electro-motive force fell to 0·17 volt. The recovery was at first very slow, and continued so till it reached 0·5 volt, the average rate of recovery being 0·03 volt per hour. After this the recovery was much more rapid, and in twenty-four hours the cell had almost completely recovered. The effect of applying a constant potential of 1·4 volts to a cell which had been "dead" short-circuited for twenty hours, was to very much hasten the recovery, so that after two and a half hours it had regained its former value. The author has found that the resistance of a Clark cell rises very rapidly if the cell is used to send any appreciable current, and he supposes that whatever is the cause of this increase of resistance and the fall of potential, it in is a great measure of the character of a "skin effect." Some tests made of two cells set up by Prof. Fleming in 1886 or 1887, seem to show that when these cells were in continuous use, so that they were employed to send small currents, and had small currents driven through them, their electro-motive forces were in very much better agreement than when standing idle. From these and other experiments the author concludes that the passage of these small currents through standard Clark cells is decidedly beneficial.

The South Slavs have a number of independent folk-songs which, unlike the great Homeric epics, have not been welded into an harmonious whole. Dr. Krauss (*Internationales Archiv für Ethnographie*, vol. ix.) elucidates these songs by notes on various customs and beliefs, especially those relating to death and burial. The South Slavs save money during the whole of life in order to ensure a grand funeral, and they honour graves and graveyards in many ways, considering it a crime to cultivate the ground of a graveyard; but the Catholic priests of Pozega did not hesitate to do so, and grew in them the best cabbages and the largest turnips in the district. There is an amusing account of cuckoo folk-lore in the same journal; and though the legends vary slightly, the cuckoo is regarded by all the South Slavs as a woman changed into a bird for excessive mourning over a dead son or brother.

WE have received from Miss E. A. Ormerod the nineteenth of her valuable "Reports on Injurious Insects," dealing with insect pests which were specially noticeable during 1895. It is fully equal, both in size and importance, to its predecessors, and is

divided into three sections, the first being devoted to insects, &c., injurious to cultivated plants; the second to flies injurious to horses, cattle, &c.; and the third to ticks. In her preface, Miss Ormerod alludes to the fact of the terribly cold weather experienced during January and February, 1895, having had no apparent injurious effect whatever on insect life. She also alludes to the great loss which entomologists have lately suffered by the death of Prof. C. V. Riley. As usual, the report is fully illustrated; but a new and striking feature is the insertion of two full-page illustrations of the foot of the Forest Fly (highly magnified, of course) the thick curved claws of which, as thus represented, present a curious and by no means remote resemblance to a pair of cow's horns. The first insect mentioned in the report is the Eyed Hawk-moth, the larva of which seems to be very injurious to apple-trees at times, though often overlooked from its colour resembling that of the leaves of the tree. As a rule, however, the larger *Sphingidæ* are rarely common enough in England to be destructive; but it is self-evident that no insects which feed on cultivated plants can be harmless, when unusually abundant. We hope to have the pleasure of receiving Miss Ormerod's annual reports for many years to come. The practical usefulness of entomology was formerly held in doubt; but such reports alone ought to be amply sufficient to remove the last remains of uncertainty on the subject.

IN a paper in the *Transactions* of the English Arboricultural Society for 1895, "On the Effect of Frost on Trees and Shrubs," by Dr. William Somerville, the growth of the Black Austrian Pine is recommended in exposed situations subject to severe cold, that tree having escaped almost entirely unscathed from the effects of the intense frost of the winter of 1894–95.

WE have received the report of the proceedings of the Annual Meeting of the American Microscopical Society, held last year at Cornell University, Ithaca, New York, contained in the *Transactions* of the Society. The address of the President, Mr. S. H. Gage, was on the "Processes of Life revealed by the Microscope: a Plea for Physiological Histology." The volume includes also reports of a number of papers in various departments of microscopy and natural history.

THE *Kew Bulletin of Miscellaneous Information* for February contains an interesting report of the result of an inquiry on a point of some importance to the Excise, the presence of natural sugar in tobacco. It has been established that saccharine matter may be present in unadulterated Virginian tobacco to the extent of 15·2 per cent., and even in tobacco grown in this country to the extent of 9 per cent. Dr. Hugo Müller is of opinion that the sugar is not in the form of either lævulose or glucose, but that it is composed of at least three different carbohydrates which appear to be new to chemistry.

PRINCE BALTHASAR BONCOMPAGNI'S heirs have decided to sell his valuable library in the Palais Cenci, Rome. The library comprises more than eleven thousand different works, and will be sold *en bloc.* The Mathematical Section contains a very rare collection of works on arithmetic; and there are also numerous works on natural science and archæology in the library. Applications for catalogues should be sent to M. l'Avv. Francesco Sirani, 14 via del Nazareno, Rome.

THE thirty-third annual issue of that most useful publication, "The Statesman's Year-Book" (Macmillan), edited by Mr. Scott Keltie, with the assistance of Mr. J. P. A. Renwick, has just come to hand. A new feature, which will be much appreciated by the numerous people who consult the annual, is the insertion of four coloured maps, to illustrate the Anglo-Russian delimitation of the Pamirs, the Anglo-French arrangement with respect to Siam, the British Guiana and Venezuela boundary dispute, and recent arrangements in Bechuanaland.

A PAPER on the progress of science in England from the seventh to the thirteenth century inclusive, read before the Manchester Literary and Philosophical Society, appears in the number of the *Memoirs* of the Society just received (vol. x. No. 1, 1895–96). Other papers to which attention may well be directed are: "On Helium and its place in the Natural Classification of Elementary Substances," and "The Indefinite Quantitative Relations of the Physical and Chemical Forces," both by Dr. Henry Wilde, F.R.S., and an account of "Experiments on the Latent Heat of Steam," by Dr. J. A. Harker.

THE second volume of "Contributions to Canadian Palæontology" (*Geol. Surv. Canada*) consists of three papers on Arthropoda, by S. H. Scudder. Of these the most generally interesting one is that describing certain Myriapods and Scorpions from the famous hollow trunks of Sigillarians found in the coalfields of Nova Scotia. Another group of palæontological papers from the same region come from the *Transactions* of the Royal Society of Canada. They contain descriptions, by J. F. Whiteaves, of Cretaceous fossils from British Columbia, which afford some confirmation of Dr. Kossmat's views as to the distribution of Cretaceous land and sea, summarised some months back in these columns.

A DETAILED account of the Upper Palæozoic (Permian and Carboniferous) formations of Central Kansas, by C. S. Prosser, is to be found in the *Journal of Geology*, vol. iii. No. 7. The importance of this region in the general correlation of these beds has long been recognised, since here, unlike the Eastern States, coal is rare, and there is an almost unbroken series of marine strata from Carboniferous to Permian. The author shows that the Carboniferous brachiopod fauna does not extend as high as had previously been asserted, and that the higher beds contain a characteristic Permian lamellibranch fauna. He is thus able to draw a fairly definite line between Carboniferous and Permian (or Permo-Carboniferous), which he draws, for convenience of mapping, at the top of certain fossiliferous shales overlying the *Fusulina*-limestone. According to these views, Waagen, in his correlation of the Upper Palæozoic strata of India and of other countries, drew the base of the Permo-Carboniferous in the Western States too low; but this correction does not affect the general value of his correlation.

A NEW monthly review—the *Revue de l'Université de Bruxelles*—has made its appearance, its foundation being a sign of the era of prosperity and expansion inaugurated by the creation of the new institutes with which the "Université libre" has lately been endowed. The review is not to be the organ of any particular school of thought, but will include within its purview history, philosophy, science, social economy, and all branches of higher education. It is intended to be the focus of all the efforts made in the University world, and particularly in the Université libre de Bruxelles, for the advancement of science and study. The first two numbers of the new publication contain articles on penal law; great biological discoveries made during this century; the Botanic Garden at Buitenzorg; constitutional law; the work of Hittorf, Lenard, Goldstein, and Röntgen; and the International University Alliance.

THE twenty-sixth volume of the *Proceedings* of the London Mathematical Society, containing the papers read before the Society during the session 1894–95, has come to hand. In Mr. A. B. Kempe's presidential address, with which the volume opens, definitions of mathematics are discussed, and a new one formulated. According to dictionaries, mathematics is "the

science of number and magnitude," "the science which treats of the propertie and relations of quantities," or more briefly, "the science of quantity." Occasional definitions of a more comprehensive character are to be found scattered here and there in mathematical and other writings, but Mr. Kempe doubts whether any of them would satisfy a large body of modern mathematicians; therefore he suggests the following as a provisional definition: "Mathematics is the science by which we investigate those characteristics of any subject-matter of thought which are due to the conception that it consists of a number of differing and non-differing individuals and pluralities." Perhaps this definition will provoke some one to formulate another.

THE playgrounds of our public schools are said to be the arenas in which British battles are fought; and, in a similar sense, we may say that the scientific societies of our colleges are the training schools of scientific investigators. The system of compulsory games tends greatly to limit the time which public schoolboys can devote to natural history or other research, but a few enthusiasts contrive to gratify their curiosity to know something about natural facts and things. The twelfth annual report of the Felsted School Scientific Society testifies to the existence of this spirit of inquiry. Among the papers it contains, we notice one on "The Geology of Felsted," by Mr. J. French, and another on "Recent and Proposed Arctic Exploration," by Mr. J. F. Hartin. The Society used only to be concerned with natural science, but its field of operations has been enlarged, and its usefulness increased, by the creation of a Chemical Section. Stern methods are taken to keep up the attendances at the meetings, for we read: "That any member failing to attend at least one ordinary general meeting in each term in which such meetings are held, without reasonable excuse, be liable to ejection from the Society." It is appalling to think what would be the result of the application of this rule to many learned societies.

A LARGE number of students, as well as persons who do not pretend to possess any special scientific culture, will be glad to know that Tyndall's "Glaciers of the Alps" (Longmans, Green, and Co.), first published nearly six-and-thirty years ago, and for a long time out of print, has been reprinted. Upon Lord Kelvin's advice, no changes have been made in the controversial portions of the book, so the text has been left practically unaltered. Messrs. Kegan Paul and Co. have published a popular edition of Sir John Lubbock's standard work on "Seedlings," reviewed in these columns in January 1893 (vol. xlvii. p. 243). The parts included in the new volume are those of most general interest, and 282 of the 684 illustrations in the original work are used to elucidate the text. A new edition has been published of "Griffin's Electrical Engineers' Price-Book," edited by Mr. H. J. Dowsing. Nearly seventy pages of new matter have been added, and the whole of the prices have been brought up to date. Electrical and other engineers and contractors know that the volume is a ready and trustworthy means of reference to the prices with which they have to deal. The new and improved edition of "Historical and Future Eclipses," by the Rev. S. J. Johnson, just published by Messrs. James Parker and Co., will be appreciated as fully as the original little volume, which came out twenty-one years ago. The book is extremely handy, and contains not only a vast amount of interesting information with regard to eclipses of past and future time, but also notes on planets, double stars, and other celestial matters, thus making it valuable to practical astronomers.

THE additions to the Zoological Society's Gardens during the past week include a Campbell's Monkey (*Cercopithecus campbelli*, ♂) from West Africa, presented by Miss Lilian Frost; two Black-backed Jackals (*Canis mesomelas*), a Puff Adder (*Vipera arietans*) from South Africa, presented by Mr. J. E. Matcham; a Condor (*Sarcorhampus gryphus*) from South America, presented by Mr. C. J. Wedderburn; a Guillemot (*Lomvia troile*), British, presented by Mr. J. L. Palmer; a Moorish Tortoise (*Testudo mauritanica*), from North Africa, presented by Mrs. Powell; a White-crowned Mangabey (*Cercocebus æthiops*, ♀) from West Africa, an Isabelline Lynx (*Felis isabellina*, ♂) from Ladakh, Cashmere, deposited; a Maguari Stork (*Dissura maguari*), a Guira Cuckoo (*Guira piririgua*), a Burrowing Owl (*Speotyto cunicularia*), a Brown Milvago (*Milvago chimango*), a Condor (*Sarcorhamphus gryphus*), a Boa (*Boa constrictor*) from South America, six Mexican Quails (*Callipepla squamata*) from Mexico, a Scarlet Tanager (*Ramphocœlus brasilius*), three Scarlet Ibises (*Eudocimus ruber*) from Para, a Ruff (*Machates pugnax*), two Redshanks (*Totanus calidris*), British, purchased.

OUR ASTRONOMICAL COLUMN.

VARIABLE STAR CLUSTERS.—The recent announcement by Prof. Pickering, of the discovery of variability in a large number of stars forming parts of star clusters (NATURE, vol. liii. p. 91), has led Dr. Belopolsky to examine some of the photographs of clusters taken at Pulkowa. Two photographs of the cluster M3 (N.G.C. 5272), in Canes Venatici, were taken in March 1894, and two more in April 1895. In the later photographs one sar was found to be two magnitudes brighter than in 1894, anddi fferences of brightness can also be traced in the case of other stars among the 1800 shown upon the photographs (*Ast. Nach.*, 3338). The Arequipa negatives of the same cluster indicated a variation of brightness in eighty-seven stars, amounting in some cases to at least two magnitudes.

THE SPOTS ON SATURN.—The inability of Prof. Barnard to detect any spots on Saturn with the aid of the Lick telescope may possibly have thrown some doubt upon the existence of such spots. Nevertheless, the observations of them by Mr. Stanley Williams have given such remarkably consistent results, that it is difficult to believe them illusory. In a recent article (*Observatory*, March, p. 112) Mr. Williams points out that there has been some misconception as to the nature of the Saturnian spots and the conditions for their satisfactory observation. While generally admitting the superiority of large telescopes, Mr. Williams holds that the spots on Saturn are such as to require a sight specially trained for their observation. The characteristics of the spots are (1) considerable size, (2) faintness, (3) extreme indefiniteness. The bright equatorial spots average about 2″ in diameter, while the dark spots on the broad double belt in the northern hemisphere have sometimes appeared as large as 4″ long by 2″ or 3″ broad. Similar spots have been noted by other observers, and the estimated positions have been sufficiently accordant to make it probable that the same objects were observed.

The planet will be in opposition on May 5, and it is to be hoped that the spots will receive the attention of observers. The spots appear to be best seen with low powers; with a power of 140 an equatorial spot has been observed to shine with almost stellar brightness, but with higher powers this peculiar brilliancy disappeared. Another point in Mr. Williams' experience is worth putting on record, namely, that in the south of England, at least, definition is usually much better about the time of sunset and for an hour afterwards than at other times.

COMPUTATION OF THE TIMES OF SOLAR ECLIPSES AND OCCULTATIONS.—In the *Revista do Observatorio* (Rio de Janeiro) for 1886, an account was given of a graphical method by which the approximate times of occurrences of solar eclipses and occultations, sufficiently accurate for first approximations, could be determined. Three years later, in a subsequent *Revista*, an application of this method to the eclipse of the sun of December 22, 1889, was made by Mr. Morize, of the Observatory of Rio. With the idea of making this method more general and applicable for all latitudes, the Director of the Observatory, Mr. L. Cruls, has published a short account of the method, simplified both as regards the computations and the graphical construction. The principle is based on the parallactic displacement of the moon in right ascension and polar distance, the values of which

have to be calculated for certain suitable and equidistant intervals of time. Knowing the hourly movements of the moon in right ascension and polar distance for the same instants from the almanack, and the elements of the phenomena, whether it be eclipse or occultation, the tracing of the positions of the bodies may be proceeded with. The plane of the drawing is supposed to represent that plane which is at right angles to the line joining the centre of the moon and the observer, at any one of the chosen instants near the time of conjunction of the two bodies. On this plane the successive projected true and apparent positions of the two bodies, sun and moon, or moon and star, are considered. The line passing through the centres of the moon in her different positions will thus represent the apparent lunar orbit, and if in addition we know the position at the moment of true conjunction of the two bodies, occupied by the centre of the sun or star, according as we are dealing with an eclipse or occultation, it will be easy to find the positions of the centres at the moments of contact, or of immersion and emersion, and also the times.

The calculation of the elements necessary for making the drawing would have for its aim the determination of the coordinates of the points of the apparent orbit occupied by the centre of the moon. This work is here rendered very easy by using the series of tables which have been prepared for reducing the calculation to a minimum. As an illustration showing the method of procedure, Mr. Cruls gives two complete worked-out cases, one of the eclipse of the sun at Rio de Janeiro April 16, 1893, and another of the occultation of α Virginis on March 22, 1894, at Greenwich. The accuracy of this graphical method may be gauged from the *observed* minus *calculated* values obtained in the two cases just mentioned.

PENDULUM OBSERVATIONS IN GERMANY.

IT is a well-known fact that, at different places on the earth's surface and at the same sea-level, pendulums change their rates of swing. The numerous observations of von Sterneck, made in the region of the Alps, suggested that such deviations from the normal might be, and were most probably, explained on the supposition of unequal distributions of the masses in the neighbourhood—that is, either inside the mountains or in the earth's crust itself. Such observations as these indicated that good work might be done in this direction, and in consequence measurements were made on Mont Blanc, while in other directions observations were being organised by the scientific societies in Vienna, München, Leipzig, and Göttingen. The gravity determinations on Mount Blanc were made at the new observatory, and M. Jannsen informs us that besides those made in Chamounix in the previous summer, and on the Grands Mulets (3050 metres elevation), by M. Bigourdan, an effort will be made to continue them this summer on the summit itself. The results which have been obtained up to the present are as yet unpublished. A region which appeared full of interest for investigating the different rates of swinging pendulums is that in the region of Göttingen and the Harz Mountains. Prof. von Könen singled out what he thought were the three most suitable spots on account of their different geological conditions for such investigations, and observations at these stations were all compared with those made at Göttingen, this being the chief observing station on account of the observatory. It is true that the instrument employed in these determinations was far too rough for accurate and reliable measurements, it being the one which Dr. von Drygalski had previously used on his Greenland expedition, and with which Sterneck made his first experiments. The actual observations were made by Prof. Wilhelm Schur and Dr. Grossmann, and the results were communicated to the *Nachrichten der K. G. der Wiss. Gött.*, Heft 2, 1895. These may be summed up as follows. In the cases of the two stations at Grünenplan and Teichmühle, the very small differences when compared with Göttingen may be neglected when the kind of instrument employed be taken into consideration. The difference for the station Sack, on the other hand, was comparatively large, the numbers being—

For Grünenplan		Sack		Teichmühle
−0·00018	...	−0·00081	...	−0·00028

The conclusion drawn by Prof. von Könen from this somewhat rough determination was that the diminution in the intensity of gravity for the station Sack might possibly be due to the present condition of the positions of the underlying superposed strata (Schichtenüberschiebung).

Since the above determinations were made, the same ground has been covered, in September and October last, by Herr Haasemann, who, at the request of Geheimrath Helmert, undertook to make a series of measurements at the same observing stations as used by Prof. Schur. In this new investigation the instruments employed were more accurate and of later design, so that the results may be looked upon as more trustworthy and accurate. Limiting ourselves to giving the actual numerical results, the differences for the three stations when compared as before with Göttingen were—

For Grünenplan		Sack		Teichmühle
+0·00007	...	−0·00003	...	−0·00011

Comparing these figures with those obtained by Prof. Schur, the large difference for Sack entirely disappears. This indicates that at these places the determinations of the rates of the pendulums give no trace of any variation in the intensity of gravity, or at least of any variation which is capable of being detected by the apparatus employed. D.

PETROLEUM LAMP ACCIDENTS.

THE report of Mr. Alfred Spencer, chief officer of the Public Control Department of the London County Council, as to the causes of petroleum lamp accidents, and as to the measures necessary for preventing them, which has just been issued, is an important document. The number of accidents due to the use of cheap and unsafe petroleum lamps has assumed alarming proportions within the past few years, that the means by which the accidents can be prevented cannot be too prominently or too frequently brought before the public. Mr. Spencer has made a thorough investigation with numerous lamps and stoves in which petroleum is used, in order to determine the conditions of safety. The results of his experiments lead him to conclude that raising the flash-point fixed by the Petroleum Acts would not alone be effectual in preventing lamp accidents, as this would not prevent the sale and use for illuminating purposes of oil below that flash-point. He remarks, however, that the prohibition of the retail sale, and the prevention of the use for illuminating purposes of mineral oil below a flashing-point sufficiently high to prevent all lamp accidents, would be effectual if it were practicable. The prohibition by statute of the sale of unsafe lamps would be another means of putting an end to lamp accidents, as both experience and experiment have proved that mineral oils, such as are now in common use, can be safely burnt in properly constructed lamps. The difficulties in the way of prohibiting the sale of unsafe oil are far greater than would be met in regulating the construction and sale of safe lamps; therefore Mr. Spencer suggests that the latter is the means of safety which should be enforced by order of the Secretary of State. His suggestions for the safe construction and proper management of lamps, revised in the light of recent experiments, are as follows:—

CONSTRUCTION.

(1) The oil reservoir should be of strong metal, properly folded and soldered at the joint, and should not be of china, glass, or other fragile material.

(2) There should be no opening between the reservoir and the burner, other than through the tube which holds the wick; and this tube should be extended to within ¼ in. of the bottom of the reservoir, and should have no opening into the reservoir except at its base.

(3) The burner should be securely attached to the reservoir, preferably by means of a strong and well-made screw attachment.

(4) There should be no openings through which oil could flow from the reservoir should the lamp be upset.

(5) Every table lamp should have a broad and heavy base, to which the reservoir should be strongly attached.

WICKS.

(6) Wicks should be soft, and not tightly plaited, and should quite fill the wick-tube without having to be squeezed into it.

(7) Wicks should be frequently renewed, and before being put into lamps should be dried at a fire and then immediately soaked with oil.

Management.

(8) The reservoir should be filled with oil before the lamp is lit.

(9) The lamp should be kept thoroughly clean, all oil should be carefully wiped off, and all charred wick and dirt removed before lighting.

(10) When first lit the wick should be partially turned down, and then gradually raised.

(11) The wick should not be left turned down, as there is then a greater liability to explosion in lamps of unsafe construction.

(12) Lamps which have no extinguishing apparatus should be put out as follows:—The wick should be turned down until there is only a small flickering flame, and a sharp puff of breath should then be sent across the top of the chimney, but not down it.

(13) Cans or bottles used for oil should be free from water and dirt, and should be kept thoroughly closed.

Note.—These suggestions apply to ordinary petroleum or paraffin lamps such as are generally used, and not to benzoline or spirit lamps.

FORTHCOMING SCIENTIFIC BOOKS.

We print below a list of books on science promised for publication during the spring season:—

Messrs. Swan Sonnenschein and Co., Limited, announce:—Analytic Psychology, by G. F. Stout, 2 vols.; Outlines of Logic and Metaphysics, by Johann Eduard Erdmann, translated from the fourth German edition, with a prefatory essay, by Dr. B. C. Burt; An Introduction to the Study of Philosophy, by Prof. Oswald Külpe, translated under the supervision of Prof. E. B. Titchener; Text-book of Palæontology for Zoological Students, by Theodore T. Groom, fully illustrated; The Indian Calendar, with Tables for the Conversion of Hindu and Muhammedan into A.D. dates and *vice versâ*, by Robert Sewell, with Tables of Eclipses visible in India, by Dr. Robert Schram; Practical Plant Physiology, by Prof. Wilhelm Detmer, translated by S. A. Moor; Introduction to the Study of Organic Chemistry, by J. Wade; Fishes, by the Rev. H. A. Macpherson; Mammalia, by the Rev. H. A. Macpherson; Birds' Eggs and Nests, by W. C. J. Ruskin Butterfield; Mosses, by J. E. Bagnall, fourth edition; The Dynamo, how Made and how Used, by S. R. Bottone, ninth edition; Geometry for Kindergarten Students, by Adeline Pullar, 499 illustrations.

Messrs. Cassell and Co., Limited, give notice of Cottage Gardening, Poultry, Bees, Allotments, Food, House, Window and Town Gardens, edited by W. Robinson, fully illustrated and containing coloured plates, half-yearly volume; new volumes of the "Century Science" Series, edited by Sir Henry Roscoe, F.R.S.:—Sir Humphrey Davy, by T. E. Thorpe, F.R.S.; J. Clerk Maxwell and Modern Physics, by R. T. Glazebrook, F.R.S.; Birds' Nests, Eggs, and Egg Collecting, by R. Kearton, illustrated; Lessons in Carpentry Workshop Practice, by Charles F. Mitchell, new and revised edition; Cassell's Gazetteer of Great Britain and Ireland, with numerous illustrations and maps in colours, vol. iii.; The Countries of the World, by Dr. Robert Brown, profusely illustrated, vol. ii. of the cheap edition; The World of Wonders, illustrated, vol. i. of the cheap edition; Science for All, illustrated; Cassell's Concise Cyclopædia, illustrated.

Messrs. Macmillan and Co., Limited, will publish Miscellaneous Papers by Heinrich Hertz, with an introduction by Prof. Philipp Lenard, authorised English translation by D. E. Jones and G. A. Scholt; Studies in the Art Anatomy of Animals, being a brief analysis of the visible forms of the more familiar mammals and birds, designed for the use of sculptors, painters, illustrators, naturalists, and taxidermists, by Ernest E. Thompson; Text-book of Comparative Anatomy, by Dr. Arnold Lang, translated into English by Henry M. Bernard and Matilda Bernard, part ii.; Macmillan's Geography Readers, book v., Europe, book vi., the Colonies of Great Britain, illustrated; A System of Medicine, by many writers, edited by Thomas Clifford Allbutt, F.R.S.; Domestic Science Readers, by Vincent T. Murché, for standards i.–vi.; Science Class Books:—Physics for Medical Students, by Alfred Daniell; the Scenery of Switzerland, by Sir John Lubbock, Bart., F.R.S.; a Dictionary of Chemical Solubilities, Inorganic, by Dr. Arthur Messenger Comey; the Theory of Sound, by Lord Rayleigh, F.R.S., vol. ii., second edition, revised and enlarged.

The Cambridge University Press has in preparation:—The Collected Mathematical Papers of the late Arthur Cayley, F.R.S., to be completed in thirteen volumes, vol. ix.; An Introductory Treatise on the Lunar Theory, by Prof. E. W. Brown; The Scientific Papers of John Couch Adams, F.R.S., vol. i., edited by Dr. William Grylls Adams, F.R.S.; A Treatise on Abel's Theorem, by H. F. Baker; Cambridge Natural Science Manuals, Biological Series, general editor, A. E. Shipley; Elementary Palæontology, Invertebrate, by H. Woods, new edition; A Manual of the Phanerogams and Ferns, Morphology, Natural History and Classification, alphabetically arranged by J. C. Willis; Physical Series, general editor, R. T. Glazebrook, F.R.S.; Electricity and Magnetism, by R. T. Glazebrook, F.R.S.; Cambridge Geographical Series, general editor, Dr. F. H. H. Guillemard; Geographical Distribution of Mammals, by R. Lydekker, F.R.S.

Mr. W. B. Clive (University Correspondence College Press) announces:—A Manual of Psychology, by G. F. Stout; A Manual of Logic, by J. Welton, complete in 2 volumes, vol. i., 2nd edition; Questions on Welton's Logic, with Illustrative Examples, by H. Holman, Key to Holman's "Questions on Welton's Logic"; A Primer of Logic, by J. Welton; Euclid, Books i.–iv., by Rupert Deakin; Deductions in Euclid, by T. W. Edmondson and J. Briggs; Geometrical Conic Sections, Co-ordinate Geometry, part ii, A Higher Text-book of Dynamics, A Higher Text-book of Hydrostatics, each by Dr. G. H Bryan, F.R.S.; Key to the Elementary Mechanics of William Briggs and G. H. Bryan, F.R.S.; The Tutorial Trigonometry, An Intermediate Text-book of Statics, An Intermediate Text-book of Dynamics, The Tutorial Algebra, each by William Briggs and Dr. G. H. Bryan, F.R.S.; The Properties of Matter, an Introduction to the Tutorial Physics, by E. Catchpool; Inorganic Chemistry, First Stage; A Synopsis of Non-Metallic (Inorganic) Chemistry, by William Briggs, 4th edition, revised by W. Hurtley; A Synopsis of Metallic Chemistry, by W. Hurtley; The Tutorial Chemistry, by Dr. G. H. Bailey; part i. Non-metals; part ii. Metals; Magnetism and Electricity, First Stage; Sound, Light and Heat, First Stage, by John Don.

Messrs. Crosby Lockwood and Son's announcements are:—Light Railways for the United Kingdom, India, and the Colonies: a Practical Handbook on their Construction, Equipment, &c., by J. C. Mackay; Nitro-Explosives: a Practical Treatise on their Manufacture, Properties, and Analysis, by P. Gerald Sanford; Colliery Working and Management: comprising the Duties of a Colliery Manager, and the Different Systems of working Coal Seams, by H. F. Bulman and R. A. S. Redmayne; The Detection and Estimation of Inflammable Gas and Vapour in the Air, by Prof. Frank Clowes, with a chapter on the Detection of Inflammable Petroleum-Vapour, by Boverton Redwood; Handy General Earthwork Tables, by J. H. Watson Buck; a fourth edition of F. W. Simms's Practical Tunnelling, revised and greatly extended, with additional chapters illustrating recent practice, by D. K. Clark; and a new edition of Warn's The Sheet Metal Worker's Instructor, rewritten and greatly extended by J. G. Horner.

Mr. John C. Nimmo promises The Flora of the Alps, being a description of all the species of flowering plants indigenous to Switzerland, and of the Alpine species of the adjacent mountain districts of France, Italy, and Austria, including the Pyrenees, by Alfred W. Bennett, with 120 coloured plates, 2 vols.; A Natural History of British Moths, by the Rev. F. O. Morris, fourth edition, with an introduction by Dr. W. Egmont Kirby, and 132 plates coloured by hand, 1933 figures of moths; A History of British Birds, by the Rev. F. O. Morris, in 36 monthly parts, vol. ii., containing 7–12, with 69 plates coloured by hand.

Messrs. Sampson Low, Marston, and Co., Limited, are preparing:—Text-book of Zoology, by Dr. J. E. V. Boas, translated by J. W. Kirkaldy and E. C. Pollard, illustrated; Short Studies in Physical Science, by Vaughan Cornish, with four plates; Handbook of Arctic Discoveries, by General A. W. Greely, with portrait and maps; The Land of an African Sultan, Travels in Morocco, by Walter B. Harris; The Wild North Land, by General Sir W. F. Butler; Textile Calculators, by E. A. Posselt; Health and Condition in the Active and the Sedentary, by N. E. Yorke-Davies, third edition, revised and enlarged.

Messrs. A. and C. Black promise Artistic and Scientific Taxidermy and Modelling, by Montagu Browne; Text-book of General Pathology and Pathological Anatomy, by Prof. Thoma,

translated by Dr. Alexander Bruce, 2 vols; Plea for a Simpler Life, by Dr. George S. Keith, fifth edition; The Evolution of Bird-song, with observations on the influence of heredity and imitation, by Charles A. Witchell.

Messrs. Smith, Elder, and Co.'s list is as follows:—The Spas and Mineral Waters of Europe, with Notes on the Utility of Spa Treatment in various Diseases and Morbid Conditions, by Drs. Hermann Weber and Frederick Parkes Weber; The Treatment of Phthisis, by Arthur Ransome, F.R.S.

Messrs. G. P. Putnam's Sons' announcements include:—The Evolution of Horticulture in New England, a History of the Art of Gardening in New England from its earliest plantation to the present day, by Daniel Denison Slade; A Scientific Demonstration of the Future Life, by Thomson Jay Hudson; Handbook for Hospitals, a manual of practical suggestions, by Abby Howland Woolset.

Messrs. W. H. Allen and Co., Limited, will publish Allen's Naturalists' Library, edited by Dr. R. Bowdler Sharpe, illustrated; British Birds, vols. iii. and iv., by the editor; Butterflies, vol. ii. by W. F. Kirby; Game Birds, vol. ii., by W. R. Ogilvie Grant.

Mr. Young J. Pentland's list contains:—Atlas of the Fundus Oculi, illustrated with figures in colours by W. Adams Frost; The Principles of Treatment, by Dr. J. Mitchell Bruce; The Edinburgh Hospital Reports, vol. iv.; a new edition of Prof. Cunningham's Manual of Practical Anatomy, in 2 vols., with additional illustrations.

Mr. Wm. F. Clay, Edinburgh, has in the press:—The Histopathology of the Diseases of the Skin, by Dr. P. G. Unna, translated from the German with the assistance of the author by Dr. Norman Walker, with double coloured plate containing nineteen illustrations and forty-two additional illustrations in the text.

Mr. Erwin Nägele, Stuttgart, announces Researches on Mimicry on the basis of a Natural Classification of the Papilionidæ, by Dr. E. Haase, translated by Dr. C. M. Child, with eight coloured plates, 4to, part ii.

Messrs. Whittaker and Co. will publish immediately:—Future Trade in the Far East, by C. C. Wakefield, fully illustrated, and containing a map showing the latest developments in the trade routes.

The Rebman Publishing Company, 11 Adam Street, Strand, W.C., have ready for immediate publication, Water and Water Supplies, by Dr. J. C. Thresh.

Mr. F. Furchheim, Naples, announces Bibliografia del Vesuvio e del suo Territorio, compiled by Federigo Furchheim.

Mr. David Douglas (Edinburgh) will issue The Vertebrate Fauna of Scotland, vols. vi. and vii.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE recent decision of the Supreme Court of the United States in favour of Mrs. Stamford, and adverse to the Government in its claim for 13,000,000 dollars, means the salvation of the Leland Stamford Junior University, at Palo Alto, California; as Mrs. Stamford will now be able to carry out the munificent plan of endowment, which has been held in abeyance pending the issue of this litigation. The Johns Hopkins University at Baltimore, on the contrary, is seriously crippled by the collapse of the Baltimore and Ohio Railroad system, which has just been put into the hands of a receiver. The University held a large amount of the securities of this line.

THE County Council of Southampton has decided not to levy a rate of a halfpenny in the pound, under the Technical Instruction Act, which had been recommended by the Finance Committee with a view of assisting the Hartley Institution, a school of science and art, in that town. As far as we can gather, Southampton is suffering from a plethora of educational authorities. Besides the Council of the above institution, the Endowed Schools governors and the School Board are also engaged in providing different grades of technical education.

WE notice that on Monday, the 16th inst., a deputation of the Lancashire Committee of the Incorporated Association of Head Masters waited upon the Technical Instruction Committee of the Lancashire County Council, to urge the claims of the secondary schools in the county upon the Committee. They based their claims upon the admitted imperfect education of the students who presented themselves at the technical schools for instruction, urging that the want of proper preliminary education could be avoided by a liberal offering of scholarships to the secondary schools, which out of the increased income resulting from the augmentation of numbers, could easily ensure a satisfactory introductory training for the future students. Attention was also very properly called to the work of this kind which had been carried out in other counties. Though the chairman expressed a fear that want of funds would prevent very much being done for secondary schools, we are sure, in view of his admission that the Committee agreed that these schools were the proper places for much of the early work in a good system of technical education, that it will not be long before the Lancashire authority does something to meet the claims urged by the deputation.

THE latest report of the Technical Instruction Committee of the Derbyshire County Council is very refreshing reading. The pamphlet is prefaced by an explanation of what the Committee considers to be the proper scope of technical education. It is rightly affirmed that a complete system has two main objects: (1) to provide for those who may naturally be expected to occupy positions of control, *i.e.* the "managers"; (2) to provide for the class from which individuals are constantly rising to positions of control, *i.e.* the "men." Recognising that the recent industrial developments of Germany are in a very large measure due to the scientific training of the managers and foremen, the Derbyshire Committee very early turned its attention to the secondary schools, as being the institutions where this class receives its early education. Very much has been done to improve the standard and nature of the instruction given in the grammar schools of the country. In giving help to these educational establishments it has in every case been insisted upon that it is desirable only to give a general education in English and languages, and to add a solid groundwork of mathematics, drawing, and pure science, without dealing with their application to specific industries. At the same time it has not been lost sight of that those students who will naturally pass on to occupy positions of high responsibility, must receive special courses of instruction at technical schools and higher educational institutions. In dealing with the requirements of the "men," the Committee have wisely decided that the teaching in elementary schools is best supplemented by a course of object-lessons in elementary science. To ensure this being well done, classes for elementary school teachers have been organised, with a view to teaching them how to give instruction in this way. The scholar's education can then be suitably continued in evening schools and science and art classes, which have been arranged in each district according to its needs. For the more advanced study which is necessary for most of the first class of students and for a considerable proportion of the second, who themselves desire it, a technical school is naturally stated to be of great importance. Instead of attempting to found such an institution themselves, the Committee have decided that the wisest course is, by a careful system of grants, scholarships, and exhibitions, to utilise the excellent colleges of Nottingham, Sheffield, Manchester and Derby, which all border upon their administrative county.

In addition to the above work, we would especially notice the initiation of the Midland Dairy Institute, the inauguration of a Department of Mining at Firth College, Sheffield, the establishment of local classes in "hosiery" at Heanor, in "calico printing, bleaching, &c.," at New Mills, and in the principle of design at various centres. The year's work is a decidedly successful one, and we hope to see several other counties following the logical and scientific methods of procedure which the Derbyshire Committee have laid down.

SCIENTIFIC SERIALS.

THE *Quarterly Journal of Microscopical Science* for February, 1896, contains:—On the early development of Amia, by Bashford Dean (Plates 30–32). *Amia calva*, possibly the sole survivor of the race of the Mesozoic Ganoids, claims our special interest as the nearest ancestral form of some, if not of all, of our recent Teleosts. In embryology the Ganoid and the Teleost still stand widely separate; there has even been a tendency to look upon these kindred forms as representing different phyla, early divergent from a primitive chordate ancestor. This, therefore, renders the details given by Dr. Dean

of special interest. About the general habits of this fish, he thinks it unnecessary to write much, as Fülleborn's notes, so recently published, are but confirmed; but we are glad that he has added some on the breeding habits, which are illustrated with sketches of the nest and of the cloud of young fry attended by the male. The author concludes that the early development must certainly be regarded as furnishing abundant evidence of intermediate characters; to the Ganoids, on the one hand, and to the Teleosts, on the other. These ontogenetic nearnesses become, accordingly, of the greatest interest, since they confirm the results of the structural study of recent and fossil forms upon the Amioid descent of Teleosts.—On *Kynotus cingulatus*, a new species of earthworm from Imerina in Madagascar, by W. Blaxland Benham (Plates 33 and 34). This interesting species is remarkable for the great number and small size of the segments composing the body; there were three anterior portions sent for examination, each about 225 mm. in length; each piece consisted of some three hundred or more segments; the whole worm being probably about 450 mm. to 500 mm. in length; it possesses a clitellum of relatively enormous dimensions, with most peculiar "claspers."—Notes on the ciliation of the ectoderm of the amphibian embryo, by R. Assheton (Plate 35), describes the distribution of the cilia over the surface of the bodies of the tadpoles of *Rana temporaria and Triton cristatus*. As the author notes, the existence of a ciliated embryo among craniate vertebrates seems often to be overlooked.—On the ontogenetic differentiations of the ectoderm in Necturus (Study II.).—On the development of the peripheral nervous system, by Julia B. Platt (Plates 36–38). Even if we assume Necturus to be a monotypic genus, it would have been advisable for the authoress to have cited a specific name for the Batrachian, whose peripheral nervous system she has so painstakingly elaborated. The summary, occupying two pages, is too long to be cited, and does not admit of being further condensed; we note that "although delicate protoplasmic prolongations connecting cell with cell initiate the specialised coordination of the nervous system, a common reticulum, such as Sedgwick describes, into which nuclei migrate, does not exist in *Necturus*" [*lateralis*]. This number contains a title and index to Volume xxxviii.

SOCIETIES AND ACADEMIES.

London.

Royal Society, February 13.—"On the Behaviour of Argon and Helium when submitted to the Electric Discharge." By Dr. J. N. Collie and Prof. William Ramsay, F.R.S.

Some years ago, Natterer published the results of experiments on the passage of electricity through various gases and vapours at the ordinary atmospheric pressure; he found that the length of the spark, or the "spark-gap" varied in length in a manner approximately proportional to the number of atoms in the molecule of the gas; thus in mercury gas the distance was very much greater than that obtained in hydrogen, oxygen, nitrogen, or other diatomic gases; and in these, the spark-gap was longer than in substances of more complex molecular constitution.

Experiments of a similar nature, carried out by us on some common gases and on argon and helium, gave the results which are summarised in the following table:—

	mm.
Oxygen	23·0
Air	33·0
Hydrogen	39·0
Argon	45·5
Helium	Probably 250 or 300

The current was of constant potential and quantity; and the hammer of the coil was kept in a constant position during the experiments. Indeed, on re-testing the spark-gap with air, after the experiments were finished, the original number was reproduced.

On lowering pressure, this spark-discharge changes into a ribbon-like discharge, before the "fluffy" appearance of a so-called vacuum tube becomes visible. It appeared that this change, occurring at a definite pressure, might be measured with fair accuracy. The results of a series of such experiments is to show that the character of the discharge changes for the under-mentioned gases at the pressures stated:—

	mm.
Air	73 or 74
Hydrogen	42 ,, 43
Oxygen	81
Carbon dioxide	92 or 94
Cyanogen	23
Nitrogen	33
Carbon monoxide	49
Helium	1270

A tube filled with helium shows all the phenomena of a vacuum tube when containing the gas at atmospheric pressure.

The visibility of the spectrum of one gas in presence of another was next investigated. For a full description of the method of filling the tubes, and altering the pressure, the original paper must be consulted. Only the final results are here reproduced.

Amount of Gas detectable in a Mixture.

	Per cent.	
(1) Helium in hydrogen	33	of helium invisible at 2·61 mm.
	10·9	,, barely visible at the lowest pressure.
(2) Hydrogen in helium	0·001	visible at all pressures.
(3) Nitrogen in helium	0·01	almost invisible.
(4) Helium in nitrogen	10	of helium difficult to detect.
(5) Argon in helium	0·06	still visible at all pressures.
(6) Helium in argon	33	invisible at 2·62 mm. pressure.
(7) Nitrogen in argon	25	,, 2·58 ,, ,,
	0·42	,, 1·7 ,, ,,
	0·08	,, 0·18 ,, ,, though just visible at 1·05 mm.
(8) Argon in nitrogen	37	barely visible at any pressure.
(9) Argon in oxygen	2·3	difficult to distinguish at 1·04 mm. pressure.

From these experiments it appears that at high pressures, a discharge passes much more readily through helium than through other gases; but at a low pressure, if passage of current can be inferred from luminosity of spectrum, all other gases convey current more readily than helium does; and nitrogen conveys current more readily than argon. This is probably connected with the known fact that decrease of pressure promotes dissociation. The experiments on the relative luminosity of these gases were made with electrodeless tubes, hence it cannot be objected that the passage of current is determined by the attraction of the material of the electrodes for the gas under experiment.

"On the Absorption of the extreme Violet and ultra-Violet Rays of the Solar Spectrum by Hæmoglobin, its Compounds, and certain of its Derivatives." By Dr. Arthur Gamgee, F.R.S., Emeritus Professor of Physiology in the Owens College, Victoria University.

The investigation, of which the chief results are communicated in this paper, had for its starting-point the observation of the late Prof. J. L. Soret, of Geneva, who showed that, in addition to the absorption bands in the visible spectrum, solutions of the blood-colouring matter are characterised by an intense absorption band in the extreme violet between G and H. The present research has been conducted with the aid of photography, quartz prisms and lenses being employed.

The following are some of the principal results of the investigation:—

I. The compounds of hæmoglobin with oxygen, carbonic oxide, and nitric oxide present, even in highly dilute solutions, an absorption band between Fraunhofer's lines G and H. In the case of oxy-hæmoglobin the mean ray absorbed coincides with λ 414·0, that is to say, the centre of absorption is slightly nearer the red end of the spectrum than Soret had stated; this observer placed the centre of absorption at *h* (λ 410·1). As Soret had indicated, in the case of the compound of carbonic oxide with hæmoglobin, the absorption band is slightly displaced towards the less refrangible end of the spectrum. The combination of hæmoglobin with nitric oxide presents an absorption band occupying precisely the position of that of the CO-compound. In the case of these two compounds, the mean ray absorbed corresponds to λ 420·5.

II. When the molecule of *dissociable* oxygen is removed from oxy-hæmoglobin, either by the action of reducing agents, or by boiling *in vacuo*, the absorption band in the extreme violet is remarkably displaced towards the less refrangible end of the spectrum, the centre of absorption corresponding to λ 426·0.

III. The absorption of the extreme violet depends on the iron-containing moiety of the hæmoglobin molecule, for, whereas it is not presented by the albuminous product of the decomposition of the blood-colouring matter, it is characteristic of the acid compounds of hæmatin and of hæmochromogen.

IV. Solutions of alkaline hæmatin, even when enormously diluted (1 : 30,000 of water), exert a general absorption of the ultra-violet and extreme violet, but present no trace of definite absorption, either in the extreme violet or the adjacent ultra-violet region.

The compounds of hæmatin with acids, *e.g.* hæmatin hydrochloride, present even in solutions of great dilution (1 : 25,000—1 : 50,000) an intense absorption band, which encroaches more and more on the ultra-violet as the strength of the solution increases. With a solution containing one part of crystallised hæmatin hydrochloride in 20,000 parts of glacial acetic acid the band extends between *h* and M, the most intense absorption being between *h* and L. In highly dilute solutions the band which is still intense absorbs both H and K.

V. Solutions of hæmochromogen (reduced hæmatin of Stokes) exhibit an intense absorption band between *h* and G. The band has the same position as the band of CO-hæmoglobin, but is more intense. From the examination of solutions of various strengths, it results that the mean ray absorbed corresponds to λ 420·0.

VI. The absorption of the extreme-violet and ultra-violet by methæmoglobin indicates that this body is the product of a partial decomposition of the molecule of oxy-hæmoglobin.

VII. The band in the extreme-violet (and ultra-violet), which is characteristic of hæmoglobin, its compounds, and certain of its iron-containing derivatives, in no respect depends upon the iron in the molecule. This conclusion is based (1) on the fact that none of the compounds of iron, organic or inorganic, possess the property of producing a definite absorption in the extreme-violet or the adjacent ultra-violet; (2) upon the study of hæmatoporphyrin, a body derived from hæmatin by the removal of the iron which this body contains.

Acid solutions of hæmotoporphyrin of extreme dilution exhibit an absorption band between *h* and H. If the solution be slightly more concentrated K is absorbed, and with increasing concentration of the solution the absorption of the ultra-violet extends more and more. Alkaline solutions of hæmatoporphyrin absorb the same spectral region, but the intensity of the absorption is greater.

VIII. Neither bilirubin, hydrobilirubin, nor urobilin present any definite absorption band in the region of the spectrum, where the absorption band of hæmoglobin and its derivatives occurs.

Physical Society, March 13.—Prof. Carey Foster, Vice-President, in the chair.—Mr. J. H. Reeves read a paper on an addition to the Wheatstone's bridge for the determination of low resistances. The piece of apparatus described can be used for measuring the resistance of metre lengths of wires of low resistance, the only additional apparatus required being a sensitive galvanometer, a Post Office form of resistance box, and a metre bridge. It differs from the ordinary Kelvin bridge in that instead of balancing by varying the length of the standard wire between the two contacts, the distance between these contacts is maintained constant, as is also the length of the wire which is being measured, and balance is obtained by altering other resistances in the network. The author has made a number of tests which show that by his arrangement the resistance of metre lengths of copper wires between the limits of No. 22 S.W.G. and a stranded cable of 7 No. 16's can be determined with an accuracy of 0·1 per cent.—Mr. Reeves also read a note on the exact value of Matthiessen's standard. Prof. A. Gray (communicated) said that the author had in his arrangement combined the fixed standard employed in Matthiessen and Hocking's modification of the ordinary bridge with the greater celerity of working arising from the smaller number of operations to be performed when the Kelvin bridge is used. Prof. Gray thinks that he, and probably others, used a method similar to that of Mr. Reeves; but that the paper is of great utility, since it shows how time may be saved and existing apparatus utilised. Prof. Ayrton said that the advantage of the method described lay in the fact that it was independent of the resistances at the contacts. In Carey Foster's method, however, the coils had to be interchanged, and inaccuracy might be introduced owing to the varying resistance of the mercury contacts. Unless the mercury cups and the copper plates at the bottom were cleaned every day and the contacts re-amalgamated, the resistance of the mercury cups was very variable. With regard to the question of Matthiessen's standard, it is to be remembered that the specific conductivity of copper has been steadily increasing. This increase was particularly noticeable in the copper prepared by the Elmore process, where, during the deposition of the metal, an agate burnisher is kept continually passing over the surface. Fitzpatrick had explained the rise in conductivity of copper by supposing that the density of the copper now supplied was greater than that of the copper used by Matthiessen, and this explanation seemed quite satisfactory. Mr. Reeves's experiments, however, have conclusively shown that this is not the true explanation. It was now possible to obtain copper in large quantity having a conductivity of 103 on Matthiessen's scale. The Chairman (Prof. Carey Foster) explained how, when using his method, the accuracy of the result depends not on the elimination of the small resistances at the mercury cups, but on the constancy of these resistances. Matthiessen and Dr. Russell found that the specific gravity of copper was apt to be low on account of the presence of dissolved oxide, and they were the first to pass hydrogen gas through the molten metal to remove this oxide. Mr. Appleyard gave a simple diagramatic sketch of the author's arrangement, and also pointed out that better results would probably be obtained with a galvanometer of one or two ohms resistance. Mr. Campbell said that it ought to be definitely settled whether Matthiessen's standard was the conductivity per unit volume or per unit mass. Since copper was always bought by weight, he, as a practical man, strongly advocated the adoption of the mass conductivity; further, in this case the measurement of the specific gravity would be avoided. Mr. Reeves having replied, a communication by Herr Puluj on kathode rays was read by the Secretary.—Herr Puluj exhibited some Röntgen photographs taken by means of a form of Crookes' tube, which he had described in a memoir published in 1889. With this tube he has succeeded in obtaining impressions with exposures of only two seconds. Herr Puluj considers that the particles of matter torn from the kathode, which convey negative electrostatic charges, by impact on the glass walls, or on screens, equalise their electric charges, and in this process call forth not merely a disturbance of the material molecules, but also of their ether envelopes. Each portion of the glass or screen bombarded by the kathode stream becomes the starting-point of ether waves, which, according to their oscillation period and oscillation character are either visible rays (phosphorescence) or invisible Röntgen rays. The oscillations of the invisible rays may take place in the longitudinal direction, but no convincing argument has up to now been brought forward to support this view.—The Secretary also read a note on permeability to Röntgen rays, by Messrs. Ackroyd and Knowles. The authors have exposed a plate on which a number of pieces of metal, oxides, and sulphates were placed to the Röntgen rays in order to see whether the permeability of bodies to these rays depends on the atomic or molecular weight of the body. In each case it was found that the opacity increased with the molecular weight. Mr. Blakesley said that he considered the Röntgen rays to be the propagation of electrostatic strain through space. With reference to the non-refrangibility of these rays, he had observed in one of the photographs, exhibited by Mr. Swinton, a dark line at the edge of the shadow of a wooden pencil, which might have been due to the refraction of the rays by the wood. Mr. Blakesley has, however, found that this line is due to the varnish on the pencil. Some Röntgen photographs of quartz and ebonite rods not only did not exhibit these dark lines, but there was a very slight indication of a bright line just on the edge of the shadow, which would indicate that the refraction of these rays was less in the rods than in the surrounding medium.—Mr. Edser exhibited some photographs taken with Mr. Jackson's form of tube, in which a concave kathode is employed. Mr. Edser said that the whole of the tube on the kathode side of the anode plate phosphoresced, so that the Röntgen rays seem to partake of the character of diffused light. Prof. Ayrton said Mr. Jackson had found that the kathode rays form a parallel beam and do not first come to a focus and then again spread out. The Chairman said that some observations made by Mr. Porter agreed with those of Mr. Edser. Mr. Blakesley described the tube used by Puluj, in which a mica screen coated with green calcium sulphide is placed between the kathode and the anode. Mr. Gardner said that there seemed to be some confusion, for when a concave kathode is employed, the kathode rays are brought to a focus and then again diverge. The phosphorescence on the inside of the glass had been shown by Lenard to be due to electricity travelling round the inside surface of the glass. Mr. Pidgeon asked if any one had tried the effect of mounting the photographic film on a metal plate. The Chairman said that Captain Abney had found that if the film was

mounted on a ferrotype plate no action took place. Prof. Perry said that he, for one, was of opinion that the Röntgen rays were undulatory. Prof. Larmor has given an explanation which seems to agree with the observed facts. This explanation supposes that the intermolecular spaces respond to vibrations of a certain frequency. The reason no refraction or diffraction effects had been observed was probably because of the extreme smallness of the wave-length of the undulation.—After a few further remarks by some of the members, the Society adjourned till March 27.

PARIS.

Academy of Sciences, March 9.—M. A. Cornu in the chair.—On the divergence of trigonometrical series, by M. H. Poincaré. A reply to some remarks by M. Hill.—On some new properties of the invisible radiations emitted by some phosphorescent bodies, by M. Henri Becquerel. The rays emitted by potassium uranyl sulphate, which has been kept in the dark for some days, are capable of discharging a gold leaf electroscope even after passing through a plate of aluminium 2 mm. in thickness. Clear evidence was obtained that these invisible rays are capable of reflection and refraction.—On the use of artificial hexagonal blende in the place of a Crookes' tube, by M. Troost. By means of the light given off by a crystal of artificial blende, rendered phosphorescent by exposure to burning magnesium ribbon, good images of metallic objects upon a sensitised plate were obtained, the rays passing through blackened paper readily. The effects produced are the same as with a Ruhmkorff coil and Crookes' tube. The time of exposure is not given.—On some conditions which govern gaseous combinations. The combination of oxygen and hydrogen at low temperatures, by MM. A. Gautier and H. Helier. By circulating the gaseous mixture through a porcelain tube packed with porcelain rods, kept at a constant temperature, and then passing the products over tubes containing phosphoric anhydride, combination can be shown to occur at as low a temperature as 180° C., explosions not occurring until about 840° C.—On the carbides of yttrium and thorium, by MM. H. Moissan and Étard. Yttrium carbide, prepared in the electric furnace, is attacked readily by the halogens, with difficulty by acids. With water the carbide yields a mixture of acetylene (72 per cent.), methane, ethylene, and hydrogen, together with a small quantity of liquid hydrocarbons. Thorium carbide, produced by a similar method, forms a crystalline transparent mass, and gives a mixture of hydrocarbons on treatment with water of the same qualitative composition as that obtained from yttrium carbide.—Aberration and regression of the lymphatics in the course of development, by M. L. Ranvier. The growth of the lymphatics at the time of their formation is often so active that they appear in organs in which they have no functional significance, from which they have to be reabsorbed. Hence occasionally long vessels, closed at both ends, are found, corresponding to portions of the lymphatic system isolated by the atrophy of the intermediate parts. These small cysts may give rise to large cystic tumours.—On malformations of the hip, by M. Lannelongue.—Influence of vaccinal exanthema on microbial localisations, by M. S. Arloing.—Remarks on communication to M. Hermite, by M. Hugo Gyldén. A correction of a previous paper.—Observations of the comets. Perrine (1895, *c*), and Perrine-Lamp (1896, *a*), made with the large equatorial at the Observatory of Bordeaux, by M. L. Picart.—Observations of the sun, made at the Observatory of Lyons, during the last quarter of 1895, by M. J. Guillaume.—On asymptotic lines, by M. E. Goursat.—On the determination of the mass of the cubic decimetre of distilled water, free from air, and at its maximum density, by M. J. Macé de Lépinay. As the final result of a series of weighings in water of a quartz cube, the mass of a cubic decimetre of pure water at 4° C. is 0·999954 kilograms with a possible error of six units in the last figure.—*Rôle* of the different forms of energy in photography through opaque bodies, by M. R. Colson. The actions capable of affecting a sensitised plate are classified as mechanical, chemical, thermal, the infra-red rays, and the X-rays.—Electric effects of the Röntgen rays, by M. A. Righi. The X-rays are capable of producing the dispersion of electric charges upon dielectrics. By dusting a mixture of sulphur and red lead, or better, of talc and manganese peroxide over the plate of ebonite, images of interposed objects resembling photographs can be produced.—On some facts relative to the Röntgen rays, by MM. A. Battelli and A. Garbasso.—On some specimens of glass submitted to the action of the X-rays, by M. V. Chabaud.—On the Röntgen rays, by MM. C. Girard and F. Bordas. An experiment tending to show that the Röntgen rays proceed from both anode and kathode, and that the fluorescence produced on the walls of the Crookes' tube has only a slight effect upon a sensitive plate.—On the technique of photography by the X-rays, by MM. A. Imbert and H. Bertin-Sans.—Remarks added by M. d'Arsonval on the same.—On the centres of emission of the X-rays, by Prince B. Galitzine and M. de Karnojitzky.—On the direction of the X-rays, by M. A. Buguet.—Photography in colours; substitution of organic colours for reduced silver in photographic prints, by M. G. A. Richard.—Action of nitrogen peroxide and air upon the chloride of bismuth, by M. V. Thomas.—On the modifications of the grisometer and on the accuracy obtainable with it, by M. J. Coquillion.—On argon in the gas from the swimming bladder of fishes, by MM. T. Schlœsing, jun., and J. Richard.—Thermochemical study of the amides and ammonium salts of some chlorinated acids, by M. P. Rivals.—On the determination of the acidity of pyroligneous products, by M. Scheurer-Kestner.—On a new series of sulphophosphides, the thiophosphites, by M. Ferrand.—On some derivatives of triphenyl-silico-protane, by M. C. Combes.—On Russian essence of aniseed, by MM. G. Bouchardat and Tardy. This essence contains a large quantity of anethol, together with small quantities of anisic aldehyde, anisic acid, fenchone, and hydrocarbons of the composition $C_{15}H_{24}$.—On a case of lumbar *spina bifida*, by M. V. Ménard. —Influence of franklinisation upon menstruation, by M. E. Doumer.—Explanation of the flowers of the Fumariaceæ from their anatomy, by M. O. Lignier.—On an old schistous synclinal, forming the heart of Mount Blanc, by MM. J. Vallot and L. Duparc.—On the eruptive rocks of the Belledonne chain, by M. Louis Duparc.—On the mode of formation of the auriferous conglomerates, by M. A. Lodin.—Examination of the meteorite that fell at Madrid on February 10, 1896, by M. S. Meunier. The substance of the meteorite appears to be identical with the mineral chantonnite.—On mathematical synthesis, by M. L. Mirinny.—On a point in the kinetic theory of gases, by M. Chapel.—On photography through substances by electric currents, by M. Vaysse.—Remarks by M. Armagnac confirming the preceding.—On a probable cause of the explosion of meteors in the terrestrial atmosphere, by M. E. Hauser.

THURSDAY, MARCH 26, 1896.

THE SCIENTIFIC CORRESPONDENCE OF GEORGE ROMANES.

The Life and Letters of George John Romanes. Written and edited by his Wife. Pp. viii + 360. (London: Longmans, Green, and Co., 1896.)

THE life of most men of science is uneventful so far as the rest of the world is concerned, and can hardly interest more than the circle of personal friends. And the letters of men of science also have, as a rule, but a limited interest. Any scientific information which they contain has usually been published elsewhere, and if of importance, is already familiar to the scientific reader. The account of the life, and the selection of the letters of George Romanes, which is here presented, offer in some measure an exception to the general rule, for they contain matters which will keenly interest others than those who may desire to follow merely the scientific career of the man. But it is the scientific correspondence which will, without doubt, be that which will chiefly interest the readers of NATURE, and it is this, therefore, with which alone we propose here to deal. And of the scientific correspondence, that which Romanes carried on with Charles Darwin during a period of nine years would alone furnish enough interest to ensure a cordial welcome to this work. For Mrs. Romanes has not confined herself, as is so often done by the biographer, to presenting only the one side of a correspondence, but has wisely decided in this and certain other instances to allow both sides to appear, far more than doubling thereby its value and interest. And since, with one exception, none of these letters of Darwin have hitherto been given to the world, and moreover he seems in them to have opened up his heart with the frankest confidence to the young devotee whose powers of thought he was one of the first to recognise, it is obvious that this correspondence must have an altogether exceptional interest. It deals mainly, as might be supposed, with subjects bearing on the question of inheritance, and especially with Darwin's hypothesis of Pangenesis. In attempts to prove this theory, Romanes devoted an immense amount of time in patient experimentation, but as the experiments yielded for the most part a negative result, showing neither for nor against the hypothesis, they were never systematically published. On this account the descriptions of some of these experiments, which are here given at length, will be welcomed by those who may be carrying on similar work in the future. The subject was one upon which Romanes was "keen" to the very last, and almost the latest experiments which he planned, had a direct bearing upon the doctrine in question. And even when his time was fully occupied with the fascinating experiments upon Medusæ, by which he first found fame as a scientific inquirer, he was able to devote attention to the carrying out of laborious work on this subject. In July 1875, he writes to Darwin:

As you have heard about the Medusæ, I fear you will infer that they have diverted my attention from Pangenesis; but although it is true that they have consumed a great deal of time and energy, I have done my best to keep Pangenesis in the foreground.

Then follows a precise account of numerous experiments on grafting of tubers and the like, after which he continues—

But as I am a young man yet (he was just 27), and hope to do a good deal of "hammering," I shall not let Pangenesis alone until I feel that it does not admit of being any further driven home by experimental work; and even if I never get positive results, I shall always continue to believe in the theory.

And a little later—

I have an idea that you are afraid I am neglecting Pangenesis for Medusæ. If so, I should like to assure you that such is not the case. . . . I confess, however, that but for personal reasons I should have postponed Pangenesis, and worked the Medusæ right through in one year. There is a glitter about immediate results which is very alluring.

To which Darwin replies—

So far from thinking that you have neglected Pangenesis, I have been astonished and pleased that your splendid work on the jelly-fishes did not make you throw every other subject to the dogs.

In another letter from Darwin the following occurs—

As you are interested in Pangenesis, and will some day, I hope, convert an "airy nothing" into a substantial theory, therefore I send by this post an essay by Häckel, attacking "Pan.," and substituting a molecular hypothesis. If I understand his views rightly, he would say that with a bird which strengthened its wings by use, the formative protoplasm of the strengthened parts becomes changed, and its molecular vibrations consequently changed, and that their vibrations are transmitted throughout the whole frame of the bird. How he explains reversion to a remote ancestor I know not. Perhaps I have misunderstood him, though I have skimmed the whole with some care. He lays much stress on inheritance being a form of unconscious memory, but how far this is part of his molecular vibration I do not understand. His views make nothing clearer to me, but this may be my fault.

In a letter written in 1877, after referring in enthusiastic terms to a lecture by Romanes on the "Evidences of Organic Evolution," he says:

I am very sorry to hear about the failure in the graft experiments, and not from your own fault or ill-luck. Trollope, in one of his novels, gives us a maxim of constant use by a brick-maker, "It is dogged as does it!" and I have often and often thought this is the motto for every scientific worker.

With characteristic generosity Darwin handed over to Romanes, who was preparing his book on "Animal Intelligence," his notes on instinct.

You are quite welcome to have my longer chapter on instinct. It was abstracted for the Origin. I have never had time to work it up in a state fit for publication, and it is so much more interesting to observe than to write.

The book in question was heralded by a lecture on the subject given before the British Association at its meeting in Dublin in 1878. A copy of the lecture, as well as a newspaper account, from which it appeared that the lecture (especially an allusion in it to Darwin himself) was most cordially received, was sent by Romanes to Darwin, who thus acknowledges the receipt:

I am most heartily glad that your lecture (just received and read) has been so eminently successful. You have indeed passed a most magnificent eulogium on me, and I wonder that you were not afraid of hearing "Oh! oh!" or some other sign of disapprobation. Many persons think that what I have done in science has been much overrated, and I very often think so myself; but my comfort is that I have never consciously done anything to gain applause.

He jocularly adds in a short note sent a few days after—

Frank says you ought to keep an idiot, a deaf mute, a monkey, and a baby in your house.

To which Romanes rejoins—

Frank's idea of "a happy family" is a very good one; but I think my mother would begin to wish that my scientific inquiries had taken some other direction.

The baby too, I fear, would stand a poor chance of showing itself the fittest in the struggle for existence.

And two years afterwards the joke is continued (the baby having in the meantime put in an appearance).

I have now got a monkey. Sclater let me choose one from the Zoo, and it is a very intelligent, affectionate little animal. I wanted to keep it in the nursery for purposes of comparison, but the proposal met with so much opposition that I had to give way. I am afraid to suggest the idiot, lest I should be told to occupy the nursery myself.

The following postscript to a letter from Darwin, dated September 14, 1880, will be of interest.

We went to the Lakes for three weeks to Coniston, and the scenery gave me more pleasure than I thought my soul, or whatever remains of it, was capable of feeling. We saw Ruskin several times and he was uncommonly pleasant.

The postscript to another of Darwin's letters (dated January 24, 1881) is the following parable:—

N.B. Once on a time a fool said to himself that at an ancient period small soft crabs or other creatures stuck to certain fishes; these struggled violently, and in doing so discharged electricity, which annoyed the parasites, so that they often wriggled away. The fish was very glad, and some of its children gradually profited in a higher degree and in various ways by discharging more electricity and by not struggling. The fool who thought thus persuaded another fool to try an eel in Scotland, and lo and behold electricity was discharged when it struggled violently. He then placed in contact with the fish, or near it, a small medusa or other animal which he cleverly knew was sensitive to electricity, and when the eel struggled violently, the little animals in contact showed by their movements that they felt a slight shock. Ever afterwards men said that the two fools were not such big fools as they seemed to be.

About this time Romanes began to consult Darwin concerning experiments as to the relative effect of flashing and continuous light upon seedlings. These experiments were pursued at intervals during the next ten years, and the results were published in a paper read before the Royal Society in 1892. He tells also of a curious experiment on the sense of direction in cats.

I have got a lot of cats waiting for me at different houses round Wimbledon Common, and some day next week shall surprise our coachman by making a round of calls upon the cats, drive them several miles into the country, and then let them out of their respective bags. If any return, I shall try them again in other directions before finally trying the rotation experiment.

Not one cat, however, did return! Romanes used to describe with much amusement the ludicrous nature of the experiment as seen by passers-by.

Darwin was engaged just now (1881) upon his book on earthworms, and writes regarding it:

Your letter on intelligence was very useful to me, and I tore up and rewrote what I sent you. I have not attempted to define intelligence, but have quoted your remarks on experience, and have shown how far they apply to worms. It seems to me, that they must be said to work with some intelligence, anyhow, they are not guided by a blind instinct.

The following interesting remarks occur in the same letter:—

Dr. Roux has sent me a book just published by him, "Der Kampf der Theile," &c., 1881 (240 pages in length). He is manifestly a well-read physiologist and pathologist, and from his position a good anatomist. It is full of reasoning, and this in German is very difficult to me, so that I have only skimmed through each page, here and there reading with a little more care. As far as I can *imperfectly* judge, it is the most important book on evolution which has appeared for some time.

I do not know whether you will discuss in your book on the "Mind of Animals" any of the more complex and wonderful instincts. It is unsatisfactory work, as there can be no fossilised instincts, and the sole guide is their state in other members of the same order and mere probability. But if you do discuss any (and it will perhaps be expected of you), I should think that you could not select a better case than that of the sand-wasps, which paralyse their prey, as formerly described by Fabre in his wonderful paper in *Annales des Sciences*, and since amplified in his admirable "Souvenirs." Whilst reading this latter book, I speculated a little on the subject. Astonishing nonsense is often spoken of the sand-wasp's knowledge of anatomy. Now will any one say that the Gauchos on the plains of La Plata have such knowledge, yet I have often seen them prick a struggling and lassoed cow on the ground with unerring skill, which no mere anatomist could imitate. The pointed knife was infallibly driven in between the vertebræ by a single slight thrust. I presume that the art was first discovered by chance, and that each young Gaucho sees exactly how the others do it, and then with a very little practice learning the art. Now I suppose that the sand-wasps originally merely killed their prey by stinging them in many places (see p. 129 of Fabre, "Souvenirs," and p. 241), on the lower and softer side of the body, and that to sting a certain segment was found by far the most successful method, and was inherited, like the tendency of a bull-dog to pin the nose of a bull, or of a ferret to bite the cerebellum.

Darwin's attitude on the subject of vivisection is very manifest in several of the letters. As all the world knows, he did not himself practise vivisection, and the probability is that his gentle nature caused him to regard with more than ordinary dislike the necessity for experiments upon animals which might involve pain. But he saw so clearly that no real advance can be made in science without experiment, that he was ready even to come forward as a champion of the cause of physiology. In 1877, when the first antivivisection agitation was at its height, he writes:

I am inclined to think that writing against the bigots about vivisection is as hopeless as stemming a torrent with a reed. . . . It seems to me the Physiologists are now in the position of a persecuted religious sect, and they must grin and bear the persecution, however cruel and unjust, as well as they can.

And in 1881—

Do you read the *Times?* As I had a fair opportunity, I sent a letter to the *Times* on Vivisection, which is printed to-day. I thought it fair to bear my share of the abuse poured in so atrocious a manner on all physiologists.

Darwin's regard for physiologists was reciprocated; he and Sharpey were the first honorary members elected by the Physiological Society (of which Romanes was one of the first secretaries), a "mark of sympathy" with which he expresses himself as being "very much gratified." Needless to say Darwin's death was an untold loss to Romanes.

Even the death of my own father—though I loved him deeply, and though it was more sudden—did not leave a desolation so terrible. Half the interest of my life seems to have gone when I cannot look forward any more to his dear voice of welcome, or to the letters that were my greatest happiness. . . . And when I think how grand and generous his kindness was to me, grief is no word for my loss.

In the words of his biographer—"Thus closed a very significant and important chapter in his life."

Of Romanes' other scientific correspondence, the

earliest (1875-76) was with Prof. Schäfer, and related to his experiments upon Medusæ. In these letters he describes many interesting results which he was obtaining, and which were, for the most part, afterwards published in the *Philosophical Transactions*. He had then and always the pen of a ready writer (in hand as well as in tongue), and was besides in the habit of illustrating his descriptions by rough diagrams, so that they are admirably clear and instructive. Nearly all the other letters to scientific men are of comparatively recent date, and deal mainly with the controversies on problems of inheritance (physiological selection and Weismannism) in which, as the readers of NATURE well know, he was so deeply engaged. His paper on physiological selection[1] was read before the Linnean Society in May 1886. It raised a storm of opposition, largely, as he thought, because its opponents would not take the trouble to understand it. To Prof. Meldola he writes :

> Physiological selection seems to have brought a regular nest of hornets about my head. . . . It seems to me that there is a good deal of misunderstanding abroad, due, no doubt, to the insufficiency with which my theory has been stated.

There are also several long letters to Mr. Thiselton-Dyer and Mr. Francis Darwin on the same subject, and a friendly controversial correspondence with Prof. Poulton on the subject of Weismannism. But most of these letters have a more or less continuous thread of argument running through them, and do not lend themselves readily to extracts. The reader who is interested in the controversies is therefore referred to the originals. Even after he had been stricken by paralysis he was not to be deterred from continuing to discuss the problems which most interested him, and he carried on a long correspondence with the Rev. G. Henslow on the subject of the direct action of the environment on plant structures. In his last illness the personal sympathy which he received from his scientific friends much touched him, hard though he felt his fate to be. In a letter to Mr. Thiselton-Dyer, dated September 1893, he writes :

> When one is descending into the dark valley, scientific squabbles seem to fade away in those elementary principles of good will which bind mankind together. And I am glad to think that in all the large circle of my friends and correspondents there is no vestige of ill will in any quarter, unless it be with —— and ——, who both seem to me half-crazy in their enmity, and therefore not of much count.
>
> As for "fortitude," sooner or later the night must come for all of us ; and if my daylight is being suddenly eclipsed, there is only the more need to work while it lasts. But, to tell the truth, I do not on this account feel less keenly the pity of it. With five boys—the eldest not yet in his teens and the youngest still in his weeks ; with piles of note-books which nobody else can utilise, and heaps of experimental researches in project which nobody else is likely to undertake, I do bitterly feel that my lot is a hard one.

Throughout the letters the character of the man comes openly to the surface, and all the world may see in them the simple child-like nature, the unvarying good humour, the gentle disposition, which were combined in him with the highest intellectual attainments ; qualities which won for George Romanes the affectionate regard of all who were privileged to know him.

E. A. SCHÄFER.

[1] An admirable epitome of this theory (and of each one of the scientific subjects which chiefly engaged Romanes' attention) is given by his biographer in the book before us.

EARLY LEGENDS AND PREHISTORIC FOLK-LORE.

The Life and Exploits of Alexander the Great; being a Series of Translations of the Ethiopic Histories of Alexander by the Pseudo-Callisthenes and other Writers, with Introduction, &c. By E. A. Wallis Budge, Litt.D. Pp. xv + liv + 610. (London : C. J. Clay and Sons, 1896.)

WITHIN recent years it has been recognised that the legends and epics of ancient peoples are something more than collections of quaint and amusing tales, that they have a scientific value, and that they yield important results when studied, classified, and compared. The sagas of many nations are well known, and have been already subjected to an exhaustive process of inquiry, but those of others have still to be unearthed. Among this latter class the legendary literature of the Ethiopians had until recently to be set, but the volume by Dr. Wallis Budge, the title of which stands above, will go some way to remove the obscurity in which the beliefs and traditions of that nation have been shrouded. Hitherto the Ethiopic literature that has been published, has in the main been biblical and of interest chiefly to biblical students ; Dr. Budge, however, has collected a goodly body of Ethiopian traditions from MSS. in the British Museum and in the Bibliothèque Nationale, Paris, two of the former having been among those which were brought to England from the Treasury of King Theodore by the British Army in 1868. The Ethiopic texts of these MSS. have been edited by Dr. Budge, and they have been printed for private circulation by Lady Meux. An English translation and introduction which accompanied the text has, however, been published separately on smaller paper, for the use of those to whom the subject-matter, rather than the text of the MSS., would be of interest ; and it is with some of the results to be obtained from a perusal of this latter volume, that we propose in the present article to deal. It is not our purpose, however, to treat the legends from a literary point of view ; our object is rather to extract from them such information as will indicate what was the condition of geographical and astronomical knowledge among early Oriental nations, and to notice briefly the stories of heroes and others which grew up when the world was yet in its childhood, and when early man was himself still mystified by the phenomena of nature he beheld around him.

The central figure round which the stories group themselves is Alexander the Great, many of them being based on traditions or stories borrowed originally from other races. For instance, the book comprises the Ethiopic version of the Pseudo-Callisthenes, which has found its way into many languages ; extracts from the Ethiopic versions of larger historical works by Al-Makîn and Abû Shâker, Arabic historians of the thirteenth century ; and an extract from the Ethiopic version of Joseph ben-Gorion's "History of the Jews." The book also contains a short account of Alexander's death, and the utterances of the sages thereon ; the "Christian Romance," which is probably an original Ethiopian work ; and an account of the "Vision of Abbâ Gerasimus." None of the Ethiopic MSS. which contain these works is actually older than the seventeenth century ; they are, however,

copied from originals which must be put back many hundreds of years, and some of the legends that are inserted are of primeval antiquity.

Among all races, and especially in the East, the figure of some great national conqueror has always served as a centre around which floating legends and stories have gathered. An historical kernel no doubt underlies the mass, but it has been overlaid with numberless accretions, comprising some ancient legends to a certain extent the common property of all races, and others the special product of the race to which the writer belonged. Each nation that has retold the story of Alexander has modified and added to it to suit its own national ideals, so that the epic in its various forms comprises legends, the sources of which range from traditions of the ancient East down to those of mediæval Europe. Thus in the history of Alexander we find the ancient legends of Babylon have been laid under contribution. Alexander makes himself small, and flies through the air on the back of an eagle, exploring the heights of the heavens, "the beauties and the terrors thereof, and the stations of the birth and the going forth of the stars," in the same way as the Babylonian hero Etana flew to heaven with the eagle, who described to him the fashion and likeness of the earth as it seemed to recede from under them; and the same legend seems to be reproduced in another form in the "Christian Romance" (p. 474), when Alexander sends scouts from the Country of Darkness to the Country of the Living by making them ride on the backs of eagles. Alexander, too, is related to have travelled in the same regions, and to have met with the same adventures as the Babylonian hero Gilgamish; while his slaying of the dragon is clearly a reminiscence of the fight of the Babylonian god Merodach with the monster Tiâmat. As an instance of the way one of his Ethiopian biographers has incorporated material from contemporary sources, we may mention the story of the musical city (pp. 457 *ff.*) which Alexander at first cannot take, as his soldiers, after scaling the walls, are overcome by the beauty of the music produced by cunning contrivances of brass, to which figures of brass continually danced—a story which probably reflects some mechanical invention famous at the time of the writer.

The travels of Alexander furnish ample opportunities for the display of his biographers' knowledge or theories concerning geography and the extent and formation of the world. Thus, when travelling in the neighbourhood of Armenia, Alexander "came down to a very great mountain gate (*or* pass) wherein were many large roads by which merchants travel." Alexander makes inquiries, and he is informed by certain sages that the mountain only "ends at the sea that surroundeth the world, that is to say the sea Bôntôs (Pontus)," and this leads to a description of the far East and the nations who were said to dwell there. The same mountain, which was supposed to surround the world "like a ring," is referred to in another passage by the angel whose duty it is to hold it firm, and who describes it as "the father of all the mountains which are upon the earth," and adds that if plucked up by the roots the destruction of the earth would follow. Another curious geographical conceit occurs in an account of the origin of the Dead Sea, which is said to "stink horribly," because of the dead bodies of men and women and the carcases of beasts and birds which lie in its depths, whither they were brought by the waters of the Flood.

We gather, too, some interesting details concerning the ancient practice of magic and astrology. For instance, Aristotle is recounted to have presented to Alexander talismans to protect him against his foes, to enable him to enter fortified cities, for supplying him with water in the desert, and for protecting him and his army against fatigue. He also gave him certain amulets with somewhat similar powers, and furnished him with a device for destroying his enemies by means of waxen figures:

> "And Aristotle also made for Alexander a chest, and he placed therein figures which were made to represent his enemies, and they had leaden swords, which were curved backwards in their hands, and which they held downwards, and bows the strings of which had been cut; and he placed them in the box with their faces turned downwards, and he nailed them down with iron pegs and fastened the box with an iron chain."

Alexander had to keep the box carefully, and by laying his hand on it, and reciting certain prayers, he was assured of success against his foes. Aristotle is also credited with a knowledge of astrology, for he compiled for Alexander

> "a number of tables, that is to say, plans or drawings, wherein a star showed the time when he should go forth against his enemies . . . and he spake unto him, saying, 'Know, O King, that the stars are the head and foundation of the dispensation of this universe, and that it is by means of them that the world which is beneath the lowest heaven of the moon standeth. Know too that a certain section of the starry vault ruleth over each district and country on the earth. Now the portion that is over Persia hath therein the planet Mercury, and its regent is Venus, and its guardian is Jupiter, and its adversary is Saturn, and the star which hath dominion over it and worketh misery therein is the planet Mars, but the Sun keepeth it in safety, and the Moon giveth it strength and power. And each of these seven planets hath power over its fortune and over its days; therefore, O King, do thou direct thy course by the dispensation of the planets Saturn and Mars, and by the spiritual force which is in them, so that thou mayest be victorious over thine enemies thereby.'"

In the course of a review it is impossible to do more than briefly indicate the value of but a few of the legends and beliefs to be found throughout the 600 pages covered by the English translation. Reference, however, at least should be made to the stories of the magic stone, the fishes and the water of life, Alexander and his diving-bell, the monsters of the deep, Alexander's converse with beasts and birds, and the ride of Gerasimus upon the lion. The material here collected is, in fact, of great interest from many points of view, and not least from that of the student of folk-lore, who will find much useful information in the notes in which Dr. Budge has worked out the origin of many of the legends incorporated or referred to in the text. Our knowledge of ancient and mediæval science and superstition is gradually becoming more extended, and we venture to think that the volume before us will do much to help on the study. To summarise the universal character of the epic of Alexander, we cannot do better than quote Dr. Budge's own words:

"Given a brave, fearless soldier marching with an army through a certain country for conquest and pleasure, it seems that the same stories must be told of his progress and exploits, whether he be Etana, Gilgamish, Nimrod, or Alexander. With the advance of time the first tolerably accurate descriptions of his life will be first distorted and then enlarged, and when he has become a mere memory his name will be made a peg on which to hang stories, legends, and myths. The details of the fabulous history of such an one will be modified to suit the country and ideas of the people among whom the writers live, and eventually it will become the popular expression of the national views of each country through which the history passes of what a hero should be. This is exactly what has happened to the Alexander story in the hands of Semitic and other writers. The Egyptians made Alexander the son of an Egyptian king, and a worshipper of Amen; the Greeks made him the type of the victorious Greek conqueror; the Persians made him a Persian; the Arabs made him a servant of Allah; the Syrians made him a Christian; and the Ethiopians depicted him as a believer in the Trinity and in the Christian doctrine of the resurrection of the dead."

FISHES, LIVING AND FOSSIL.

Fishes, Living and Fossil: an Outline of their Forms and Probable Relationships. By Bashford Dean, Ph.D. Pp. xiv + 300. (New York and London: Macmillan and Co., 1895.)

DR. BASHFORD DEAN is known to zoologists, first, as the author of exhaustive and critical articles in the publications of the United States Fish Commission, on the systems of oyster culture pursued in Europe, and, secondly, as an embryologist who has lately been doing good work on the development of various Ganoid fishes and the comparison that may be instituted with Teleostei. His recent addition to the well-known "Columbia University Biological Series," now being brought out by Macmillan and Co., under the editorship of Prof. H. F. Osborn, is an interesting volume upon fishes, in which considerable prominence is given to the fossil forms, and the whole subject is presented to us from the point of view of the evolutionist. This is the characteristic feature of the book. From the very first page of the introduction to the last page in the volume, preceding the index, which is a table of the supposed descent of the groups of fishes, the book is full of the spirit and the language of evolution.

The fossil forms are introduced in their places amongst the living members of their group, and the plan of treatment of the groups in each chapter may be exemplified by No. vi., dealing with the Dipnoi, where we have first a short account of the lung-fishes, then the description of their structural characters, with an account of the fossil and of the living forms, and finally a discussion of their phylogeny and relationships with other groups. The figures in all parts are numerous and good, and many of them original.

The classification adopted is in the main that of Smith Woodward, in which the class Pisces excludes the Marsipobranchii (not that these are excluded from the book), and includes as sub-classes the Elasmobranchii, the Holocephali, the Dipnoi, and the Teleostomi. Our author considers then the Chimæroids as a distinct group equivalent to Elasmobranchii and Dipnoi, but adds: "The kinships of the Chimæroids seem unquestionably nearer the stem of the sharks than that of other fishes." He considers that the lung-fishes (Dipnoi) as a group "may not unreasonably be looked upon as descended from the primitive Elasmobranch stem." They are "an advancing phylum from which the amphibians may early have diverged." The remarkable fossil Arthrodira (*Coccosteus*, &c.), he follows Smith Woodward in considering provisionally as an order of extinct and highly-specialised lung fishes. A fine figure of the head of the giant predatory member of the group *Dinichthys intermedius*, one-tenth of the natural size, forms the frontispiece. These forms are now dissociated from *Pterichthys* and other lowly Ostracoderms, and also from the Siluroids, with which at various times they have been compared, and are united with the Dipnoi. The author believes, however, that the Arthrodirans may almost as well be referred to the sharks as to the lung-fishes, and that they may, perhaps, ultimately come to be regarded as worthy to rank as a distinct class. Dr. Dean builds his phylogeny largely on the solid basis of Palæontology.

After the systemic part of the book comes a chapter on development, in which, in addition to general remarks on eggs and breeding habits, a brief but adequate account is given of the embryonic and larval development of the five types—Lamprey, Shark, Lung-fish, Ganoid, and Teleost, with the view of contrasting the groups of fishes. This section includes a summary of Semon's observations on *Ceratodus*, and is illustrated by useful figures.

Throughout, structure is treated largely from the developmental point of view, which adds to the value, interest and freshness of the book. The author sums up against Gegenbaur's archipterygium, and in favour of the derivation of paired fins from lateral fin-folds. This view is supported by the simple condition of the pectoral and pelvic fins in the ancient fossil shark *Cladoselache*, the knowledge of whose archaic characters we owe to Dr. Dean himself. The vexed question of the precise function of the sense organs of the lateral line is still left undetermined. Beyond "feeling," in a broad sense, the author merely suggests "the sensory tracts along the sides of the body are certainly well situated to determine the direction of the approach of friend, enemy or prey." It is interesting—even if one can scarcely help feeling slightly disappointed—to read that: "It must for the present be concluded that the pineal structures of the true fishes do not tend to confirm the theory that the epiphysis of the ancestral vertebrates was connected with a median unpaired eye." He considers rather that the epiphysis was connected with the innervation of the sensory canals of the head.

At the end of the book we find a list of derivations of names, a good bibliography classified under groups and systems of organs, and, lastly, a series of tables giving in contrast form a statement of the comparative anatomy and embryology of the different groups of fishes, illustrated, like the rest of the work, by a series of clear figures drawn from the best sources, and many of them original. No doubt specialists on fossil fishes will be able to find defects and omissions, but for the ordinary student of the subject Bashford Dean's volume will prove useful and interesting.

W. A. H.

OUR BOOK SHELF.

British Moths. By J. W. Tutt. Pp. xii + 368. Illustrated. (London: George Routledge and Sons, 1896.)

THE last of the many recent additions, superficial and profound, to the stock of books on British Lepidoptera, is essentially a book for the beginner, but one which challenges consideration as an attempt "to deal with our moths on lines which the study of the last twenty-five years has convinced all true naturalists are the correct ones." The points by which this claim is redeemed consist mainly in the substitution of an arrangement based on Dr. Chapman's division of the Lepidoptera by pupal characters for the old order so long accepted, and by numerous statements of phylogenetic relationship. Supported as they are by very little in the way of explanation to make them intelligible, these innovations are not so much an improvement as a snare; it is of no use to talk glibly in a beginner's book about "Obtectæ and Incompletæ," "offshoots from a Pyralid stirps," and the like, unless these things are fully and clearly explained. Much of the phylogeny so confidently put forward is not that accepted by other recent writers on Lepidoptera and is unfit matter for dogmatic assertion, especially as first impressions thus acquired are hard to unlearn. Neither is the writer consistent, for the Hepialidæ, Micropterygidæ, and Eriocephalidæ are separated from each other by numerous families, although the position, remote from all other Lepidoptera, that has been assigned to the three is one of the most important and widely-accepted of recent changes. Turning to those parts of the book which have no special claim to novelty of treatment, we find, as is to be expected from so competent a lepidopterist, that his statements are accurate and often valuable. But far too much space is taken up, particularly in the Noctuæ, with brief remarks on species which convey no real information. In spite of another claim put forward in the preface, it is only here and there that a species is described in recognisable terms. If all perfunctory mention of species had been excluded, and the work confined, as a book of limited scope may well be, to such moths only as are common and of wide distribution, space could have been gained for an adequately-full treatment of the species retained. The coloured illustrations are fairly good; there is but one diagram of neuration, and that is incorrect. W. F. H. B.

Moorland Idylls. By Grant Allen. Pp. 257. (London: Chatto and Windus, 1896.)

By Tangled Paths. By H. Mead Briggs. Pp. 203. (London: Frederick Warne and Co, 1896.)

THE descriptions of scenes of pastoral life contained in the first of these volumes have, we believe, already appeared in one of the monthly magazines, though no reference is made to that fact. They may be regarded as science diluted with sentiment, and that is the kind of literature which the average man and woman will sometimes read. Nevertheless, if Mr. Allen's idylls lead people to observe and think about the habits and characteristics of common plants and animals, they will accomplish a useful purpose. The sympathetic spirit in which they are written will attract lovers of nature, and will do much to foster a feeling for the preservation of our native fauna.

Mr. Briggs's dainty volume is much the same in character as that of Mr. Grant Allen's, the chief differences being that it is a little more poetical, and a little less instructive. The contents furnish suitable reading for persons who muse over the poetry of nature; and judging from the abundance of literature of a similar character, there must be many who like to engage their minds on natural things.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Sun Columns at Night.

A REMARKABLE phenomenon, similar to that which I described in 1888 (NATURE, vol. xxxviii. p. 414), was witnessed by me on the evening of March 13. At 7h. 7m. p.m. I saw on the western sky five silvery white columns coming evidently from the sun, which set at 6h. 1m. The columns extended over the whole sky, and, like meridians on a globe, converged to a point in the eastern sky, which was about as high above the eastern horizon as the sun was below the western horizon. The sky was full of stars, a powerful wind having swept it clear; and at 7h. 25m., fifteen minutes before complete night had set in, the rays still reached the zenith. The rays cannot be *straight* sun rays, for the calculation of the height of the atmosphere by Alhazen's method would yield an abnormally high value, and they could not meet in the east, like meridians, but they must be *curved* and pass *along* the upper strata of the atmosphere. This is either due to reflection, or, more probably, the phenomenon is one of an electrical nature, similar to that described in NATURE of March 12 (p. 437), which has just reached me, by Dr. O'Reilly.

The remarkable fact that at 7h. 25m., when the sun was about 14° below the horizon, the perpendicular arc reached the zenith, whereas that passing along the equator extended to about Cancer, appears to prove that the equatorial diameter of the atmosphere greatly exceeds the polar diameter. The phenomenon disappeared at 7h. 28m. BOHUSLAV BRAUNER.

Bohemian University, Prague, March 16.

Kathode Rays or X-Rays?

TO the reader of the numerous papers that have recently been communicated from various sources on the subject of Dr. Röntgen's great discovery, considerable obscurity is caused by the confusion of the above terms. Until quite recently what has been meant by "kathode rays" or "the kathodic discharge" has been that discharge of matter from the negative electrode in a highly-exhausted vacuum tube, which can be deflected by a magnet, produce heat, mechanical energy, and phosphorescence, can be brought to a focus by using a curved kathode, and in this case will project an inverted image of the kathode upon either the inside walls of the tube, or upon a phosphorescent screen placed inside the tube to receive it. As is well known, this discharge has been very thoroughly investigated abroad by Hittorf, Puluj, and others, and in England by Crookes, and has been called by him the discharge of "radiant matter." The X-rays of Dr. Röntgen are said to be generated at the spot where the kathodic discharge of radiant matter impinges upon an obstacle, be it the phosphorescent walls of the vacuum tube, or a plate of metal similarly placed to receive it. The distinction is perfectly clear in Dr. Röntgen's paper, as the following extracts from the translation, published in this journal on January 23, show.

"In general, other bodies behave like air; they are more transparent for the X-rays than for the kathode rays. A further distinction, and a noteworthy one, results from the action of a magnet. I have not succeeded in observing any deviation of the X-rays even in very strong magnetic fields. The deviation of kathode rays by the magnet is one of their peculiar characteristics."

"Hence I conclude that the X-rays are not identical with the kathode rays, but are produced from the kathode rays at the glass surface of the tube."

"I have obtained them in an apparatus closed by an aluminium plate 2 mm. thick."

It will therefore surely be better to retain the term proposed by their discoverer, X-rays, or else to call them Röntgen rays, and thus avoid the confusion that must result from calling them "kathode rays." JAMES H. GARDINER.

A Remarkable Meteor.

THE slow-moving meteor of March 1, 8h. 31m., described by Mr. J. E. Clark at York (NATURE, March 12, p. 437), was observed by Mr. T. W. Backhouse at Sunderland, and he noted

the path as from $\beta - \alpha$ Canis Minoris eastwards passing $170° \pm 0°$ and disappearing behind a cloud about $5°$ beyond the latter point. The duration was $6\frac{1}{2}$ seconds.

Comparing the two observations, I find the radiant was in Pisces at $18° + 5°$, which at the time of the meteor's appearance had an altitude of about $4°$ only in due west. The meteor was first seen from Sunderland when it was over a point near York at a height of 59 miles, and when last seen from York it was over Heligoland at a height of 49 miles. The Sunderland observer noticed the meteor a little earlier in its flight than the observer at York; while at the latter place it was retained much longer in view than at Sunderland, where a cloud appears to have obscured the terminal stages of the phenomenon. The whole length of its path was about 370 miles; Mr. Backhouse, at Sunderland, watched the meteor traverse 195 miles, so that his estimate of the duration would give 30 miles per second for the velocity. Mr. Clark saw 338 miles of the path, and his estimate of 32 seconds would give $10\frac{1}{2}$ miles per second. The difference may be partly accounted for on the supposition that owing to the resistance of the atmosphere the meteor slackened considerably in speed during the latter part of the flight.

When last seen by Mr. Clark, the meteor was close to its anti-radiant and travelling in a nearly direct line away from the observer, so that its apparent motion would be very very slow, and the object must have looked like a hazy almost motionless star near the eastern horizon.

The radiant point at $18° + 5°$ in Pisces indicates a place in the heavens where no meteor shower has ever been observed in the first quarter of the year—in fact, on March 1 it is only $35°$ east of the sun. In the summer and autumn, when the constellation Pisces is favourably presented in the dark sky, many meteor showers radiate from it and some brilliant fireballs have been directed from a similar position. The following instances may be noted:—

The mean position seems to be about $13° + 5°$. It declines so far to the west in November that no showers have been seen from it afterwards, though it occasionally yields fine slow-moving fireballs. Thus in 1891 Dec. 20, 8h. 38m., I saw a meteor, equal to Venus, moving very slowly from $124° + 64°$ to $159° + 49°$, and presumably from this radiant in Pisces.

Bristol, March 19. W. F. DENNING.

Barisal Guns.

IN regard to the "barisal guns" or "mist pouffers," lately described in NATURE, similar sounds have been heard in this region.

On July 4, 1808, the expedition of Captains Lewis and Clark was at this place. Under that date we find the following entry in their journal: "Since our arrival at the Falls we have repeatedly heard a strange noise coming from the mountains in a direction a little to the north of west. It is heard at different periods of the day and night, sometimes when the air is perfectly still and without a cloud, and consists of one stroke only, or five or six discharges in quick succession. It is loud, and resembles precisely the sound of a six pound piece of ordnance at the distance of three miles. The Minnatarees frequently mentioned this noise like thunder, which they said the mountains made, but we paid no attention to it, believing it to be some superstition or falsehood perhaps. The watermen also of the party say that the Pawnees and Recaras give the same account of a noise heard in the Black Mountains [Black Hills] to the west of them."

The mountains towards which these noises were heard were the main range of the Rockies, and distant about eighty miles. In 1854, Mr. Doty, of Governor Stevens's party, heard similar noises. He was near enough to the mountains to be certain that the noises came from them. The locality where Mr. Doty heard them was where the direction observed by Lewis and Clark would strike the mountains.

Plenty of white men have been in this country for the last thirty years, or since 1866. I have made careful inquiry among pioneers, but cannot learn that the noises have been heard since Mr. Doty's report.

In 1810 a party, outfitted by John Jacob Astor, made an overland trip from the Missouri to the mouth of the Columbia. They tried to go through the Black Hills, but were obliged to withdraw and flank them. In these hills they note as follows: "In the most calm and serene weather, and at all times of the day or night, successive reports are now and then heard among these mountains, resembling the discharge of several pieces of artillery. Similar reports were heard by Messrs. Lewis and Clark in the Rocky Mountains.

Such explosions are also said to occur frequently in Brazil. "Vasconcellis, a Jesuit father, describes one which he heard in the Sierra, or mountain region of Peratininga, and which he compares to a park of artillery." CHAS. H. ROBINSON.

Great Falls, Montana, March 5.

Ostwald's Energetics.

IT may not perhaps be irrelevant to point out that even were it permissible to assert—as Prof. Fitzgerald conclusively shows that it is *not*—that because certain natural processes do not under actual conditions reverse, therefore they are irreversible, the examples of irreversibility in nature, on which Prof. Ostwald founds his "fourth attack" on the mechanical theory, are singularly ill-chosen. He directs us to the life-histories of organisms, these life-histories themselves being but a very brief portion of the indefinitely long series of transformations which the matter for that short time identified with them is going through. Yet even within this narrow range reversible actions are to be found. Surely all metabolic processes must be regarded as such. Moreover at this very moment there may quite possibly be built into our own bodily tissues, matter which some generations ago entered into the physical composition of our ancestors, has since been degraded from the rank of organic substances altogether, and is now through new-old combinations and re-combinations once more raised to its former position and forms part of a living organism. If this can come to pass, vital phenomena are clearly not irreversible. It may take much more than the lifetime of a man or of a tree for the whole cycle of operations to be complete; but when it is complete, we have as fair an example of a reversible series as we are likely to find in nature. E. M. C.

"E. M. C." calls attention to the fact that if trees do not grow into seeds they do grow seeds. This and other cases of reproduction are no doubt cases of *reproducing* the original condition, but Prof. Ostwald would rightly refuse to recognise them as cases of *reversion* to the original condition in the dynamical sense. In the case of a dynamical reversal the flow of energy is reversed. In order to have a case the reverse of the growth of a tree, it would be necessary to have a tree which radiated heat back to the sun in the reverse direction to the flow which at present takes place from the sun to the tree. Otherwise Prof. Ostwald would rightly deny that it was a genuine case of dynamical reversion. It was on account of this complication involved in Prof. Ostwald's example that I cited the very much more simple cases of irreversible thermodynamic operations, such as friction and flow of heat from hot to cold. To cite the very complex organic cases of irreversible operations instead of the simple ones, is only to cloud the question with complexity.

Prof. Boltzmann has already devoted himself to combat Prof. Ostwald's Energetics, and it would be well for those who feel any leaning towards the latter to study the views of this father of the kinetic theory of gases. GEO. FRAS. FITZGERALD.

Trinity College, Dublin, March 18.

Classifying Crushed Ore by Trommels.

IT was very pleasing to me to read in your valuable publication of November 7, 1895, the favourable criticism written by your correspondent, Mr. T. K. Rose, on my report on the loss of gold in the reduction of auriferous veinstone in Victoria. Nevertheless, permit me to make a few remarks to endeavour to

remove a misapprehension under which, it seems to me, that he was labouring, after perusing my report, with regard to the limit to which I suggest volumetric sizing. He seems to think I advocate that the grading of the sand, which has been separated, as far as feasible, from the slimes (which are to be subsequently classified separately in four Spitz-Kästen), should be effected through very fine sieves—60-mesh screens, or under. I quite agree that to attempt to do so would fail. Such, however, is not the meaning, or, I think, the construction which can be placed on the context of my report. A glance at the diagram illustrating the sequence of the methods of reduction, clearly shows, I submit, that it is only the *coarser sands issuing from the bottom of the slime separator*, that are subjected to "volumetric sizing" in a trommel, which classifies them into three grades, the finest being through a 40-mesh sieve, which is, I apprehend, practically, the most suitable grade for the Frue-vanners to do close work; the overflow from the concentrates flowing into the Spitz-Kästen.

I trust that these observations will dispel the misapprehension which your correspondent entertained on this point at the time when he wrote his article, as I respect his opinion, and would regret to be misunderstood by him. HENRY ROSALES.

I REGRET to have misunderstood Mr. Rosales, whose report is certainly entitled to most respectful and careful consideration. My mistake (a natural one, I think) arose from a statement made on p. 13 of the report. Here Mr. Rosales says, in speaking of the Johnson's Reef Gold Mines Company, Eaglehawk, that "the battery sand should previously be classified into different grades by 'sizing'. . . . Such could be accomplished by delivering it into trommels fitted with screens of different meshes. The mantel of the first trommel might be a sieve of 40 to 50 holes to the lineal inch, and the second trommel might be covered with *a screen of* 64 *holes to the lineal inch*. . . . This system of sizing would certainly be applicable." (The italics are my own.) On p. 50, where Mr. Rosales recurs to the subject of trommels, he does not mention any screen finer than 40-mesh, but, on the other hand, does not state that this is the finest that should be used, and refers to it merely in the following words:—"Supposing it [*i.e.* the trommel] to be covered with $\frac{1}{30}$ or $\frac{1}{40}$ wire gauze." Mr. Rosales' explanation will, I feel sure, be gladly received by others, besides myself, who have read his valuable report.

T. K. ROSE.

Crush-Conglomerates in Ireland.

IN your issue of March 5 there is a letter from Mr. McHenry, in which he mentions the occurrence at Portraine and Lambay Islands, Co. Dublin, of conglomerates which he considers to be of the nature of crush-conglomerates. During the past two summers we have been examining these sections, and can corroborate Mr. McHenry's statements with regard to the presence of crush-conglomerates; but our investigations have not led us to conclusions altogether similar to his, with regard to the igneous rocks of the district. We hope to publish our results before very long.

S. H. REYNOLDS.
C. I. GARDINER.

CLAUDIUS PTOLEMY AND HIS WORKS.

CLAUDIUS PTOLEMY! What reader of the most elementary science is not familiar with his name, at least in adjectival form, in connection with the Ptolemaic system, and yet how little is known of him as a personality. That he lived in Egypt during the reigns of Hadrian and Antoninus Pius, and made astronomical observations chiefly on a terrace in Alexandria, sums up nearly the whole. But his works (addressed to Syrus, of whom also nothing is known) were the standards of authority in geography and astronomy for many centuries after his death; and though the tide of science has left them far behind, they can never be quite forgotten or cease to be of high interest in scientific history. His great astronomical work was translated into Arabic (changing its name in the process), and on the revival of learning in Europe was translated from that language into Latin, as it afterwards was from the original Greek. A French version was published by Halma at Paris in 1813–16, but no English rendering (except of small portions) has ever appeared. The British Museum Catalogue shows that our national collection contains a large number of Greek editions and Latin translations of the Almagest (as the Μαθηματικὴ Σύνταξις is always called, from the Greek for "greatest," with the Arabic definite article prefixed) and Geography of Ptolemy, as well as of most of his smaller works; Halma's editions of the Greek of the Almagest and Geography, with French translation in parallel columns; and Italian translations of the latter and of the Optics. Every student of Ptolemy must be under so much obligation to Halma, that it may be of interest to state that he was born at Sédan in 1755, and after being Principal of the college of his native town, became Professor of Mathematics at the Prytanée at Paris, where he held at various times other offices, one of them being that of librarian to the Empress Josephine. Besides his version of Ptolemy and of the not very lucid Commentary of Theon (father of the ill-fated Hypatia) on part of the Almagest, he published a French translation of the Phenomena of Aratus, and died in 1828. His edition of the Almagest is preceded by an elaborate and interesting preface, and has appended to it some Notes by Delambre. Two of Ptolemy's minor works, the Planisphærium and the De Speculis, appear to be extant only in Latin versions; the chronological table, however, of reigns up to his own time still exists in the original, whilst of the astrological work called "Tetrabiblos" or "Quadripartitum," we have not only the Greek, but Latin, French, and English translations.

The Almagest was so exhaustively examined and commented on by Delambre, that little can be added to his conclusions.[1] It is evident that Ptolemy's work is founded chiefly upon the observations of Hipparchus, which were made at Rhodes about three centuries before. Lord Macaulay's omniscient schoolboy probably believed that Ptolemy founded the system by which sun, moon, planets, and stars all moved round the earth, though the thought may have crossed his mind that this view was held before the appearance of the Alexandrian astronomer. This is, in fact, somewhat akin to the extensively-believed idea that Newton discovered the fact that external bodies are drawn or attracted to the earth. What is really due to Ptolemy as the author of the Ptolemaic system, is the reducing into a systematic form for explaining the planetary motions the ingenious imaginative machinery of epicycles and deferents. This is now so generally understood that we need not enlarge upon it here. It is almost remarkable that his discussion of the motions of the inferior planets, Mercury and Venus, did not lead him to the elaboration of the Tychonic system, something akin to which Vitruvius and Pliny seem to have had in mind, and which would in that case have held its ground for centuries; when actually started by the Danish astronomer, it was behind the age and soon stranded by the advance of science, his own contemporaries seeing that its cause was hopeless from the first. More credit is due to Ptolemy for his investigations respecting the motions of the moon, which led him to the discovery of the inequality known as the lunar evection. The inequalities he endeavoured to explain by epicycles, but for the latter he introduced in addition an eccentric, the centre of which turned about the earth in a direction contrary to that of the motion of the epicycle. A not inconsiderable portion of the Almagest is devoted to eclipses and their prediction; and we are indebted to Ptolemy for an account of three eclipses of the moon which were observed at Babylon in the years B.C. 721 and 720 under a king whom he called Mardokempados, but whose real name was Merodach-Baladan, and who, after a long contest, was completely crushed and de-

[1] A very able though shorter discussion is given in Narrien's "Historical Account of the Origin and Progress of Astronomy."

prived of his dominions by Sargon, the greatest of the Assyrian monarchs.

Ptolemy describes his method of attempting to determine the distances of the moon and of the sun. To the former he obtained a very fair approximation, making it equal to about fifty-nine semidiameters of the earth; but the sun's distance he thought to be only about 1210 of these semidiameters, or about twenty times the distance of the moon, which is in that unit only about the square root of its true amount. The eighth book of the Almagest contains the earliest extant catalogue of stars, founded upon that of Hipparchus. Six stars are marked red or reddish, one of which, Sirius, has ceased to be so, furnishing a remarkable instance of change of colour; the reading in Ptolemy was contested, but there is no real reason (as has been pointed out by Dr. See) to doubt its genuineness, and the red colour of Sirius in ancient times is confirmed by the testimony of several classical writers.

We must now turn from Ptolemy as an astronomer to Ptolemy as a geographer. If his work in the former department is founded principally upon that of Hipparchus, so does he take for the basis of his geographical system the work of Marinus the Tyrian, which in its latest form but little preceded his own. Those only who are ignorant of both can accuse Ptolemy of plagiarism in this, seeing how fully he recognises his obligations to his predecessor whilst pointing out the necessity of modifying some of his conclusions with regard to the most distant known regions of the world. But for Ptolemy, indeed, we, in these days, should never have heard of Marinus at all. "It is clear," says the late Sir E. H. Bunbury, "that he did not attempt to present his readers with a complete body of descriptive geography such as was furnished by the comprehensive work of Strabo. His object, like that of Eratosthenes at an earlier period, was simply to correct and reform the map of the world so as to adapt it both to the increased knowledge of distant countries and to the improved state of mathematical science, which were possessed in his day." Much more was then known than in the time of preceding geographers of the extent of Africa towards the south and of Asia towards the east; but, in applying this increased knowledge, Marinus exaggerated the extensions so greatly as to distort his map of the world almost as much as theirs, though in the opposite way. This led him to what was, to some extent, a retrograde step—the idea that Asia had an indefinite extension towards the east, similar to that entertained by Columbus when he expected to reach the Indies by a voyage to the west, little dreaming of another isolated continent between.

Ptolemy refers to his astronomical in his geographical work, so that the latter must have been composed subsequently to the former, and its date was probably near the end of the reign of Antoninus Pius, who died in A.D. 161. He fully appreciated the necessity, if positions in the world were to be accurately laid down, of determining their latitudes and longitudes and mapping them thereby. But, unfortunately, in his time the number of places for which this had been done was so small that he was obliged, to a very great extent, to rely upon results obtained from itineraries by the old rough method. These he places before us, both on his map and in extensive tables, as if they had been really founded upon scientific determinations. To quote Bunbury again: "He saw clearly the true principles upon which geography should be based, and the true mode in which a map should be constructed. But the means at his command did not enable him to carry his ideas into execution; the substance did not correspond to the form, and the specious edifice that he reared served, by its external symmetry, to conceal the imperfect character of its foundations and the rottenness of its materials." Some of the exaggerated conclusions of Marinus, particularly with reference to the distances of places in the east of Asia, he rejects, but can only suggest conjectural reductions of them. But even in lands within the bounds of the Roman Empire, few indeed were the places of which even the latitudes, still less the longitudes, had been scientifically determined. Hipparchus had suggested the observation of lunar eclipses at different stations as a means of finding the difference of longitude of these stations; but even in the time of Ptolemy, no such determinations had been actually made, though he refers to one which took place on September 20, B.C. 331, shortly before the battle of Arbela, or rather Gaugamela, which was observed, but not with sufficient accuracy to make it the basis of calculation. In inquiries of this nature, a remark made by the late Sir George Airy often comes into one's mind: "The first man who made good astronomical observations was the first man who made good clocks"—a graphic way of saying how essential was an accurate means of measuring time.

We have reserved but a short space to speak of what may be called Ptolemy's minor works. The principal of these are his Tetrabiblos or Quadripartite, which is in fact a treatise on astrology in the modern sense of the word, and his Harmonics, in which he gives an account of the theory of music. The former (as well as the Centiloquy, or hundred aphorisms, which forms a sort of supplement or summary to it) has been translated into English, the last time by J. M. Ashmand, whose version was published in 1822, and dedicated (like the Prince Regent's famous bumper in Scott's presence) to the author of Waverley. There does not appear any good ground for doubting its genuineness, though many have wished to do so from their admiration of Ptolemy, and feeling that it was unworthy of him. Great astronomers, however, in later times than that of Ptolemy, have believed in the delusive and imaginary "science" of judicial astrology, which still serves to charm some of the ignorant and foolish, and excite apprehensions in others of that still large family. The translator of the Tetrabiblos (who appeared before the public only in that capacity) had no feeling of this kind, and endeavours in a note to parry an objection to astrological predictions as old as the time of Cicero by citing a case of a man who, he tells us, was born within a few moments of George III., and in the same parish, went into business in the same month (October 1760) in which that king came to the throne, was married, like him, on September 8, 1761, and died, like him, on January 29, 1820, "coincidences," we are told, "highly remarkable." However, if any one can derive amusement from astrology, we need not object. Flamsteed drew the horoscope of the Royal Observatory, Greenwich, at the moment of its foundation, though he affixed a line from Horace asking who could forbear laughter. So we may take a few of Ptolemy's notions, one of which was that natural characteristics in different regions and climates was caused by the planets and constellations holding sway there, whence the inhabitants of Britain, for instance (and let us remember that by the argument this still applies), are, he tells us, wilder, bolder, and more ferocious than others.

Ptolemy's Harmonics was edited, with a Latin translation, by Dr. Wallis, in 1682, and an abstract of it is given in Rees's Cyclopædia. We cannot describe here his proposals for the reformation of the musical scale; but we cannot help regretting to find him, in the third book, going off into fanciful musical relations amongst the celestial spheres in a way which reminds us of some portions of his book on astrology.

Our author wrote a work on Optics, which is only known to us through Latin versions made from incomplete Arabic manuscripts. He is said to have discovered the fact of the refraction of the rays of light by passing through substances of different density; but, like

Descartes with regard to the law of this refraction, he was probably anticipated, and by a much longer interval. His Planisphere and other smaller works scarcely call for notice. On the whole, it may be said that Ptolemy was rather a collector and condenser of the scientific facts and methods than an original discoverer or investigator. And with all proper Baconian admiration for the wisdom of the ancients, we may be thankful that in our time, at least in the domain of natural science, the wisdom of the moderns has been added to it.

W. T. LYNN.

A VIEW OF KILAUEA.

THE interest of Kilauea is perennial. Popocatapetls may arise in a night, or Krakatoas may be blown to shivers, and attention may thus be temporarily withdrawn from the great Hawaiian volcano. But such cataclysms are exceptional. Kilauea, on the other hand, is always available to the student of vulcanicity, while Dutton's beautifully illustrated memoir, and Dana's great monograph enable observers to use their opportunities to the fullest advantage. Dr. Benedict Friedlaender's papers in *Himmel und Erde* (Bd. viii. 1895) are the latest addition to the extensive literature upon this subject, and give a series of photographs, which are a useful supplement to those of the two American authors. Dr. Friedlaender's narrative shows that the mountain can now be studied without inconvenience. A good track runs from Kilo, on the north-eastern coast of Hawaii, to the summit of Kilauea. It passes first through plantations of sugar-cane and banana, and past clumps of screw-pine (*Pandanus*). At the height of about 1000 metres the tropical vegetation is left behind; trailing Freycinetias and great Cibotias give place to tree ferns and an undergrowth of plants of temperate affinities, such as cranberries (*Vaccinium*). On the north-eastern edge of the crater, at the height of 1230 metres, is a good hotel, in telephonic communication with the coast. Dr. Friedlaender's description of the mountain takes us over a good deal of old ground; but his account records recent changes, and his notes and views bring out several characteristic features of the volcano. In the first place he emphasises the fact that though Mauna Loa rises to the height of the Jungfrau, neither it nor Kilauea have any claim to be called mountains. Whereas some of the Italian volcanoes have slopes of 30°, that of Mauna Loa is only 6°, and that from the summit of Kilauea to the north-east cape of the island is only 1° 35′. The summits of the volcanoes are not mountain summits, but only a high plain. Orographically, Kilauea is only a lateral crater on Mauna Loa; but geologically they must be regarded as two distinct volcanoes, as eruptions sometimes take place on Mauna Loa, while the lava lake in the other is at rest. As Mauna Loa is 3000 metres higher than Kilauea, and the weight of a column of basaltic lava of that length is 900 atmospheres, this independence of the two volcanic centres appears at first sight to be in contradiction to the fundamental principles of hydrostatics. The author explains this by the assumption, that the lavas in the central pipe of Mauna Loa are of lower specific gravity than those of Kilauea, owing to the greater abundance of

The lava lake.

(a)
(b)
(c)

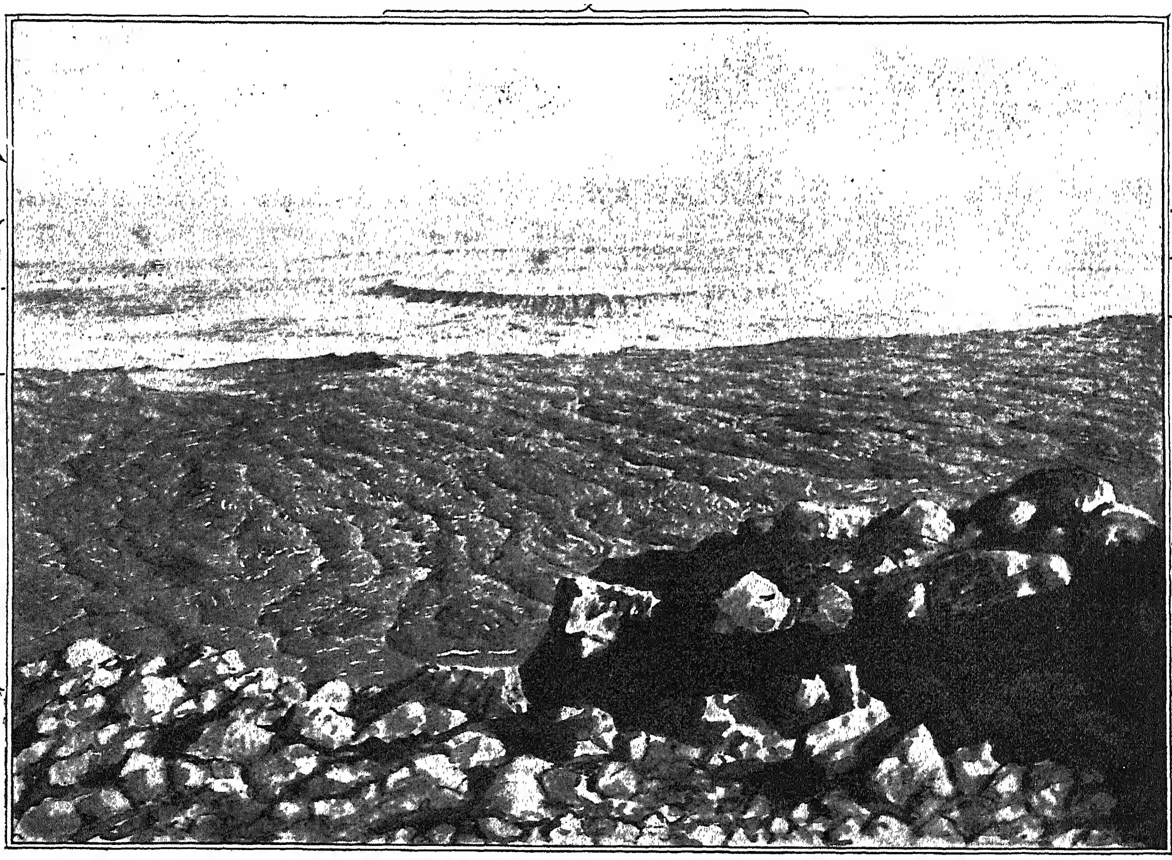

FIG. 1.—(*a*) Hut. (*b*) Margins of the secondary crater. (*c*) Margins of the primary crater. (*d*) Secondary crater. (*e*) Primary crater.

gas in them. The insignificant action of steam in Kilauea is declared by the author to be the most remarkable fact about it; for he says that it works "practically without steam, but with colossal quantities of highly fluid lava." Hence explosive action is very exceptional, though such an eruption did once occur in that year of violent upheavals 1789. It is owing to Kilauea having been built by the slow, quiet, piling up of lavas without explosions, that its crater is so very different from that of the Italian volcanoes. Instead of a narrow, deep, gullet, it is a broad, open, cauldron-shaped depression. The accompanying view illustrates the nature of the crater; it is from a photograph taken from the north-western corner, and looks due southward. In the foreground are some blocks of lava, on the margin of the plateau in which the crater lies; beyond this is the flat floor of the primary or major crater, at the foot of a vertical lava wall, 140 metres in height. The greatest diameter of the major crater is 4·7 kilometres; but the width to the opposite wall, seen in the figure as a long, low line in the far distance, is at this point only a little over 3 kilometres. In the centre of the view is seen the famous lava lake, 250 metres in diameter; this occurs in a raised tertiary crater in the centre of the depressed secondary crater. This latter extends across the view from side to side, but it is small in comparison with the primary crater; its average diameter is only 700 metres, so that its area is only about half a square kilometre, whereas the major crater occupies 10·6 square kilometres. The depth of the secondary crater is about 20 metres.

Dr. Friedlaender remarks that in addition to the subjective difficulty in the description of a volcano, there is, also with Kilauea, the objective difficulty of the rapid changes that take place there. These render necessary frequent periodical re-descriptions. One such change is now in progress, for after a pause of fifteen months the mountain is again in active eruption.

NOTES.

THE British Section of the International Memorial to Pasteur has now assumed definite shape, and the Provisional Committee, which already includes the names of the Dukes of Devonshire and Westminster, and many distinguished men of science from all parts of the United Kingdom, held its first meeting last Friday, at the rooms of the Royal Society, Burlington House, under the presidency of Sir Joseph Lister. It was unanimously decided to apply for subscriptions towards the erection of a monument to Pasteur in Paris, from persons in the United Kingdom, India and the Colonies, interested in science and the various industries which have been benefited by Pasteur's labours. An Executive Committee was formed, consisting of Sir Joseph Lister, Sir John Evans, Sir Henry Roscoe, Dr. Thorne Thorne, and Prof. Percy Frankland (Hon. Secretary). Subscriptions may be sent to Sir John Evans, who will act as Hon. Treasurer, at the Royal Society, Burlington House, W.

AT the stated meeting of the Royal Irish Academy, held on March 16, the Earl of Rosse, K.P., F.R.S., was elected President, in succession to Dr. J. Kells Ingram, whose term of office had expired. The President nominated as Vice-Presidents—The Rev. Dr. Haughton, F.R.S., the Most Rev. Bishop Donnelly, D.D., Dr. J. Kells Ingram, and Dr. Ben. Williamson, F.R.S. The following were elected Honorary Members in the Department of Science—Sir Joseph Lister, Bart., P.R.S., Sir W. H. Flower, K.C.B., Rev. T. G. Bonney, F.R.S., and Prof. Wm. Ramsay, F.R.S.

IN the Japanese Imperial Budget for the current year, we observe that a sum of 21,639 dols. has been set aside for earthquake investigation. This is a grant over and above the usual expenditure of the Central Observatory controlling the seismic survey of the country.

THE monument to Lobachevsky will be unveiled this autumn at Kazan. It consists of a bronze bust of the late geometer, one metre high, placed on a column of black polished granite, about 50 centimetres in diameter and 1·4 metres high, standing upon two steps of grey unpolished granite. The total height of the monument is 3·6 metres, and its cost about 3,300 roubles (£330).

WE learn from the *British Medical Journal* that Prof. Behring has given the half of the Alberto Levi prize of the Paris Academy of Sciences, recently awarded to him (amounting to £1000) to the Prussian Government Fund for the Furtherance of Research on Serum Treatment. The moneys received by the official control stations, where the diphtheria antitoxin is tested before it is allowed to be sold, will also be paid into this fund.

THE National Academy of Sciences, acting on the request of the Secretary of the Interior of the United States, has reported a Commission to investigate the forestry problem, consisting of Charles S. Sargeant, Alexander Agassiz, Henry L. Abbot, William H. Brener, Arnold Hague, and Gifford Purchot. The Secretary will recommend to Congress an appropriation of 25,000 dols. to cover the expenses of the Commission.

GENERAL JOHN B. WOODWARD, under whose able administration the Brooklyn Institute developed into the largest local scientific society in the world, with a membership of 3700, died on March 7, of pneumonia, after a short illness. General Woodward was for many years President of the Brooklyn Institute, but declined re-election last spring. He held many other prominent stations, having been a general in the army during the war of the rebellion, a bank president, candidate for mayor of the city, and President of the Society of Titans, none of whom were less than six feet two inches high. He was sixty years old.

THE Brooklyn Institute has completed negotiations for the purchase of the collection of Lepidoptera made by the late Berthold Neumoegen, comprising 40,000 to 45,000 specimens comprising 13,000 to 14,000 species, upwards of 1000 being type-specimens. This is the finest collection in America. As much as 100 dols. was paid by Mr. Neumoegen for a single specimen in several instances. The Institute will also secure the collection of Jacob Doll, of over 55,000 specimens, and will employ Mr. Doll as curator. Edward L. Graef will present his collection of about 20,000 specimens. The Institute already owns the Calverley collection; and the aggregate of all will give it the most complete collection of Lepidoptera in the world.

THE opening of the bicycle season shows the importance of that vehicle as a means of locomotion, and its potency as a factor in promoting good roads. The New York and Brooklyn Bridge has just been made free to bicycles, a change which required an Act of the Legislature to secure it. The grant for paving in New York City this year includes 1,000,000 dols. for asphalt pavement in a total amount of 1,250,000 dols. The pneumatic tire has been applied to ambulances in Brooklyn with great success. The ingenuity of inventors is taxed to devise improvements in all parts and appliances of the machine; and while the New York Cycle Exhibition last January was the largest exhibition of any special machinery that has been held in America, the exhibition now in progress in Brooklyn adds several apparently useful novelties not shown heretofore.

THE Governor of New Jersey has signed the Bill ceding the palisades of the Hudson to the United States Government for a national park.

THE General Electric Company and the Westinghouse Electric Company have combined, and each will be allowed to use the patents of the other.

IN connection with the Hungarian Millennial Exhibition, which will be opened on May 2, a Congress of Mining and Geology will be held at Budapest on September 25 and 26.

THE third International Congress of Dermatology will be opened in London on August 4, and will terminate on August 8. The President will be Mr. Jonathan Hutchinson, F.R.S.

WE regret to record that Prof. Sappey, the distinguished anatomist, died at Paris on March 14. His elaborate "Treatise on Descriptive Anatomy" is one of the best contributions to anatomical literature published in any language. He was a member of the Section d'Anatomie et Zoologie of the Paris Academy of Sciences.

THE *Scientific African* states that Mr. M. A. Schlechter, of the Botanical Museum, Grünewald Strasse, Berlin, is about to start on a collecting tour in South Africa. He will visit the Coud-Bokeveld, Namaqualand, Transvaal, and the Limpopo and Zambesi rivers.

RUSSIAN astronomers are completing their arrangements for viewing the forthcoming eclipse of the sun. The Pulkova Observatory will send an expedition to the Lower Amur; the Academy of Sciences has chosen Novaya Zemlya for the seat of its operations; so has the Kazan Society of Naturalists; while the Geographical Society will send the Director of the Irkutsk Meteorological Observatory, A. V. Voznesensky, to Olekminsk, on the Lena, for meteorological observations. Prof. Glasenapp and L. G. Vuchikhovsky propose to go to Finland on their own account. The young Russian Astronomical Society (it was founded only in 1891) directs its chief attention to physical observations, and it will have three parties of observers, provided with photographic appliances. The chief station will be on the Lena, where the duration of the eclipse is the longest, and it is proposed to photograph there the corona by Schaeberle's method, with an objective of long focal length, and also to photograph, by means of two spectrographs, the spectrum of the corona, as well as the limb of the sun, by means of a camera provided with a Rutherford prism. At the second station, on the bay of the Ob, the corona will be photographed by means of several ordinary cameras; while at the third station, in the eastern parts of the Uleaborg province, to the north of Enontekis, the corona will be photographed by means of several cameras following the movement of the sun; and it is intended to establish a comparison between the spectrum of the corona and that of helium. The usual determinations of the duration of the eclipse will be made at the first and third stations.

MR. R. H. SCOTT has sent us a cutting from the *Diario Oficiel*, which records that on March 2 a well-marked earth-movement passed over the capital of Mexico at 0h. 24m. a.m., Mexico time, the direction being from north-east to south-west, and the duration about twelve seconds. The shock was recorded at other places as follows:—

Place.	Time. h. m.	Duration. s.	Direction.
Tecuitatlan	11 57	20	—
Colima	12 3	30	W.N.W. to E.S.E.
Morelia	12 12		S.S.E. to N.N.W.
Manzanillo	12 20	30	—

THE question as to the desirability of retaining the Museum of the Geological Society has formed the subject of long deliberations by the Council of the Society. It was announced at the recent annual meeting that, in accordance with the report of a special Committee, the Trustees of the British Museum had been asked whether they would undertake to house and care for the collections, keeping type-specimens and specimens illustrative of papers read before the Society distinct, and defraying also the expenses of transference. To these conditions the Trustees have assented, and the matter will before long be submitted to the Fellows for their decision at a special general meeting.

PROF. STROUD informs us that in obtaining photographs with Röntgen rays, the time of exposure can be reduced by placing a card covered with barium platino-cyanide immediately in front of, and in contact with, the sensitive plate. A very good shadow-picture of the bones of the fingers was thus obtained by Prof. Stroud with a two minutes' exposure, whereas without the fluorescent card an exposure of from twelve to fifteen minutes was required to give a similar result. It is suggested that the introduction of some suitable fluorescent substance (rendered active by X-rays) into the sensitive film of photographic plates would greatly shorten the time of exposure requisite.

THE gigantic extinct birds of the order "Stereornithes," which are peculiar to the Eocene beds of Patagonia, have been until lately quite unrepresented in the museums of Europe. Sir William Flower has just acquired for our National Collection the series of the remains of these birds belonging to Señor Florentino Ameghino, of Buenos Ayres. This includes a complete skull of *Phororachos inflatus*, which is of most extraordinary size and appearance, and the lower jaw of an allied species (*P. longissimus*), about two feet in length.

UNDER the name *Canis holubi*, Dr. L. V. Lorenz has lately described a new wild dog from Western Matabeleland. The specimens of this new species, received by the K.K. naturhistorische Museum of Vienna from Dr. E. Holub, had been previously assigned to *C. adustus*, Sund., but Dr. L. v. Lorenz (*Verh. Zool.-Bot. Ges.* in Wien, 1895) now points out the differences between these two nearly allied species. In a subsequent paper (*Ann. d. K.K. naturh. Hofmuseums*, xi. h. 1), Dr. Lorenz gives further particulars, and figures the skull of *C. holubi*.

UPWARDS of sixty ornithologists assembled on Wednesday, the 18th inst., at the monthly meeting of the British Ornithologists' Club, held at Frascati's Restaurant in Oxford Street. The proceedings were of special interest on account of the splendid series of more than 900 eggs of the Cuckoo, which were on view on this occasion, having been assembled together from the cabinets of various collectors by the energy of Mr. Edward Bidwell. Most of the Cuckoos' eggs were accompanied by clutches of the eggs of the foster-parents, in the nests of which the mother-cuckoo had placed them. There are about 110 foster-parents at present known of *Cuculus canorus*, and examples of the eggs of 76 of these foster-parents, accompanied by one or more Cuckoos' eggs, were exhibited to the meeting. The conclusions arrived at by Dr. Eugene Rey, as stated in a recent number of this journal (see NATURE, December 26, 1895, vol. liii. p. 176), were well illustrated by this excellent series, which was believed to be the largest ever got together on one occasion.

IN a recent number of NATURE, February 27 (vol. liii. p. 393), under the heading "The Destruction of Trees by Lightning," we gave an account of the investigations which had been carried out by Jonescu and others to determine, if possible, the reasons underlying the observed facts that some kinds of trees are more liable to be struck by lightning than others. It was there stated that the whole question seemed to turn on the nature of the tree—that is, whether it was a tree rich in resin, or one rich in starch; further, the degree of conductivity seemed to increase the less oil and the more starch the tree contained. Some interesting statistics are given in the current number of *Prometheus* (No. 336, p. 383), concerning the white poplar. In the neighbourhood of Moscow, out of 597 trees struck by lightning, no less than half of them—more accurately 302—turned out to be the white poplar. This fact is sufficient to show that the degree of conductivity of this tree must be very high, and it has been suggested that country people should plant these

trees for natural lightning conductors. The pyramid-poplar has also for a long time been known to be specially attached to the lightning flash, so that by planting many of these round the farmhouses they should form natural and inexpensive lightning conductors, more effective perhaps than many now in use.

ACCORDING to Hermann Feigl ("Die Religion der Chinesen," *Oesterreich. Monatsschr. für den Orient*, xxii., 1896, 1), the primitive belief of the Chinese has been suppressed by Confucianism and Buddhism. Chinese religion has never had the puerilities, the animal cults, the cruelties and fanaticism of other religions. Like the Jews, the Chinese had very vague ideas of future rewards and punishments and of life after death. Their ancestor cult had no mythologic motive like that of India or Japan. The Chinese, like the Jews and ancient Egyptians, had the philosophic conception that continuation of life lies not in the immortality of the soul, but in the perpetual remembrance of the righteous by mankind. The Chinese could not persevere with metaphysical problems, and so did not advance. Confucius appeared at a time when the Chinese felt the need of a religion; but the greatest of their religious reformers was Lao-tseu, who was born about 604 B.C., or half a century before Confucius. He introduced the word Tao, "way," for the idea of divinity, which previously was confused with the visible sky (Schang-ti). Tao is the element from which everything comes, and to which everything returns. Lao-tseu also taught that the departure of the soul from the body was no disaster for us. But he was too vague to be a convincing reformer. Confucius was not an original thinker like Lao-tseu; he culled what he liked from the older writers, and allowed people to believe what they chose. When consulted he spoke in an oracular manner, and while satisfying no one he offended nobody.

PERHAPS the most interesting region visited by H.M.S. *Challenger*, during her memorable expedition, was that designated by Dr. John Murray as the "Kerguelen Region of the Great Southern Ocean." Leaving the Cape of Good Hope on December 17, 1873, the *Challenger* proceeded in a south-easterly direction, visiting in succession Prince Edward and Marion Islands, the Crozet Islands, Kerguelen Island, and Heard Island, then southward, until on February 16, 1874, having reached longitude 78° 22′ E., some ten miles beyond the Antarctic Circle, she turned north-easterly, for Melbourne, arriving there on March 17, 1874. During this three months' cruise many trawlings were made, and some of the rarest and most remarkable forms were met with. Each one of the staff of writers will remember with what excitement and delight he approached the examination of the results of some of the deep-sea dredgings, from this region, especially the eight trawlings from the most southerly position reached, where the depth was between 1260 and 2600 fathoms. It is of this region, and of the zoological treasures found therein, that Dr. J. Murray writes in a memoir published in the early part of this year in the *Transactions* of the Royal Society of Edinburgh (vol. xxxviii.), thus enabling the student to obtain, within a brief compass, the story, as far as it is as yet recorded, of the marine fauna of this part of the ocean. After a short introduction, we have full lists of the Metazoa found by the *Challenger*, arranged according to the depths. About some of the islands, Kerguelen especially, many of the species were taken from quite shallow water; this is followed by a list of Metazoa recorded from sources other than the *Challenger*, a list of great importance for purposes of comparison. A list is given of identical or closely-related forms, found in the extra-tropical regions of the Northern and Southern hemispheres, but unknown hitherto within the tropics. There are also lists of the Foraminifera, Diatoms, and surface organisms of the region, and of the Radiolaria found in the deposit dredged from a depth of 1950 fathoms, at Station 157 in the Southern Indian Ocean.

PROF. E. C. PICKERING has communicated to the *American Meteorological Journal* for this month, the results of an investigation carried out by Prof. S. I. Bailey, on the diurnal oscillation of atmospheric pressure at the Peruvian stations of Harvard College Observatory. The stations, which are eight in number, are situated along a line nearly four hundred miles long, drawn approximately north and south across the Andes. The lowest station has a very small elevation above the sea-level, while the highest, that on the Misti summit, has an altitude not far short of 20,000 feet, the others being admirably chosen with a view to obtaining meteorological results from a great variety of elevations. The stations are well supplied with instruments, including in every case a Richard barograph, although no mercurial barometer has been regularly in use at any station except Arequipa Observatory. The natural difficulties of visiting the Misti summit have been increased by the civil war, and in consequence of this the continuity of the record has suffered. Energy less active than that possessed by Prof. Pickering and his assistants would have led to the evacuation of the station. At Arequipa Observatory (elevation 8000 feet), where the annual range of the barometer varies from 22·626 inches to 22·404 inches, a comparison was made between the results obtained from the mercurial barometer and the Richard barograph, and after a certain uniform correction had been applied to the latter, it was found that the monthly barographic means were liable to an error as great as 0·034 inch, and that the mean error for the year was 0·013 inch. At all the stations the diurnal oscillations are well marked, and very uniform from day to day. There are striking differences, however, between the records in the different localities, especially in the hour of the morning maximum, and the intensity of the afternoon maximum and minimum. The paper contains the curves for the mean diurnal variation for the year April 1894–March 1895, together with the corresponding values for a single day, selected at random, and the investigation points out this important result, that "from these curves it appears that the retardation of the morning maximum is at least, in part, a function of the altitude." The diagram shows that the time of maximum near the sea-level is 9 a.m.; at 4000 feet, about 9h. 20m.; at 8000 feet, about 9h. 40m., while at the Misti summit the maximum pressure is near noon.

THE Pilot Chart of the North Atlantic Ocean for the current month contains a chart showing the tracks of the storms during March for the six years 1890–95, north of the 35th parallel and west of the 30th meridian. The diagram shows that the portions of the North Atlantic within the prescribed limits in which storms are most frequent during March are (1) the region immediately to the east of Cape Hatteras and the New Jersey coast, and (2) the area included between the parallels of 45° and 50°, and the meridians of 30° and 40°. Each track bears a number, by which the date of the appearance of the storm may be obtained by reference to a table. The information is both interesting and useful, and no doubt similar tracks will be given for other months.

THE Zi-ka-wei Observatory has published the first of a proposed series of papers entitled "Typhoon Highways in the Far East." The present paper is by the Rev. L. Froc, S.J., and refers to the storms which have occurred near the south end of Formosa Strait, between 1877 and 1895, and especially to the typhoon of September 19 last. The principal conclusions arrived at are (1) that a violent typhoon may be expected to traverse the south end of the Formosa Channel at least once a year; (2) the direction from the South Cape varies between N. 20° W. and N. 85° W., the *ensemble* of the storms forms a kind of fan, whose point lies upon the south end of Formosa Island, and which thence spreads out to the coast of China; (3) the period of occurrence is from the middle of July to the beginning of

October; a curve of the monthly frequency shows that a considerable maximum coincides with the equinox. The most striking characteristics are the suddenness of their appearance and the narrowness of the storm area; in some cases Father Dechevrens has shown that the diameter did not exceed fifty miles, and that the velocity of translation may vary from eight to twenty-six miles per hour. The author discusses, at some length, the various signs which precede the occurrence of the typhoons.

THE numbers of the *Naturwissenschaftliche Wochenschrift* for February 16 to March 8 contain an account, by Dr. H. Hallier, of a botanical investigation of Central Borneo, organised at the instance of the Dutch Government, under the direction of Dr. Treub, of Buitenzorg. This portion of the island is an almost unknown land from a natural history point of view; previous explorations having been made from Sarawak, Labuan, British North Borneo, and Dutch South Borneo. A very large collection was made, calculated to amount to about 3000 distinct species of dried plants, as well as a considerable quantity of alcohol material, and many living roots. These are now being examined at the Botanical Institution at Buitenzorg. The mountain K'nepai was ascended, about 1125 metres high. Its flora is described as being especially rich in Orchideæ and in species of *Nepenthes*.

THE interesting question has been recently again raised, by Messrs. Gotschlich and Weigang, as to whether the virulence of cholera cultures is dependent upon the number of bacilli present, or whether the age of the culture affects the toxic character of the individual bacilli. Estimations have been made of the number of bacilli present in cholera cultures at different periods of time, and it has been found that a rapid diminution takes place with the increasing age of the culture. Thus at 37° C. at the end of two days, only 10 per cent. remained of those present at the close of the fully virulent age of twenty hours, whilst after three days only 1 per cent. were left. Messrs. Gotschlich and Weigang have also determined the approximate number of individual cholera bacilli which constitutes a lethal dose, and this they state to be from 200 to 300 million bacilli, and that as long as this number is present, it is a matter of no consequence whether the dose is abstracted from a twenty hours' old culture or from a three days' old culture. The apparent diminution in the virulence of cultures some days old, is not due to the attenuation of the bacilli at this age, but is attributable to a smaller number being present in the culture, for equally fatal results were obtained when larger quantities of such cultivations were employed.

PSYCHOLOGY has found in America a congenial field for development, one of the clearest marks of its vitality there being the excellent *Psychological Review*. The March number of that journal contains the address recently delivered by Prof. McKeen Cattell as President of the American Psychological Association; and how great has been the academic recognition of the subject in America during the past few years is shown by his remark, that "psychology is a required subject in the undergraduate curriculum wherever studies are required, and among university courses psychology now rivals the other leading sciences in the number of students attracted, and in the amount of original work accomplished." The following other indications of growth are recorded in the same journal:—The psychological department of Cornell University has moved to Morrill Hall, where it is said to have nine rooms and four thousand square feet of floor space. The psychological laboratory of the University of Nebraska has been moved into the first-floor of the new library building, and occupies a series of five rooms with a floor space of three thousand square feet. In the new biological buildings, which the University of Chicago will erect with a part of the million dollars given by Miss Culver, ample provision will be made for the psychological laboratory. In the new Schemerhorn Hall of Natural Sciences, to be erected for Columbia University at a cost of about 400,000 dollars, more than one-tenth of the building is allotted to psychology. At this rate of progress, America will soon rival Germany in psychological laboratories and productions.

THE Académie Royale de Belgique announce the following prize subjects for 1897:—New researches on the thermal conductivities of liquids and solutions. An important contribution to the geometry of straight lines. A discussion, from the theoretical point of view, of the question of variations of latitude, and their causes, the paper to include a criticism of the works of geometers on the subject, from Laplace to the present time. New researches on the physiological *rôle* of albuminoid substances in the nutrition of animals and plants. New anatomical and systematic researches on insects of the group Aptera. Does there exist a nucleus in Schizophytes? If so, what is its structure, and what its mode of division? A discussion of the changes made in the classification of the deposits which constituted the *Laekenian* system of Dumont, most of which are usually referred to the Upper Eocene; to bring forward new evidence in support of the classification adopted. The value of the prize to be awarded for the best work in each of these subjects is six hundred francs. Memoirs may be written in French or Flemish, and should be addressed to the Secretary of the Belgian Academies before the beginning of August next year.

MESSRS. WILLIAMS AND NORGATE have just issued a classified list of recent scientific publications, chiefly of foreign origin. Book-hunters seeking scientific works would do well to consult the list.

MR. HIRAM S. MAXIM is contributing a series of illustrated articles on "Automatic Firing Guns" to *Industries and Iron*.

A PAPER on "The Food and Labour-Power of Nations," contributed by Prof. F. S. Nitti to the March number of the *Economic Journal*, contains a large number of facts and figures of interest from a physiological, as well as from an economic and social, point of view.

THE Tōkyō Mathematico-Physical Society has recently published in its *Proceedings* a reprint of Clifford's Translation of Riemann's Habilitationschrift (1854), viz. on the hypotheses which lie at the bases of geometry (NATURE, vol. viii. Nos. 183, 184, and *Mathematical Papers*, pp. 55–71).

AN elaborate discourse on Helmholtz's investigations on the "Grundlagen der Mathematik und Mechanik," which was delivered in November last at Heidelberg University, by Prof. Leo Koenigsberger, the occasion being a celebration in memory of the founder of the University, has now been published by B. G. Teubner, of Leipzig. A photogravure of Helmholtz forms a frontispiece to the reprint.

WE are glad to receive from the agricultural department of the University Extension College, Reading, the second annual report of field experiments on hay, pasture, potatoes, swedes and mangels, carried out in Berkshire, Hampshire, and Oxfordshire, during 1895, under the direction of Mr. Douglas Gilchrist and Mr. P. H. Foulkes. A notable feature of the work is that it was carried out on land placed at the disposal of the experimenters by various land-owners and farmers, who also gave assistance in the actual superintendence and cultivation of the plots. Two important Farmers' Clubs have also co-operated in the work. By thus enlisting the help of farmers, interest in agricultural experiments is greatly increased, and the results are more likely to command the attention of practical men than if they were obtained by flower-pot cultivation.

THE opening address for the Session 1894–95, delivered to the Royal Physical Society of Edinburgh by Prof. H. A. Nicholson, has recently been published in the *Proceedings* of that Society, and will be found to be an admirable summary of the evidence that has accumulated of late years against the doctrine of Ocean Permanence. The distribution of land and sea in former periods is discussed, and the truly abyssal characters of certain sediments now forming part of continental masses are pointed out in some detail, while mention is made of the evidence for a former Antarctic continent, and other matters are more briefly discussed.

A RECENT number of the *Annali* of the Meteorological and Geodynamic Office of Rome contains an interesting paper, by S. Arcidiacono, on the Syracuse earthquake of April 13, 1895. The disturbed area comprises the south-east corner of Sicily. On the map which accompanies the paper, eight isoseismal lines are drawn, corresponding to intensities 1 to 8 of the Rossi-Forel scale. These are elliptical in form, and have a common axis running from Cape Passero in a north-westerly direction through Vizzini, which is close to the centre of the meizoseismal curve. Applying the method of Dutton and Hayden, the depth of the seismic focus is estimated at about 7400 metres. The axis of the isoseismals coincides nearly with that of the ridge of Monte Lauro, and joins the two principal volcanic centres, now extinct, of the Val di Noto.

THE additions to the Zoological Society's Gardens during the past week include a Diana Monkey (*Cercopithecus diana*, ♂) from north of River Prah, Ashanti, presented by Captain Edgar E. Bernard; an American Tapir (*Tapirus americanus*, ♂) from Brazil, presented by Mr. Basil J. Freeland; a Markhoor (*Capra megaceros*, ♂) from Peshawur, presented by Colonel Paterson; three Canarian Laurel Pigeons (*Columba laurivora*) from the island of Gomera, Canary Islands, presented by Mr. E. G. B. Meade-Waldo; a Common Mynah (*Acridotheres tristis*) from India, presented by Mrs. Sibyl E. Kennedy; a Herring Gull (*Larus argentatus*), British, presented by Dr. E. Goddard; two Grey Ichneumons (*Herpestes griseus*) from India, deposited; two Amherst Pheasants (*Thaumalea amherstiæ*, ♀ ♀) from Szechusan, China; two Swinhoe's Pheasants (*Euplocamus swinhoii*, ♂ ♀) from Formosa, a Bar-tailed Pheasant (*Phasianus reevesi*) from North China, two Great American Egrets (*Ardea egretta*) from America, a Porto Rico Pigeon (*Columba corensis*) from the West Indies, a Vinaceous Pigeon (*Columba vinacea*) from South America, two Rosy Parrakeets (*Palæornis rosa*, ♂ ♀) from Burmah, two Musky Lorikeets (*Trichoglossus concinnus*, ♂ ♀) from Australia, purchased; two Barbary Wild Sheep (*Ovis tragelaphus*, ♂ ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE FIFTH SATELLITE OF JUPITER.—The opposition of Jupiter in 1894 occurred at a very unfavourable time for observations at Mount Hamilton, but a few measures of the fifth satellite were secured with some difficulty by Prof. Barnard. During the observations of the satellite, the planet was obscured by a piece of smoked mica covering half the field. For the measurement of distances the micrometer wires were usually placed perpendicular to the belts on the planet; but on November 18 they were set parallel to the belts, and these measurements accordingly enable the Jovian latitude of the satellite to be determined. Only one eastern elongation was observed. This was on December 3, and the distance was found to be 59″·5; or, reduced to the mean distance of the planet = 5·20 astronomical units, 48″·17. On this date the elongation occurred at 23h. 43·6m. G.M.T., the corresponding time in Marth's ephemeris being 23h. 42m. G.M.T., so that the observed time was over a minute behind the computed time. The ephemeris is based on a period of 11h. 57m. 22·6s., and the observed elongation indicates that this period will represent the motion of the satellite with sufficient accuracy to find it for several years to come (*Astronomical Journal*, No. 367).

THE YERKES OBSERVATORY.—Additional particulars as to the proposed equipment of the new Yerkes Observatory of the University of Chicago are furnished by Bulletin No. 1, the first of a series of notices which will be published at irregular intervals in the *Astrophysical Journal*. The resident staff is to consist of Messrs. Hale, Burnham, Barnard, Wadsworth, Ellerman, and Ritchey, the last-named as optician. The 40-inch object-glass has been completed by Mr. Alvan Clark, and recent tests have shown the definition to be fully equal to that of the Lick telescope, while the light-gathering power is considerably greater. Electro-motors are provided to give the various movements to the instrument and to the elevating floor. The attachments to the great telescope include a solar spectroscope, a spectroheliograph for photographing the solar chromosphere in monochromatic light, a stellar spectroscope, and a photoheliograph of long focus for photographing the direct image of the sun on a large scale. A 12-inch refractor and a 24-inch reflector will also be erected. The meridian-room is designed to contain a large meridian circle, but will be provisionally occupied by a transit instrument. An instrument shop and optical laboratory will be fully equipped with the necessary tools, and it is hoped that it will be possible to construct many of the instruments and laboratory apparatus which may be required in occasional investigations. The main building is now under roof, and will be completed during the summer.

THE PROPER MOTION OF τ TAURI.—A discussion of the meridian observations of τ Tauri, which has been undertaken by Dr. Fritz Cohen (*Ast. Nach.*, 3341), indicates a variable amount of proper motion in declination, but there is less certainty as to the motion in right ascension. For an explanation of the irregularities it is suggested that the star is attended by a dark companion similar to that associated with Procyon, and only giving evidence of its existence by its gravitational effects on the brighter star, causing it to describe an orbit round the common centre of gravity. It is true that the star is already known to be double, the magnitudes of the components being 4·5 and 8·5; but the distance of the visible companion is so great (79″), that the detection of an orbital movement in the comparatively short period covered by the meridian observations is scarcely probable. There is an increase of 11″ in the distance measured in 1823 as compared with that determined in 1783, but as the distance and position angle in 1823 agree substantially with those in 1895, the earliest recorded measure is not to be depended upon. An investigation of the movements of the star by means of micrometric measurements in relation to neighbouring stars is suggested. The association of dark bodies with bright stars, in some cases producing variability either by eclipses or other means, but in others having no appreciable effect on the brightness, is a very notable feature of recent astronomical discoveries.

TWO REMARKABLE SOLAR PROMINENCES.—Father Fenyi reports the observation of two very striking solar prominences (*Astrophysical Journal*, vol. iii. p. 192). One observed on July 15 last was remarkable for its enormous velocity of 858 km. per second in the line of sight; the other, on September 30, for its great height of 11′ 28″, which it attained with a mean velocity of 448 km. per second.

The first one was found precisely at a point on the sun's limb where a group of sun-spots was passing out of view, and its form changed with extraordinary rapidity.

The second prominence was unusually bright, and at 10 a.m. was about 1′ high; eleven minutes later it had mounted to 4′, and the maximum altitude of 11′ 28″ was reached at 10.20, the velocity in the line of sight then being 746 km. per second. Half an hour from the beginning, the prominence was only 3′ 16″ above the photosphere. The spot associated with the latter prominence showed a considerable proper motion in the earlier days of its existence, amounting to about 600 km. per hour The convergence of some of the brighter "stream lines" of the prominences towards a spot was especially marked in these observations, and it is suggested that they have a radial arrangement with respect to the spots. This structure seems to point to the existence of currents in the solar atmosphere, directed either towards the interior of a spot, or outwards from it.

It is stated that an explosion taking place over a sun-spot would accord well with the appearances usually seen in the great prominences which have been observed at Kalocsa, but it is by no means asserted that actual explosions take place.

THE MEASUREMENT OF DOUBLE-STARS BY INTERFERENCE.

An interesting form of micrometer is described by Herr Karl Schwarzschild in *Astronomischen Nachrichten*, No. 3335. The idea is gathered from the instrument which Michelson suggested and used for measuring small diameters and distances, an account of which appeared in the *Memoirs* of the National Academy of Science, Washington, 1891. Michelson, it may be remembered, placed before the object-glass of his refractor a disc in which were two parallel movable slits that set up interference phenomena; and an observation consisted in noting simply the disappearance and reappearance of the interference bands. Schwarzschild's disc, or more accurately oblong framework, on the other hand, contains several slits cut out at equal distances from one another, which cause several images to be visible at the eye-end of the telescope, forming a true multiple-image micrometer.

If one considers the case of the ordinary glass grating as used in spectroscopic work, it is well known that with a bright point as the source of light, we obtain a series of images, the angular distances of which from the unrefracted central image, for a certain wave-length, are given by the formula sin $\alpha = \lambda . n/d$, when λ is the wave-length, d the distance between the lines on the grating, and n their number. In the case of daylight the centre image becomes sharp and white, while the others become broader and broader, in fact small spectra. By exaggerating this idea of the grating, and cutting out of a card slits three millimetres broad and ten millimetres distant from one another, the angular distances of the images for wave-length $\lambda = 570\,\mu\mu$ become very small, and can hardly be separated with the unaided eye. Such a grating as this placed before the object-glass of a telescope directed to a star would show, in the field of view, one colourless image accompanied on its right and left sides by several other images, the first of which would differ only slightly in sharpness and colour from the middle image. It is only to these three images that Schwarzschild pays attention. Of course it is necessary that some means should be at hand by which these images may be moved with respect to one another, and this he accomplishes very simply.

To the object-glass ring, and in a plane parallel to it, he fixes a framework capable of rotation in this plane. Two circular rods, at opposite ends of a diameter of the object-glass, and perpendicular to the framework, are rigidly fixed to the latter, and to these rods is connected the apex of two inclined smaller frameworks containing the slits, the other two extremities of which slide in the grooves of the large frame. Since the distance of this apex from the object-glass can, by means of a rack and pinion movement, be increased or decreased, and since also the distances of the different slits vary consequently in a simple known manner, the displacement of the images in the field of view can be easily calculated.

In bringing a double star into the field of view, two parallel series of images would thus be seen, one series from the primary, the other from the companion. The whole framework containing the grating was then rotated in position-angle until the two lines of images coincided; the position of this line was then determined by means of a micrometer eyepiece, and the position-angle read off. To measure the distance between the stars, the rack and pinion motion connected with the apex of the two frames containing the grating was then used, until the image of he companion appeared exactly between the two images of the primary. The position of the grating was then read off, and a brief calculation gave the distance required. From a series of observations of several binaries, the total mean gave as a probable error of the mean for each evening:

Distance	Probable error in Distance	Probable error in Position angle
2″·3	0″·050	0″·052

The numbers show, as Herr Schwarzschild points out, that greater accuracy can be obtained by this means than by the thread micrometer. He is not, however, very confident about the usefulness of the method, for when the distances to be measured exceed 5″, the colour of the first images becomes very apparent, and thus destroys the accuracy in measuring. Further, the nature of the method stops it from being useful for measuring pairs dimmer than the 7th magnitude, because the aperture of the object-glass is cut down very considerably when the grating is much inclined and the light is distributed over several images. The simplicity of the method has, however, much to recommend itself to many, more especially to those who possess large apertures, and can therefore afford to spare a little light.

D.

FLORA OF ZERAFSHAN.

In a communication to the St. Petersburg Society of Naturalist (*Proceedings*, 1895, i.), M. Komaroff thus sketches the flora of the Zerafshan region of Russian Turkestan. The Aral-Caspian flora covers the lowlands up to the 1000 to 1500 feet level. Next comes the prairie, or Steppe, zone, which spreads up to about 3500 feet of altitude. In its upper parts it is characterised by Steppe-bushes, of which the almond-tree (*Amygdalus spinosissimus*, Bunge) is the most characteristic representative. Higher up, from 3500 to 6000, or 6200 feet, comes the zone of deciduous trees, which may be subdivided into a lower sub-zone of Mediterranean trees (*Pistacia vera*, *Celtis australis*, *Amygdalus communis*, *Acer monspessulanum*, &c.), with a prevalence of fragrant Labiatæ, which attains approximately the 4500 feet level; and an upper sub-zone characterised by maple-trees (*Acer lactum*). The zone between 6000 feet and nearly 8500 feet is taken by the Juniperus-trees which correspond in Zerafshan to the coniferous trees of other regions. It is covered at its upper limits with rampant bushes of *Juniperus nana* and *pseudosabina*, *Comarum*, *Cotoneaster*, *Lonicera*, *Astragalus*, and so on. The Alpine zone attains the levels of 11,000 and 12,000 feet—the morainic plants, *Didymophysa fedtschenkoana*, *Corydalis fedtschenkoana*, *Cerastium lithospermifolium*, *Saxifraga axillaris* and *Allardia tomentosa* reaching the highest altitudes. On the Zerafshan glacier, at a spot where it was covered with some gravel, the author found specimens of *Saxifraga axillaris*, *Epilobium latifolium*, *Arabis tibetica*, *Poa karataviça*, and one *Carex*—a fact which shows how careful one must be in interpreting the real sense of plant-bearing strata imbedded amidst morainic deposits. It is also worthy of note, that the botanic zones of Zerafshan very much correspond to the zonal geological structure of the highlands. The Aral-Caspian flora covers the æolic deposits of the great desiccated inner sea of Central Asia; the Steppe flora covers the Loess girdle; the Mediterranean trees and shrubs occupy the limestones and the marls, while the Juniperus zone spreads over the crystalline slates and limestones, and the Alpine flora covers the higher granitic massives of the highlands. Man evidently alters to a great extent the character of the vegetation—pistachio-tree groves and the *Juniperus excelsa* trees being rapidly destroyed; while the hundreds of thousands of sheep which are brought every year to the Zerafshan mountains from the lowlands, entirely destroy the Alpine prairies—thickets of *Artemisia dracunculus* taking the place of the grasses.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—One of the arguments which are brought forward for granting the degree of B.A. to students from Newnham and Girton Colleges is that, when they apply for educational positions, they are at a disadvantage as compared with students from other universities which do grant the degree of B.A. Dr. W. H. Besant points out in a circular, which he had addressed to the members of the Senate, that this difficulty would be entirely removed if a charter were granted to Newnham and Girton Colleges, creating a Women's University, which should have the power of granting degrees. This need not interfere with the present arrangements for the teaching and for the examination of the students in the various subjects, the study of which they now undertake. Mr. J. L. Strachan-Davidson has suggested that Oxford, Cambridge, and Dublin—the three universities which have not as yet conferred degrees on women—should join in a petition to the Crown to grant a charter for a university whose sole function it shall be to give degrees to women. A scheme similar to that supported by Dr. Besant has been practically adopted by the University of Harvard.

The members of the Skinners' Company visited Tonbridge on Saturday last, for the purpose of opening a new second-grade school which they have just built at a cost of upwards of £10,000

THE following are among recent appointments:—Dr. C. A. Strong to be lecturer on psychology in Columbia University; Mr. H. C. Warren to be assistant professor of experimental psychology in Princeton University; Herr H. Hinterberger to be professor of photography in the University of Vienna; Prof. James Holm, of University College, Nottingham, has arrived at Cape Town, to succeed Prof. Smith as professor of applied mathematics and physics in the South African College; Prof. G. F. Atkinson to be full professor and head of the department of botany in Cornell University; Mr. Arnold Philip to be professor of electrical engineering and applied physics in the Merchant Venturers' Technical College, Bristol, in place of Prof. W. Wilson, who will shortly vacate the chair in consequence of his appointment to the post of principal of the Salford Municipal Technical School.

THE plans and drawings of the Women's Medical Institute, the new Russian college for granting medical diplomas to women, are, says the *Lancet*, completed. The building operations will begin next month, and it is hoped that they may be finished in time to open the new institution in August of next year. It has been liberally subsidised by Government and by the municipality of St. Petersburg, and private subscriptions and donations have been neither few nor small. At present the whole capital amounts to about 600,000 roubles (nearly £64,000). But of this at least 450,000 or 475,000 roubles will be required for building and furnishing the institute. The late Prof. Tchudnofski, whose recent death has created a vacancy in the chair of General Therapeutics in the Army Medical Academy, has left to the Women's Medical Institute his entire medical library, containing over 4000 volumes. The number of students who will be admitted to the courses at first has been fixed at 125. Already over 100 applications have been received.

YALE UNIVERSITY is having a run of good fortune. The widow of Thomas G. Sloane will remarry soon after Easter, thereby forfeiting to Yale the sum of 200,000 dols. left by her first husband on condition of her remaining unmarried. She will let the money go without a contest. The will of the late George Bliss, of the great banking house of Morton, Bliss, and Co., was admitted to probate in New York on March 11. Among the bequests is one of 50,000 dols. to Yale, to be disposed of as the President of the University shall direct. A new dormitory is to be erected on the college *campus* this season, at a cost of nearly 100,000 dols. Ground was broken on March 9. at Washington, for the new American University, the Hall of History being the first building to be erected. This is a university of the Methodist Church, and Bishop Hurst of that Church presided. About 1,000.000 dols. has been secured towards the University fund. This should not be confounded with the proposed University of the United States. Nothing has yet been done regarding the latter, except the introduction of a Bill in Congress; and the fate of the measure is still problematical.

WHEN shall we be able to chronicle so many gifts from private persons to science and education in England as the following, which *Science* announces in a single number?—The will of the late Mr. Hart A. Massey, of Toronto, leaves about 650,000 dols. to educational and charitable institutions, including the following bequests: Victoria College, Toronto, 200,000 dols.; Wesley College, Winnipeg, Man., 100,000 dols.; Mount Allison College, Slackville, N.B., 100,000 dols.; Wesleyan Theological College, Montreal, 50,000 dols.; American University, Washington, D.C., 50,000 dols.—The Finance Committee of the Senate of the State of Virginia has presented a Bill appropriating 50,000 dols. annually, instead of 40,000 dols. as heretofore, to the University of Virginia.—The will of the late Mr. Charles L. Colby, of New York, bequeaths 20,000 dols. to Brown University.—Morris M. White and Francis T. White have given to Earlham College, a Quaker institution in Richmond, Ind., 25,000 dols., to be added to the endowment fund and to be known as the John T. White memorial fund, in honour of their father.—Mrs. Josiah Fiske, of New York City, has given 5000 dols. to Radcliffe College, in memory of her late husband. The College has also received 6568 dols., the balance of a bequest by the late Caroline B. Perkins.—Mr. T. E. Bondurant, of De Land, Ill., has offered to give 20,000 dols. to the endowment fund of Eureka College, Illinois, provided the Board of Trustees will secure 100,000 dols. additional by March 1, 1897. Mr. T. J. Underwood, of Sangamon County, Ill., has donated 10,000 dols. towards the fund.

A RETURN made to the Department of Science and Art, showing the extent to which, and the manner in which local authorities are applying funds to the purposes of technical education (including science, art, technical and manual instruction), has been published as a Parliamentary Paper. The return shows that the total expended on technical education during the year 1893-94 in England, Wales, Scotland, and Ireland was £647,632; and that the estimated total expenditure on technical education for the year 1894-95 was £737,421. These amounts are exclusive of the sums devoted to intermediate and technical education under the Welsh Intermediate Education Act. In England, 41 out of the 49 County Councils (excepting the County of Monmouth) are applying the whole of the residue received under the Local Taxation (Customs and Excise) Act to technical education, and 8 County Councils a part of it to the same purpose. Of the Councils of the 61 County Boroughs, 55 are devoting the whole of the residue to technical education, and 8 a part of it; while in one case only, the County Borough of Preston, the residue is not being applied to educational purposes, but to relief of rates. Further, the Councils of 11 County Boroughs, 51 Boroughs, and 86 urban districts are making grants out of the rates under the Technical Instruction Acts; and 8 local authorities are devoting funds to technical education out of the rate levied under the Public Libraries' Act. In Wales and Monmouth, the 13 County Councils and the Councils of the 3 County Boroughs are devoting practically the whole of the residue grant to intermediate and technical education, and several Councils are making grants out of the rates. As regards Scotland, 21 out of the 33 County Councils are applying the whole of the residue to technical education, and 9 a part of it, while 3 use it for the relief of rates. Of the 195 Burghs and Police Burghs, more than half (101) apply the whole of the grant to the relief of rates.

DESPITE Prussia's open secret of a Treasury exhausted for the Army vote, and the consequent amenities between the Ministers of Education and Finance, the necessity of maintaining the trade schools in some degree of efficiency is present to the German official mind. The want of funds applicable to educational purposes in Prussia, is among the causes making for the spread of social democracy, and this is particularly the case in the straitened salaries of the teachers of the *Volksschulen*. A review of the Technical Education item in the Prussian Budget for the last five years shows, however, a healthy growth. For altogether, apart from the continuation schools in West Prussia and Posen, for which special provision is made, the grant for 1895-96 was 1,947,257 marks (£97,362 17*s*.), which was an increase in the total State subvention of £22,304 14*s*., or nearly 30 per cent. of the entire grant. To take the trade schools (*Fachschulen*) alone, these were especially well treated. The State's expenditure on them rose from 896,993 marks (about £44,850) in 1891-92, to 1,263,157 marks (about £63,158) in 1895-96, or by more than 40 per cent., while their internal history shows an equally satisfactory development. In 1891-92 there were forty-four trade schools subsidised by the Treasury. Of these, four of the least significant have since been closed, while, on the other hand, no less than eight new ones have been started, involving a vote for the current year of more than £10,500. Three of these new schools are for building, two for weaving, one for pottery, one for engineering, and one for art industries. Similarly, the contribution to the continuation schools (*Fortbildungsschulen*) reveals an increase by more than 20 per cent., from £22,000 in 1891-92 to £26,500 in 1895-96. These figures are at least reassuring, and give hope that during the present year the Treasury will not look askance on the Education Office when it begs for money for the growth of its good work.

SCIENTIFIC SERIALS.

American Meteorological Journal, February.—The rainfall of the Malay Archipelago, by Dr. A. Woeikof. This article is chiefly based upon the observations which have been for fifteen years published in considerable detail by the Observatory of Batavia. It is generally considered that near the equator the rains are everywhere heavy and of nearly daily occurrence. Dr. Woeikof shows that in many localities, *e.g.* on the open sea, this is not the case. In the region in question, some of the wettest and some of the dryest stations lie within $1\frac{1}{2}°$ N. and 1° S. of the equator. The most rain falls on the west coast of Sumatra; the more level Eastern Sumatra and Western Borneo

have less rain, and less contrasts also. On the north-east of the peninsula of Celebes the rains are comparatively light, and there is a well-marked dry season. In Java, the rainfall is lightest in the east, and the dry season is longer and more sharply defined, so that vegetation has a time of arrest corresponding to our winter.—Psychrometer studies, by Prof. H. A. Hazen. This is a continuation of a discussion between Prof. Hazen and Dr. Ekholm, of Stockholm, on the behaviour of the psychrometer with respect to water vapour and ice vapour.

Bulletin of the American Mathematical Society, vol. ii. No. 5, February.—"Remarks on the progress of celestial mechanics since the middle of the century" is the presidential address delivered before the Society on December 27, 1895, by Dr. G. W. Hill. The address opens with the statement that a thoroughly satisfactory history of the subject has yet to be written, and then the author rapidly analyses some of the books that touch upon it, as Gautier's "Essai historique sur le problème du trois corps" (1817), Laplace's historical chapters in the last volume of the "Mécanique Céleste," Todhunter's "History of the Theories of Attraction and the Figure of the Earth," and Tisserand's "Traité de Mécanique Céleste." The scarcity of memoirs and books on the same subject accessible to American students, unless they work abroad, is dwelt upon, and then Dr. Hill opens with a consideration of Delaunay's method (*cf.* his "Théorie du Mouvement de la Lune"). Pointing out that Delaunay's method has not yet received all the developments and applications it is susceptible of, he next merely mentions Hansen's treatise on the perturbations of the small planets, and then confines his attention to a careful examination of the labours of Prof. Gyldén and M. Poincaré. He here enters into considerable detail, and closes with the remark that we owe much to M. Poincaré for his attack, "but the mist is not altogether dispelled; there is room for further investigation." This last remark is made with reference to the Lindstedt series, which "if convergent, would establish the non-existence of asymptotic solutions" (*cf.* a paper by the same author in the January number of the *Bulletin*, noticed in NATURE, No. 1373, p. 382).—A short note follows on Kronecker's linear relation among minors of a symmetric determinant, by Prof. H. S. White.—Dr. G. A. Miller's note on the lists of all the substitution groups that can be formed with a given number of elements, is a valuable historical *résumé* of recent and past work in this subject.—On Cauchy's theorem concerning complex integrals, by Prof. M. Bôcher, closes the mathematical papers.—From the Notes we learn that Prof. White's paper was read before the Society.

In the December number of the *Botanical Gazette* (vol. xx.), Mr. Frederick V. Coville, the Botanist of the U.S. Department of Agriculture, contributes a very interesting account of the botanical explorations of Dr. Thomas Coulter in Mexico and California, between the years 1824 and 1834. Among the chief botanical explorers in North America during the first half of the present century was Coulter. His collections were the basis of important contributions to the descriptive botany of Mexico and California. Born near Dundalk, Ireland, in 1793, he graduated in the Dublin University in 1817, studied under De Candolle at Geneva, and published his monograph of Dipsaceæ in 1824. He was Keeper of the Herbarium of Trinity College, Dublin, from 1834 to 1843. This account is accompanied by a copy of the principal part of the map published with Coulter's "Notes on Upper California," and Mr. Coville adds that he hopes in the near future to publish the letters of Coulter to A. Pyramus and Alphonse De Candolle, of which, through the courtesy of Dr. Casimir De Candolle, he has had copies. He further earnestly begs for any additional facts relating to Coulter, which should be sent to him to the Agricultural Department, Washington, U.S.

L'Anthropologie, Tome vi. No. 6.—Researches on the weight of the brain among the lunatics at St. John's Hospital, Copenhagen, by F. Meyer and P. Heiberg. In these investigations, which have extended over more than ten years, the authors have excluded brains that have suffered great loss of substance, those that have been the subjects of considerable cerebral hæmorrhage, and those that presented large tumours; on the other hand, brains suffering from œdema, anæmia, hyperæmia, atrophy, or periencephalitis have been included. The mean weight of 398 brains of men was found to be 1320 grammes; the greatest weight was 1866 grammes, and the least 995 grammes. 292 brains of women were examined; the mean weight was 1177 grammes, the heaviest weighed 1509 grammes, and the lightest 780 grammes. It appears that the brain gradually diminishes in weight after about fifty years of age.—On marriage amongst the Polynesians of the Marquesas Islands, by Dr. Tautain. Some of the marriage ceremonies described by the author clearly point to a time, not very remote, when all the women were common property, and marriage was unknown. A man on his marriage acquires the right of a husband over all his wife's sisters, and at the same time his brothers are entitled to exercise similar privileges with respect to the newly-made bride. In the author's opinion the Marquesans are a degraded people, and do not deserve the least sympathy.—Prehistoric stations in the neighbourhood of Marseilles, by E. Fournier. In this paper are recorded the results of digging operations at 110 stations, 45 of which have yielded evidence of the fauna and of prehistoric industry. They may be arranged in four groups: (1) The Magdalenian, (2) those belonging to the transition period, (3) the Lower Neolithic, (4) the Upper Neolithic.—Sculpture in Europe before Græco-Roman influence, by Salomon Reinach. The author enters upon the last part of his inquiry, viz. the representation of animals in primitive art, and the association of the human form with the forms of animals.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 5.—"On the Diurnal Periodicity of Earthquakes." By Charles Davison, M.A.

Reference is made to the previous work of De Montessus and Omori, the former endeavouring to show that the diurnal periodicity of earthquakes is apparent rather than real, and the latter pointing out that a marked diurnal periodicity characterises the after-shocks of great earthquakes in Japan.

The results of twenty-six registers obtained by means of continuously recording instruments in Japan, the Philippine Islands, and Italy are subjected to harmonic analysis with the following conclusions:—

(1) The reality of the diurnal variation of earthquake-frequency seems to be proved by the approximate agreement in epoch (mean local time) of the first four components (24, 12, 8, and 6 hours) for the whole year at Tōkiō and Manila, and for the winter and summer halves of the year at Tōkiō.

(2) In ordinary earthquakes, there is in nearly every case a marked diurnal period, the maximum generally occurring between 10 a.m. and noon. The semi-diurnal period, though less prominent, is also clearly marked, the maximum occurring as a rule between 9 a.m. and noon and between 9 p.m. and midnight. Other minor harmonic components are also occasionally important, the first maximum of the eight-hour component probably occurring about 6.30 a.m., and that of the six-hour component about 3 or 4 a.m.; but for these two epochs the results are not always concordant.

(3) Though the materials are insufficient for any general conclusion, the weaker shocks seem to be subject to a more marked diurnal periodicity.

(4) In the case of after-shocks of great earthquakes, the diurnal periodicity is as a rule strongly pronounced. The maximum of the diurnal period occurs within a few hours after midnight, but the epochs of the other components are subject to wide variation, possibly on account of the short intervals over which the records extend. A special feature of after-shocks is the prominence of the eight-hour and four-hour components.

The epochs of the first four components representing the diurnal variation of seismic frequency are compared in several cases with those for barometric pressure and wind velocity. While the variation of the former cannot be attributed exclusively to either of the latter phenomena, it seems not improbable that the diurnal periodicity of ordinary earthquakes may be due chiefly to that of wind velocity, and the diurnal periodicity of after-shocks chiefly to that of barometric pressure.

Geological Society, February 26.—Dr. Henry Hicks, F.R.S., President, in the chair.—On the structure of the Plesiosaurian skull, by Charles W. Andrews. Owing to the imperfection of the specimens described, various previous accounts of the Plesiosaurian skull were incomplete, and differed from one another in important particulars. There was in the National Collection a fine skull of *Plesiosaurus macrocephalus* which had lately been cleared from the matrix, with a description of which the author was mainly occupied, though other specimens, which were of assistance in clearing up some

difficulties, were also noticed. The author particularly considered the structure of the palate, and only such points in the structure of the rest of the skull as added to or were at variance with previous descriptions were considered.—On certain Granophyres, modified by the incorporation of Gabbro fragments, in Strath (Skye), by Alfred Harker. The rocks described formed a group of irregular intrusions, the largest less than a mile in length, situated in the tract of volcanic agglomerate north and west of Loch Kilchrist. They differed from the normal Granophyres, abundantly developed in the neighbourhood, in being darker, denser, and manifestly richer in the iron-bearing minerals, while in places were seen numerous small rock-fragments evidently of extraneous origin. In the discussion that followed, Sir Archibald Geikie pointed out that the paper had a double value. In the first place, it was important in regard to the local geology of the Western Isles, for it demonstrated by new evidence the posteriority of the Granophyres to the Gabbros; and in the second place, it had a suggestive bearing upon questions of theoretical interest regarding the possible modification of eruptive rocks by the incorporation of foreign material into their substance.—Observations on the geology of the Nile Valley, and on the evidence of the greater volume of that river at a former period, by Prof. E. Hull, F.R.S. The author drew attention to the two great periods of erosion of the Nile Valley, the first during the Miocene period, after the elevation of the Libyan region at the close of Eocene times, and the second during a "pluvial" period extending from late Pliocene times into and including the Pleistocene. In the second part of the paper the terraces of the Nile Valley were described, and full details given of the characters of a second terrace, at a height varying from 50 to 100 feet above the lower one, which is flooded at the present day. This second terrace was traceable at intervals for a distance of between 600 and 700 miles above Cairo. Two old river channels were also described, one at Koru Ombo, and the other at Assuan itself. The author discussed the mode of origin of the second terrace and the old river valleys, and believed them to be due to the former greater volume of the river, and not to subsequent erosion of the valley. He gave further evidence of the existence of meteorological conditions sufficient to give rise to a "pluvial" period, and pointed out that other authors had also considered that the volume of the Nile was greater in former times.—The fauna of the Keisley limestone, part i., by F. R. Cowper Reed. The author had examined a very full series of fossils from the Keisley limestone of Westmoreland, and proposed to describe the fauna of the limestone. In this (first) part of the paper a description of the Trilobites was given.

Zoological Society, March 3.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—Mr. G. E. H. Barrett-Hamilton exhibited two skeletons and other bones of the Norway lemming (*Myodes lemmus*), obtained by Dr. H. Gadow from caves in South Portugal. This discovery had increased our knowledge of the distribution of the Norway lemming in past times. In present times the Norway lemming was, roughly speaking, only to be found in Norway and Lapland, its southern range extending to about $58\frac{1}{2}°$ N. lat.; but its remains had been met with in England, and in Quedlinburg in Saxony. Dr. H. Gadow, F.R.S., gave an account of the caves in Southern Portugal in which he had procured these lemmings' bones along with those of other animals.—Mr. Sclater opened a discussion on the rules of zoological nomenclature by reading a paper on the divergences between the rules for naming animals of the German Zoological Society and the Stricklandian code usually followed by British naturalists (see NATURE, March 5, p. 427).—A communication was read, from Graf Hans von Berlepsch and M. J. Stolzmann, on the ornithological researches of M. J. Kalinowsky in Central Peru. The collections made in the years 1890–93 had been transmitted to the Branicky Museum of Warsaw, and contained examples of 295 species and sub-species, of which an account was given in the present paper. Five species and twenty-two sub-species were described as new.—Dr. David Sharp, F.R.S., on behalf of the Committee for investigating the flora and fauna of the West India Islands, communicated a paper on West Indian terrestrial Isopod Crustaceans prepared by M. Adrien Dollfus. The paper contained an account of the Armadilloidian Isopods, of which specimens had been obtained by Mr. H. H. Smith in the islands of Grenada and St. Vincent and the adjacent islets. These were referred to thirteen species, all but one of which were described as new to science.

Entomological Society, March 4.—Mr. Walter F. H. Blandford, Vice-President, in the chair.—Mr. Percy H. Grimshaw exhibited specimens of *Cephenomyia rufibarbis*, Meigen, a new British bot-fly parasitic on the red deer. The specimens were collected in Ross-shire, in June and July 1894, and in the Cairngorm Mountains in 1895.—Mr. C. G. Barrett exhibited, for Mr. Porritt, a black variety of *Polia flavicincta*, taken at sugar in his garden at Huddersfield.—Mr. A. H. Jones exhibited specimens of the butterflies captured at Coomassie by Major Henry P. Northcott during the recent expedition.—Sir John T. D. Llewelyn, Bart., M.P., exhibited specimens of a small species of Diptera which he believed to be parasitic on *Trochilium sphegiforme*, as he had bred a number from that species. He remarked that *T. sphegiforme*, although one of the most local moths in this country, had occurred last year on the estate of Sir J. Hills-Johnes, K.C.B., in Carmarthenshire, in such numbers in the larval state as almost to destroy the whole of the alders growing there. Mr. G. H. Verrall said that the insects belong to a species of *Phora*, possibly *Phora rufipes*, which fed on almost everything.—Mr. Hampson exhibited an exotic species of Locustidæ which Lord Walsingham, F.R.S., had found in his conservatory at Merton Hall, Norfolk.—Dr. Sharp, F.R.S., exhibited specimens of the pupæ of *Micropteryx* (probably *semipurpurella*) and drawings to illustrate their structure. The pupæ were sent to him by Dr. Chapman, who had described their peculiarities in the *Transactions* of the Society in 1893. Dr. Sharp considered the pupa to be that of a Trichopterous insect; most of its structures were those of Trichoptera, and the account given by Dr. Chapman of its emergence showed that this was essentially the same as that of Trichoptera. Mr. McLachlan said that so long ago as 1865 he had suggested the close affinity of *Micropteryx* to the *Trichoptera*. Mr. Hampson, Mr. Barrett, and Mr. Blandford also took part in the discussion which ensued.—Mr. McLachlan exhibited a singular instance of monstrosity in a dragon-fly. The insect was a male of *Hetærina occisa*, Hag., from Venezuela.—Mr. E. E. Green exhibited a larva of an Homopterous insect—one of the *Cicadinæ*—from Ceylon, having what appeared to be a head at its caudal extremity.—M. Louis Péringuey contributed a paper, entitled "Descriptions of New Species of South African Coleoptera, chiefly from Zambesia."—Dr. Sharp read a paper, by Prof. Williston, entitled "On the Diptera of St. Vincent, West Indies. Part I."

Chemical Society, March 5.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read:—The explosion of cyanogen, by H. B. Dixon, E. H. Strange, and E. Graham. When cyanogen, mixed with an equal volume of oxygen, is fired in a long tube, it burns directly to carbonic oxide, and by the use of a photographic method of recording the explosion wave, it is seen that the wave-front is followed by only a very short luminous tail; when a mixture of one volume of cyanogen and two of oxygen is fired, the sharply defined wave-front in which combustion to carbonic oxide occurs, is followed by a long highly luminous tail in which combustion to carbon dioxide occurs.—On the mode of formation of carbon dioxide in the burning of carbon compounds, by H. B. Dixon. The author discusses the various current views respecting the function of water vapour in making a mixture of carbonic oxide and oxygen inflammable; in connection with the dissociation theory of the action, it is shown that the Röntgen rays do not cause the dry mixture to become inflammable.—On the explosion of chlorine peroxide, by H. B. Dixon and J. A. Harker. When cyanogen, acetylene, or carbon disulphide vapour is detonated at one end of a long tube in which it is contained, the explosion wave is not propagated far along the tube; mixtures of chlorine peroxide and oxygen when similarly treated, however, decompose regularly, a true explosion wave being propagated through the gas at about 1100 metres per second.—Note on the use of certain phosphorescent substances in making X-rays visible, by H. Jackson. The most suitable form of vacuum tube for examining the Röntgen rays is one containing a concave aluminium kathode and an inclined platinum anode; the latter spreads the rays from the kathode in all directions, apparently by scattered reflection. A high vacuum is necessary for good results. The most brilliantly phosphorescent substance out of three hundred examined by the author is potassium platinicyanide; it crystallises with $3H_2O$, and since it is most active in its fully hydrated state, should be painted on to black cardboard or vulcanite for use as a screen, in such a way that it can be kept moist. The other

platinicyanides and the platosamine salts are less fluorescent. A study of the discharge phenomena observed during the exhaustion of the tube shows that the rays proceeding from the concave kathode meet at the centre of curvature of the latter, and then diverge in a solid cone; as the vacuum becomes higher, this cone gradually narrows until it becomes at length a straight line. It is interesting to note that this latter would be the behaviour of non-elastic particles emanating normally from the concave kathode.—The union of carbon and hydrogen, by W. A. Bone and D. S. Jordan. On heating carefully purified sugar charcoal to a white heat in hydrogen, 1 to 2 per cent. of the latter is converted into methane. During the burning of an electric arc lamp in hydrogen, acetylene and another hydrocarbon, probably methane, are produced.—Note on the $\alpha\alpha_1$-dimethylglutaric acids, by W. A. Bone and W. H. Perkin, jun.—The symmetrical dimethylsuccinic acids, by W. A. Bone and W. H. Perkin, jun.—The cis- and trans-methylisopropylsuccinic acids, by W. H. Bentley, W. H. Perkin, jun., and J. F. Thorpe. In these three papers the preparation and properties of the acids named are described.

Linnean Society, March 5.—Mr. W. Percy Sladen, Vice-President, in the chair.—On behalf of Capt J. Marriott, Mr. Harting exhibited an antler of the Burmese deer (*Cervus Eldi*), and described a singular condition in another example which for eight years had continued to exude a blood-coloured liquid from a puncture on the under surface of the brow-tine. Prof. Stewart, to whom some of the substance had been submitted for examination, had found no blood-corpuscles therein, and considered it to be grease in a semi-fluid condition, the nature of the colouring matter being as yet undetermined. Mr. Druce thought the substance exuded might be the excretion of the larvæ of some insect feeding upon the internal surface of the horn, and suggested the examination of a section, if possible.—Mr. Harting exhibited a drawing from life of a Klipspringer antelope (*Oreotragus saltator*), lately received (for the first time in this country) at the Zoological Society's Gardens.—Mr. Thomas Christy exhibited several cases of butterflies collected by Mr. Horace Billington in Old Calabar, on which remarks were made by Messrs. W. F. Kirby and H. Druce.—Mr. B. D. Jackson, in directing attention to an English translation by Mr. J. Lucas of that portion of Pehr Kalm's "Travels" which relates to England, remarked that few persons were aware that Kalm, a pupil of Linnæus, had in 1748 spent six months in this country and had diligently noted the plants which he met with. Thus he had recorded no less than sixty plants for Hertfordshire alone, deriving some of his information from an examination of the contents of two haystacks in that county—in this way anticipating by more than a century one of the methods employed by Sir John Lawes and Sir J. H. Gilbert, and by Prof. Fream.—On behalf of Prof. Gustav Gilson, of Louvain, two papers, entitled "Studies in insect morphology," were communicated by Prof. Howes. In the first of these, on segmentally disposed thoracic glands in the larvæ of *Trichoptera*, the author found that in *Limnophilus flavicornis* the prothoracic prominence gives exit to an underlying tubular gland. In *Phryganea grandis* each thoracic sternum gives exit to a glandular apparatus of the same category, the prothorax alone developing a prominence.—In the second paper by Prof. Gilson and M. J. Sadones, on the larval gills of *Odonata*, the authors described in each branchial lamella of *Libellula depressa* three conical processes which are functional in preventing adherence of the lamella to its fellows, and in maintaining full exposure to the surrounding medium.

Mathematical Society, March 12.—Major MacMahon, R.A., F.R.S., President, in the chair.—The President read the following abstract of a paper by Prof. Lloyd Tanner, on the enumeration of groups of totitives. The paper explains a method of determining how many groups of given order can be formed with the totitives of any integer, n. In the investigation use is made of a function formed from a binomial coefficient by replacing each factor, say r, of the numerator or denominator by p^r-1, so that the binomial coefficient is in fact the limiting value of the function as p approaches 1. There are indications of the existence of a reciprocity theorem (viz. that the number of groups of order ν is equal to the number of groups of order $\tau(n)/\nu$), but this theorem is not proved. The attempt to establish the theorem has led to the discovery of some notable properties of the functions—a Van der Monde-theorem, for instance. The functions in question are well known. They were used by Euler as generating functions for the number of partitions, and by Cayley ("Researches on the Partition of Numbers," *Phil. Trans.*, cxlv.). Jacobi in a memoir (*Crelle*, xxxii., 1846), starting with a more general function, obtained a number of formulæ which appear to be different from those used in this paper. Gauss, in the *Summatio serierum quarundam singularium*, used these functions, the base being a complex number of modulus 1. They have been used too (in Schellbach's treatise) as a means of forming the theta-functions. The present application is of a different kind. As in Euler's theory, they are used for enumeration; but the number sought is given by the actual value of the function when the base p is a prime factor of τn.—Prof. Greenhill, F.R.S., next read a paper on the associated dynamics of a Top, and of a Body under no Forces. Jacobi's theorems (*Werke*, ii. p. 480) flow naturally from Darboux's representation by means of the deformable hyperboloid (Despeyrous, *Mécanique*, ii. Note xx.). The hyperboloid is constructed, in Henrici's manner, flattened in the plane of the focal ellipse, by placing the generating lines tangential to the focal ellipse, and knotting together at the points of crossing the generators of opposite systems. Planes are drawn through any point H perpendicular to the generators HP_1, HP_2, through H (the tangents to the focal ellipse through H), the perpendiculars OG, OC are drawn from the centre O upon these planes, and the perpendiculars OY_1, OY_2 on the generators HP_1, HP_2. Then, during the deformation of the hyperboloid, the lengths OG, OC, or HY_1, HY_2 remain constant, and the points Y, T, P in which a generator meets the principal planes are fixed points on the generators; so that the planes through H perpendicular to the generators are tangent planes at H to two fixed coaxial quadrics, the squares of whose semi-axes are numerically equal to the rectangles HY.HV, HY.HT, HY.HP, the sign being taken positive or negative according as Y and V, or T, or P are on the same or opposite sides of H. These quadrics are the momental quadrics of Jacobi's two associated bodies moving under no forces; but as the quadrics are unrestricted in shape, the bodies must be composed of matter which is capable of having a negative density, as is the two-fluid theory of electricity. The curve described by H is a polhode curve common to the two momental quadrics; it is also a line of curvature formed by the intersection of a confocal ellipsoid and a hyperboloid of two sheets; thus any such line of curvature may be taken as a polhode on either of two momental quadrics, the generating lines of the confocal hyperboloid of one sheet through any point being the normals of the quadrics. If OG is held in a vertical position, OC will imitate the associated motion of the axis of a top, if H is moved always in a direction perpendicular to the plane OGC, and OH will represent the resultant angular momentum. If the momental spheroid of the top at the fixed point O is a sphere, then OH will also represent the resultant angular velocity; but in the general case the resultant angular velocity is represented by the vector OI to a point I fixed in the generator HP_2. In constructing *pseudo-elliptic* cases of motion, the ratio of the axes of the focal ellipse is taken as the modulus of the elliptic functions, and the position of P corresponding to a parameter one-nth part of a period will be determined geometrically by means of the poristic relation of a polygon of n or $2n$ sides, circumscribed to the focal ellipse and inscribed in a confocal. The secular term, associated in general with the azimuth, can be cancelled by placing H in the tangent at P_1 in a position given by a simple relation; and now the cone described by OC is algebraical, as also the herpolhode described by H in the plane perpendicular to OG. Thus for Halphen's algebraical herpolhode, P_1 is at Fagnano's point, and H is the mid-point of P_1Y_1. If P_2 is at the end of the minor axis of the focal ellipse, the axis OC of the top describes cusps. If H is placed at Y_2, then OC represents the motion of the thread of a spherical pendulum. After a brief discussion, in which the President and Mr. Love, F.R.S., took part, Prof. Greenhill made a communication on the Catenary on the Paraboloid and Cone. Clebsch's equations for the form of a chain wrapped on a sphere, which is revolving about a vertical axis with sufficient rapidity for the attraction of gravity to be negligible, are here shown to be immediately applicable to the case of a chain on a vertical paraboloid, when gravity is again taken into account. An elliptic integral of the third kind is required, with a pole at the vertex of the paraboloid, and this integral can be compared immediately with the standard form of the pseudo-elliptic integral, by the solution of a certain Jacobian quartic. The arc of the catenary is also directly reducible to the form employed by Abel (*Œuvres*, ii.). The motion of a little ball, rolling on the paraboloid, is re-

ducible to integrals of a similar nature; but in no case does it appear that its path, nor the catenary, can become of a purely algebraical nature. In the catenary on the vertical cone, as well as in the motion of a sphere rolling on the cone, the integrals are more directly reducible to the Jacobian form. In each case the developed catenary or trajectory is the form assumed for a constant central attraction or repulsion.—Lieut.-Colonel Allan Cunningham, R.E., gave a proof that $\frac{1}{4}(5^{11}-1) = 12,207,031$, and $\frac{1}{8}\cdot\frac{1}{23}(7^{11}+1) = 10,746,341$, are both prime numbers.

Royal Meteorological Society, March 18.—Mr. E. Mawley, President, in the chair.—Mr. Frederic Gaster, of the Meteorological Office, delivered a lecture on weather forecasts and storm warnings, how they are prepared and made known, which he illustrated by numerous instruments, diagrams, and lantern slides. Mr. Gaster said that in the preparation of forecasts the position held by the barometer was so much more important than that of any other instrument, that its action must be fully comprehended if the rest of the work was to be at all clearly understood. The lecturer having fully explained this, referred to the use of a single isolated instrument, and showed how new light was thrown on the observer who could have telegraphed to him simultaneous observations from a large number of places scattered over a considerable area of the earth's surface. The kind of variation in the distribution was dealt with, isobars were drawn, and the phenomena which they exhibit in the way of high and low pressure areas described. An explanation was given of the terms "cyclonic" and "anticylonic," and the generally opposite characteristics of these two systems were referred to. Mr. Gaster next drew attention to the obvious importance of the variation in the weather over a given area caused by alterations in the position of the cyclonic and anticyclonic systems, and the importance of the fact that the former tended to move round the latter from left to right. This led to some remarks on the indications observed when disturbances were advancing towards our islands from different points. Attention was drawn to secondary systems, both of high and low pressure, the forms they assume, and their effect on the weather which, but for their presence, would probably have accompanied their primaries; and the necessity for allowing for such systems in sending warnings to our coasts. The lecturer then remarked on the value of auxiliary information, such as is to be obtained from decided changes in the direction of the wind, sudden changes of temperature, the movements of clouds at different levels, observations made at high-level stations, and telegrams from the United States. Mr. Gaster next explained how the information is made known to the public. Forecasts are issued by the Meteorological Office in the *Daily Weather Report*, and also communicated to the press, &c. Hay harvest forecasts are issued to certain selected authorities, who circulate them as much as possible in their neighbourhood. Storm warnings are telegraphed to our coasts with instructions to hoist the cone-point up when the gale is probable from northerly to easterly points, and point down when from southerly to westerly points. In conclusion the lecturer drew attention to the marked improvement which had occurred in these warnings in recent years, and to some of the occurrences which from time to time caused failures.

EDINBURGH.

Royal Society, March 2.—Prof. Geikie in the chair.—A paper was read by Mr. C. A. Fawsitt, on peroxide of hydrogen in reference to its use as an antiseptic. Since its introduction into surgery by Sir Benjamin Richardson, peroxide of hydrogen had not become so popular as was expected. It possessed undeniable advantages—*e.g.* when its oxygen was given off only water remained. But it had the disadvantages of irritability and instability. The former was due to the presence of acids, usually HCl, and solid matter. This was to be avoided by exercising great care in its preparation. The instability of H_2O_2 varied with the method of preparation adopted. Mr. Fawsitt recommended that whenever it was procured, it be diluted to the strength required in practice, and kept in a dark place.—Dr. D. Fraser Harris communicated the results of experiments he had been conducting on some points in the physiological chemistry and coagulation of milk. He found that the small globules, as well as the large, contained fat in direct, and "caseinogen" in indirect proportion to their size. Milk that was heated nearly to boiling point gave the best results with artificial digestion.—Mr. R. C. Mossman read a paper on the seasonal death-rate from certain diseases in Edinburgh during the period 1878-94, with remarks on the relation between weather and mortality. He exhibited the curves of the mortality from various diseases plotted above those denoting temperature, variability of temperature, and rainfall. The most marked result was that bronchitis, pleurisy, and pneumonia, while only very slightly influenced by low temperature, were very directly associated with variability of temperature.

March 16.—Prof. Copeland in the chair.—Mr. J. Y. Buchanan read a paper on the action of water on monochloracetic acid.—Dr. David Hepburn communicated a revised description of the dorsal interosseous muscles of the human hand, with suggestions for a new momenclature of the palmar interosseous muscles, and some observations on the corresponding muscles in the anthropoid apes. The shaft of each metacarpal bone, with the exception of the first, presents two triangular areas, a larger in the dorsal aspect and a smaller in the palmar aspect, neither of which affords origin to muscular fibres. It follows, therefore, that the palmar aspect of the various metacarpal bones are more fully occupied by muscles than the dorsal aspects. The dorsal interosseous muscles, which are abductor in function, are smaller than current descriptions lead us to believe. This is quite in accordance with the comparatively feeble nature of the abductor movements. Each digit is provided with a short flexor muscle presenting radial and ulnar heads, which are capable of acting *independently*, and thereby producing a certain amount of abduction and adduction according to their position with regard to the middle line of the hand. Every muscle of the dorsal or abductor series is inserted in common with *one of the heads* of a short flexor muscle, and in consequence of their close fusion the line of separation between them is somewhat obscured and has been overlooked. The members of the palmar or true adductor stratum have all disappeared from the human hand with the exception of the adductor *Pollicis obliquus et transversus*; hence the action has been thrown upon certain heads of the short flexors, and in consequence these heads stand out more distinctly, especially as their presence is not marked by fusion with any other muscle. Whenever true adductor muscles are found, as in certain of the apes, they are inserted in conjunction with those heads of the short flexors which are capable of supplementing this action. In the case of the human pollex, which possesses the one true adductor muscle, not only is this muscle inserted in common with one head (the ulnar) of the *Flexor brevis pollicis*, but in consequence that that head is always obscured, and in many cases extinguished.—Mr. A. T. Masterman communicated a note on the structure and affinities of Phoronis. He suggested that Phoronis should take its place amongst the Hemichordata, since it showed various points of resemblance to Balanoglossus, to Cephalodiscus, and to Rhabdopleura.—Dr. W. Peddie communicated the second part of a paper on the torsional oscillations of wires. In the first part it was proved that the formula $y^n(x+a) = b$—where y represents the range of oscillation, k represents the number of oscillations which have taken place, and n, a, b are constants—expresses the law of decrease of the oscillations with great accuracy in any one experiment. The value of n is increased by increase of the initial range, and also by fatigue. A theoretical deduction of the formula was also given, it being assumed that the loss of energy per oscillation was proportional to a power of the range. When n is zero the curve changes form and becomes logarithmic. Thus the well-known law for small oscillations is accounted for. In the second part of the paper, additional proof of the great accuracy of the formula is given. The relation $nb = BK^n$ is established between the quantities n and b, B and K being absolute constants. And it is further shown that K is, in terms of the particular angular unit employed, the value of a *critical angle* for the given wire. This critical angle is such that, when the range is equal to it, the loss of energy per oscillation is totally independent of the magnitude of the initial range or of fatigue. When the range exceeds the critical angle, the loss of energy per oscillation is increased by fatigue; when the range is less, the loss of energy is decreased by fatigue. A theoretical explanation of the existence of a critical angle was given. In the particular wire employed, the critical angle corresponds to a twist of about 0·1° pe centimetre of length.

CAMBRIDGE.

Philosophical Society, March 9.—Prof. J. J. Thomson, President in the chair.—Notes on the geological history of Monocotyledons, by Mr. A. C. Seward.—A description of the

skulls found at Girton in 1881, by R. Horton-Smith.—On some scratched stones from the Permo-Carboniferious rocks of South-east Australia and the bearing of the evidence on the question of recurring Ice Ages, by Prof. Hughes. Prof. Hughes exhibited some specimens and photographs given to him by Prof. David of the University of Sydney, pointing out that the glaciation of South Australia as generally understood had been entirely disproved; that there had been no glaciers in the district in question, but that the traces of glaciation were due to ice floating from the south over a subsiding area, with, as he inferred, a compensating elevation elsewhere. He gave a *résumé* of the new evidence which he had collected in favour of the view that the recurrence of local glacial conditions was always connected with movements of elevation and depression, and appealed to physicists to explain the overthrusts and contortions of the surface of the earth, not solely by shrinkage of the nucleus nor by deformation of the whole mass, but by some conditions affecting regions limited in extent and depth, with perhaps a certain amount of periodicity determined by some more general cosmical causes.—On some chipped flints from the higher plateau gravel of Salisbury, by Prof. Hughes. Prof. Hughes criticised the evidence which had been adduced in favour of the discovery of man older than the Palæolithic Age, exhibiting in illustration a collection of so-called Palæotoliths from the plateau gravels near Salisbury, from the stony surface between Six-Mile Bottom and Balsham, and from Kent. As far as he had seen, no satisfactory evidence had been adduced in favour of the higher antiquity assigned, in the case of any of the flints which could be said to bear marks of design.—On the leakage of electricity through dielectrics traversed by Röntgen rays, by Prof. J. J. Thomson and Mr. J. A. McClelland. This paper contains an account of a series of experiments made with the object of investigating the laws regulating the passage of electricity through dielectrics transmitting Röntgen rays. This phenomenon has been discussed by one of the authors in a paper read before the Philosophical Society on January 27, and also in one read before the Royal Society on February 13. The first experiments relate to the rate of leak through different gases under similar conditions as to pressure and potential gradient. The gases used were hydrogen, ammonia, carbonic acid, air, coal gas, sulphuretted hydrogen, chloroform, chlorine, bromine, iodine, sulphur chloride and mercury vapour. Numbers showing the rate of leakage in these gases relatively to that in air are given. In general, though the rule is not without exceptions, the greater the molecular weight of the gas the more rapid the leakage. In hydrogen the leak was slowest, and in mercury vapour fastest; the rate in the vapour of boiling mercury was about twenty-eight times as fast as hydrogen. The rapid rate in mercury vapour is interesting, for this gas offers great opposition to the passage of an ordinary electric discharge. The rate of leak in the halogens is also very rapid, and a tube containing a charged plate in chlorine gas is a very sensitive and convenient method of measuring the intensity of these rays. The rates of leakage in air at different pressures were investigated; it was found that the rate of leak was slower at a low pressure than at a high one, and was over a considerable range of pressure approximately proportional to the square root of the pressure. The effect of temperature was also investigated, and it was found that through air the rate of leak was slower at a very high temperature than at the temperature of the room, but there was an intermediate temperature at which the rate was a maximum. The most remarkable thing about this leakage under the influence of these rays is that the rate is almost independent of the potential difference. Thus when the high potential plate was 5 volts above that of the low, the rate of leak was appreciably greater than when the potential difference was 1 volt, but the rate was no greater when the potential difference was 500 volts than when it was 5. A series of experiments were made to find how the rate of leakage varied with the distance from the bulb; the bulb was placed behind a metal plate with a hole in it: it was found that in the neighbourhood of the phosphorescent glass the reciprocal of the rate of leakage was a linear function of the distance from the phosphorescent patch, but at greater distances it diminished more rapidly than is indicated by this law. The measurements are not inconsistent with the view that the rate varies inversely as the square of the distance from a place in the neighbourhood of the *negative electrode*. Some experiments on the rate of leakage produced by the rays after passing through a varying number of strips of tinfoil seem to indicate that these rays are not all of one kind.

Dublin.

Royal Dublin Society, January 24.—Prof. George F. Fitzgerald, F.R.S., in the chair.—The following papers were read:—On carborundum, a substitute for emery, by Dr. Charles E. Fitzgerald; some remarks on difficulties of meridian circle work, by Mr. Arthur E. Lyster; a method of using common petroleum as the illuminant for beacons and buoys, by which a continuous light for weeks or months may be maintained day and night, without the necessity for the attendance of a light-keeper, by Mr. John R. Wigham At this meeting, Prof. D. J. Cunningham, F.R.S., exhibited and described puppies of the Cape hunting dog (*Lycaon pictus*), preserved in spirit. The animals were born in the Royal Zoological Gardens, Dublin.—Mr. Richard J. Moss described acetylene, the new illuminant.

February 19.—Prof. G. F. Fitzgerald in the chair.—The following two papers were read:—On Hamilton's singular points and planes on Fresnel's wave-surface, by Prof. William Booth, of Hoogley College, Bengal, communicated by Prof. Thomas Preston; on the continuity of transformation from the liquid to the gaseous state, by Prof. Thomas Preston.—There were exhibited at this meeting the Lenard-Röntgen X-rays, and their properties were described by Dr. J. Joly, F.R.S., photographic results being exhibited by Dr. Joly, Mr. W. E. Wilson, and Mr. Richard J. Moss.

Philadelphia.

Academy of Natural Sciences, February 25.—Papers under the following titles were presented for publication: "The Colouring Matter of the Axil of *Celastrus scandens*," by Ida A. Killer; "The Crystallisation of Molybdenite," by Amos P. Brown. The Anthropological Section having precedence, Dr. D. G. Brinton made a communication on the use of the cranio-facial line in determining racial and individual characters on the living subject. The relation of the diameters of the cranium formerly relied on had been found unsatisfactory. He specially recommended a line closely resembling that suggested by the sculptor Charles Rochet. It connects the two auditory foramina, forming a slight curve, the superior border of which connects the internal commissures of the eyes. This line, it is claimed, divides the ideal, normal head into two perfectly equal parts, although in nature, of course, this proportion is not maintained, but varies as a racial character and in individuals. The relations of the lines may also indicate the cranial capacity, as the plane of the curve continued posteriorly is approximately the base of the skull. He further pointed out that the distance between the distal extremities of the curve gives the width of the head and the face; and that a series of curves, described from the fixed points indicated, offers, probably, the simplest and most accurate method of obtaining significant head-measures on the living subject.—Dr. Harrison Allen commented on the difficulty of obtaining satisfactory cranial measurements, and referred to Oldfield Thomas's, taken from the outer margin of the orbits to determine the projection of the nose. He did not think the true horizontal plane of the skull could be fixed. The so-called Frankfurt plane is the one most commonly accepted.—Dr. Seneca Egbert stated that he had demonstrated the action of the X-rays through plates of platinum from ordinary sunlight. Illustrative pictures were exhibited, and the published results of other experimenters were discussed.—Prof. Maxwell Summerville exhibited beautiful specimens of chipped arrow-heads made from common green bottle-glass by the natives of North-western Australia. He also called attention to a stone carved to resemble a miniature grotesque head, from the valley of the Delaware, opposite Milford, and an object used in phallic worship by the natives of Poonah, India.—Dr. D. G. Brinton called attention to the importance of obtaining systematic data for the study of American anthropology, and suggested the wide distribution, under the auspices of the Anthropological Section of the Academy, of circulars of inquiry, similar to those in use by the Committee appointed by the British Association for the Advancement of Science for the study of the ethnography of Great Britain.

March 3.—Messrs. Morris E. Leeds and J. S. Stokes, on behalf of Messrs. Queen and Co., made communications on the historical development of studies in connection with Röntgen photography, presented the most advanced views as to the nature of the X-rays as published by various investigators. They also exhibited a series of fine pictures illustrating the application of the process to the study of biology, and the results obtained by the use of quick and slow plates and various developers. Dr. Egbert having alluded to

the results obtained by him from the direct rays of the sun through platinum plates, Mr. Leeds called attention to the desirability of experimenting with the sun's rays reflected from a mirror. If a positive result be obtained, it would demonstrate either that Röntgen rays can be reflected, or that those producing Dr. Egbert's effects are not Röntgen rays.—Mr. J. Willcox presented a collection of 308 recent and fossil Fulgurs from various localities and geological horizons, illustrating with extraordinary completeness the evolution of the forms.—A preliminary announcement was made of the presentation by Mr. A. Donaldson Smith of fine collections of mammals, birds, reptiles and insects, made by him during his recent exploration of Western Somaliland, Africa.

PARIS.

Academy of Sciences, March 6.—M. A. Cornu in the chair.—The President announced to the Academy the death of M. Sappey, Member of the Section of Anatomy and Zoology.—On the underground pendulum of the Paris Observatory, by M. F. Tisserand. The pendulum is buried to a depth of twenty-seven metres, where its temperature does not vary by more than ·01° to ·02° during the year. Although an attempt was made to keep the pressure of the air round the pendulum constant, the variations in rate were found to follow the variations in the atmospheric pressure.—On a new carbide of zirconium, by MM. H. Moissan and Lengfeld. An account of a second zirconium carbide, ZrC; distinguished from the carbides of allied metals by not reacting with water either at 0° or 100° C.—Actinometric observations made at the Observatory of Montpelier in 1895, by M. A. Crova.—On a log with instantaneous readings, by H. A. Coret.—On the errors in astronomical instruments caused by variations of temperature, by M. Hamy.—On uniform functions defined by the inversion of total differentials, by M. P. Painlevé.—On the principle of an accumulator for light, by M. C. Henry.—On lunar barometric waves and the secular variation of the climate of Paris, by M. P. Garrigou-Lagrange.—Cryoscopic researches, by M. A. Ponsot. Data are given for the limiting values of the molecular lowering of the freezing point of water for ten salts.—On the structure and constitution of the alloys of copper and zinc, by M. G. Charpy.—On the *rôle* of alumina in the composition of glass, by M. L. Appert. The introduction of alumina into glass tends to prevent devitrification, and allows of a considerable quantity of lime to be present.—The constitution of rhodinol, by MM. P. Barbier and L. Souveault. From a study of its oxidation products rhodinol is shown to be a primary unsaturated alcohol.—Explanation of the cruciferous flower from its anatomy, by M. O. Lignier.—On the geological constitution of the strata in the vicinity of Heraclea (Asia Minor), by M. H. Douville.—On a meteorite that fell near Fisher (Minnesota) on April 9, 1894, by M. N. H. Winchell. This meteorite consists chiefly of olivine and enstatite, together with small quantities of iron, troïlite, tridymite, and maskelynite.—On the meteor of February 10, 1896 (Madrid), by M. Miguel Merino.—On a meteor represented by Raphaël in his "Madone de Foligno," by M. P. Masson.—A confirmation of the results of M. Le Bon on dark light, by M. Ellinger.—On some experiments demonstrating the action of the Röntgen rays on fluorescent bodies, by M. G. Campos.—On a point in the kinetic theory of gases, by M. Chapel.

BERLIN.

Meteorological Society, February 4.—Prof. Börnstein, President, in the chair.—Prof. Zuntz spoke on mountain-sickness, and gave an account of the experiments on respiration he had carried out, in conjunction with Dr. Schumburg, at great altitudes on Monte Rosa. He found that when resting the consumption of oxygen was greater than at lower levels, but not very markedly so, and differed with different individuals. During work, which consisted in climbing a steep incline, the amount of oxygen consumed was per kilogramme-metre of work nearly three times as great, indicating a correspondingly increased expenditure of energy. In accordance with the above, the so-called mountain-sickness cannot be due chiefly, if at all, to the diminished partial pressure of oxygen at the higher level. He considered that it is rather the outcome of a lessened cardiac activity brought about by the powerful stimuli of insolation acting on the eyes and skin, by the action of cold, of increased air-currents, and of psychical excitement united to the antecedent fatigue. The deleterious effects of these abnormal stimulations can be lessened, or even done away with, by practice; and the effect of the diminished partial pressure of oxygen, which is observed in the case of some persons, may be prevented by mixing a little (about 2 per cent.) carbon dioxide with the inspired air, since this gas induces somewhat deeper inspirations.

Physiological Society, February 7.—Prof. Zuntz, President, in the chair.—Prof. Goldstein exhibited a series of photographs taken with Röntgen X-rays.—Dr. Abelsdorff spoke on the visual purple of fishes, which shows a maximum in its absorption spectrum differing from that in the similar spectrum obtained from amphibia, birds and mammals. He exhibited a solution of visual purple obtained from fish; it was at first of an obvious violet colour, became speedily yellow under the action of light, and then finally and very slowly colourless. By treating fish-eyes with alcohol and formalin he had obtained preparations which showed the retina of a brilliant purple colour as looked at anteriorly.—Dr. Benda spoke on the regeneration of blood corpuscles in man, and on the structure of the organs therein concerned, as based on serial sections through lymphatic nodules, the spleen, and the marrow of bones. He came to the conclusion that in the nodules the germinal centre, the germinal layer, and the more peripherally placed leucocytes form part of one developmental series. He found similar structures in the spleen, and also that in the marrow of bones the red corpuscles exhibit a similar series.

February 21.—Prof. du Bois Reymond, President, in the chair.—Dr. Frenzel exhibited photographs taken on bromide of silver-paper with Röntgen X-rays. Of these the most interesting was that of a frog taken on twelve sheets of the paper laid one upon the other; the photograph came out equally well defined on each sheet.—Dr. Schulz spoke on the influence of temperature on the working-power of unstriated muscles. He had studied the isotonic and isometric contractions of strips from the muscular layer of a frog's stomach in response to maximal electrical stimuli at temperatures between − 6° and + 45° C. From the temperature of the room onwards the height of circulation increased up to 35°, the tension up to 32°, while at the same time, and up to the same temperatures, the latent period and duration of the contraction diminished. Above these maxima all the phenomena were exactly reversed. At 45° the muscles gave no further reaction, and a temperature of 60° to 65° caused a permanent shortening. On cooling below the temperature of the room, both the height of contraction and the tension diminished progressively, whereas the latent period and duration of contraction increased down to a lower limit of − 5° to − 6° C., at which temperature there was no further reaction. When slowly rewarmed contractions again made their appearance. Between − 8° and − 10° the muscle contracted suddenly and permanently; but this contraction disappeared on slow warming, the muscle now being inert even at higher temperatures. Comparing the striated with the unstriated muscles, Dr. Schulz laid stress on the fact that with a rise of temperature the latter exhibit a gradually increasing efficiency up to the maximal, whereas the former, according to Gad and Heymans, show a secondary minimum at 19°.

Physical Society, February 14.—Prof. du Bois Reymond, President, in the chair.—Prof. Börnstein exhibited photographs of a hand taken directly on to paper by means of Röntgen X-rays.—Prof. von Bezold spoke on balloon voyages from their scientific point of view. Starting with the fundamental physical principles which underlie the events taking place in cyclones and anticyclones as also in the general atmospheric circulation, he proceeded to show the necessity for more exact measurements of temperature and humidity in the upper strata of the air, and of ascertaining the height at which air passes over from a cyclone into an anticyclone. In conclusion, he gave the values of this height as far as they have so far been determined by means of balloon ascents made from Berlin.—Prof. Neesen exhibited specimens of the photographic effects he had obtained by means of kathode rays which were reflected by means of a mirror in the vacuum tube into a lateral tube, and then passed out of the tube through an animal membrane. It was found that a thin glass plate materially weakened the action of the rays, whereas they passed just as readily through the animal membrane as do the Röntgen rays through the fleshy parts of the hand. Prof. Goldstein stated that the Röntgen rays may be concentrated, and hence sharply-defined images obtained, by using as kathode an aluminium disc backed with a glass plate, and nearly filling the vacuum tube.

—Dr. Koehne announced that he had succeeded in obtaining an electrolytic solution of carbon. Using pure carbon as anode, hot sulphuric acid as electrolyte, and platinum as kathode, he observed that the fluid became yellow and then dark brown or black, while at the same time a thin layer of graphite was deposited on the kathode. By means of carbon, hot sulphuric acid, and peroxide of lead, he obtained a galvanic cell, with a resistance of 100 ohms, which gave a current of one volt.

February 28.—Prof. du Bois Reymond, President, in the chair.—Dr. Martens spoke on the magnetisation of horizontal discs rotating in the terrestrial field, and made of various samples of iron, steel, and nickel, explaining how he had measured their magnetism by means of an astatic needle, and giving the values he had obtained.—Mr. Goode exhibited a vacuum tube for the production of Röntgen rays, on to which a system of bulbs and tubes had been fused and partially filled with mercury, so as to admit of the removal of any gases which had collected in the tube.—Mr. H. Starke explained a simple method of determining the electrical constants of solid bodies. It is based on the introduction into one arm of a Wheatstone bridge of a condenser between whose plates fluid mixtures of various dielectrics with varying electrical constants can be placed, and on the finding of a mixture such that when the given solid is immersed in it the constants of the mixture are not altered.—Prof. Lampe exhibited a series of Röntgen photographs taken by Prof. König in Frankfurt a-M., which were remarkable for their sharpness and the shortness of the exposure necessary for their production.—Prof. Rubens demonstrated Hertzian vibrations whose wave-length was 4½ cm., and which, after being made parallel by means of a glass lens, were then polarised by the use of a set of three glass discs.

NEW SOUTH WALES.

Linnean Society, November 27, 1895.—Mr. Henry Deane, President, in the chair.—On some developments of the mammalian prenasal cartilage, by R. Broom.—On a small fossil diprotodont marsupial, with large grooved premolars, by R. Broom. A more complete description from more perfect specimens of the little fossil marsupial described under the name *Burramys parvus* at the June meeting.—On a small fossil *Petaurus*-like marsupial, by R. Broom. Under the provisional name *Palæopetaurus elegans* was described a small fossil marsupial from a bone-breccia deposit in the neighbourhood of Taralga.—On the organ of Jacobson in an Australian bat (*Miniopterus*), by R. Broom.—Observations on a gravid echidna, by R. Broom.—Stray notes on Papuan ethnology, by C. Hedley. An interesting carved figure-head, of the bird and crocodile design, "geroma," from a village in Bentley Bay, British New Guinea, was described. It was interesting as setting at rest the identity of the bird, a cassowary, which Prof. Haddon had in his monograph been unable to determine. He also described an ingenious palm-leaf basket "porha" in common use among the natives of Eastern British New Guinea.—On an undescribed structure in the leaves of certain plants, by Alex. G. Hamilton. In this paper was given a detailed account, with figures, of certain structures which have been found to be present in the leaves of more than thirty species of plants referable to various natural orders, respecting which the text-books and other literature available, beyond an incidental allusion or two, seem to furnish little or no satisfactory information. In their most complete form the structures in question appear as hair-lined cavities in the leaf substance, situated in the axils of the primary or secondary veins, and opening to the exterior on the under-surface of the leaf by a small opening with a thickened rim (as in *Pennantia Cunninghamii*, Miers, and *Coprosma lucida*. Experimental evidence was adduced against the view that they are catchment hollows for water; and the author was led to think that they were structures once useful, but now no longer functional, and in course of disappearing.—Preliminary note on the occurrence of a placental connection in the bandicoot (*Perameles obesula*); and on the fœtal membranes of certain macropids, by Jas. P. Hill.—Notes on the eucalypts of New South Wales (No. 1), by Henry Deane and J. H. Maiden. The authors having for a considerable period made a special study of the eucalypts of this colony, both in the field and from dried specimens, gave the results of a series of observations in regard to the botanical structure, geographical distribution, &c., of a number of species belonging to the *Renantheræ*.—Descriptions of some new Australian plants, by J. H. Maiden and R. T. Baker.

THE HISTORY AND MANUFACTURE OF EXPLOSIVES.

Geschichte der Explosivstoffe. Von S. J. von Romocki. Two parts, pp. 394 and 324. (Berlin: Robert Oppenheim, 1895, 1896.)

The Manufacture of Explosives. By Oscar Guttmann, A.M.I.C.E., F.I.C. Two volumes, pp. 348 and 444. (London: Whittaker and Co., 1895.)

THE first part of the first of these two works is a most curious compilation, drawn from all sources, of historical matter connected with the manufacture and different uses of explosives. The author appears to have spared no trouble in hunting up old documents and engravings illustrating the different engines of war, which have depended on villainous saltpetre for part, at least, of their destructive attributes. These engravings are extremely quaint, and give one a good idea of the state of mediæval art as applied to printing; that shown on pp. 288–289 ("Verteidigung eines Engpasses mit Landtorpedos") depicts a most theatrical ambuscade in which the "special artist" has surpassed himself, and the enemy thoroughly deserve the destruction which has overtaken them. Naturally most of the text is German, but there is also a large amount of French and Latin intermixed, here and there, with a little Greek and Arabic, or even Chinese, and one can only regret that the exigencies of modern life prevent most people from acquiring even a very superficial knowledge of the numerous and varied tongues with which the gifted author appears to possess so great a familiarity.

In part ii. the author continues the narrative in dealing with the various natures of ordinary and the more modern descriptions of gunpowder, and includes much interesting matter relating to the production of chlorates, nitrates and picrates, and to the history of the discovery of guncotton by Schönbein, as well as of the subsequent prolonged attempts in Austria to utilise it in guns as a smokeless propellant. These attempts proved futile, and ended finally in the idea being abandoned, though not before several accidents had taken place. The manufacture of the several explosives is dealt with to some extent, but apparently simply with a view to including them in the historical records of the various patents which covered their invention.

As an interesting statement of historical facts connected with gunpowder, these volumes leave little to be desired; but the reader will find no new data regarding the results, ballistic or chemical, of the new powders, nor are the given results of the older powders so complete as to render the work really valuable to the student.

Mr. Oscar Guttmann's work on explosives is of quite a different type, and makes no pretence whatever to dilettanteism; on the contrary, everything is described in an eminently practical way, with the intention of interesting only those who are concerned in the manufacture or use of explosives. To the military and to civilians the work is strongly recommended, as it is practically the only trustworthy one on the manufacture of modern explosives in the English language, and as it consists of a most careful and extensive selection of the experience gathered by manufacturers of explosive material, or of the allied substances necessary in the manufacture of explosives.

The historical prelude, which has now become an inseparable portion of all technical works, is brought within reasonable limits and occupies about 22 pages, of which 17 are employed on speculations regarding the origin of gunpowder; but no very convincing conclusions are arrived at, except that, perhaps, the honour of the invention of guns—not gunpowder—belongs to Berthold Schwarz, a Freiburg monk. In England it is our conceit to consider Roger Bacon, also a monk, as the inventor of gunpowder. This, however, is very problematical, but the curious fact remains that the clerical profession have always taken a deep interest in the improvement of engines for the destruction of human life; we may instance the two monks aforesaid—without mentioning the many bishops who, in mediæval times, themselves wielded the mace on the battle-field; then we have the inventor of percussion-caps and more lately we have two clergymen, each distinguished as the inventor of a ballistic instrument, and to one of whom the art of gunnery owes a deep debt of gratitude.

The preparation of the prime materials are dealt with mostly in volume i., and include the more important substances necessary in the production of ordinary black powder, and, what is far more interesting, of the new smokeless powders. The production of glycerine and nitric acid are fully dealt with; but for sulphuric acid the author modestly refers the reader to Lunge's work. The preparation of charcoal is treated exhaustively, with the exception of that particular variety used in the manufacture of brown powder, the exact treatment of which is kept a secret; and it may be for the same reason that brown powder itself is not dealt with. This is, however, of small moment, as the use of ordinary gunpowder, of both black and brown varieties, is becoming very restricted as propellants, and even in mining operations black powder is being gradually ousted in favour of the so-called flameless explosives.

The important point of blending is dealt with only so far as this operation is performed by mechanical means—*i.e.* for small grain powders; but in the manufacture of prismatic powders, slight variations of density are unavoidable in different batches of prisms, and blending by hand has to be resorted to. Similarly with smokeless powders, it is found that different lots of cotton give rise to some slight variations in the guncotton produced, which, although of a trifling nature, are quite sufficient to affect the ballistics of the resulting powder; so that such powders as cordite or ballistite in sticks or tubes require to be hand-blended.

Volume ii. is a most interesting and valuable addition to the literature on explosives: the manufacture of nitrocellulose—both the true guncotton and collodion-cotton varieties—is described fairly completely, and, although apparently so simple, there are certain difficulties of an economical nature in connection with the production of collodion-cotton having a definite degree of nitration. The production of nitro-glycerine receives the attention

which this dangerous substance deserves, and manufacturers and users of it will find much valuable information regarding precautionary measures in dealing with this explosive or with the dynamites, of which it forms practically the only explosive ingredient. But neither guncotton nor dynamite would be of much service without the detonator, which consists of a copper capsule filled with that curious substance, fulminate of mercury. The production of this material is briefly described, and an attempt is made to elucidate its chemical constitution; the subsequent charging of caps and detonators is dealt with at greater length. In connection with the late terrible explosion of dynamite at Johannesburg, it is stated that the detonators and dynamite were carried in the same railway truck; and if this really were so, no surer means of producing an "accidental" explosion could have been devised.

Users of the so-called safety explosives—ammonite, bellite, &c.—will be interested in tracing the preparation of the different ingredients, the principal of which is generally one of the nitro-compounds of benzene.

The subject of smokeless powders is treated well, and the different machines used are illustrated in such a manner as to show their general construction and essential parts. The manufacture of cordite, as carried out at the Government factory at Waltham Abbey, is one of the most interesting, inasmuch as it is the powder adopted by the War Office for use in rifles and in guns of all calibres. The procedure is, however, somewhat varied in private factories, as, for instance, the cordite paste, instead of being mixed by hand, is sometimes mixed more or less mechanically under water, and in consequence handling the paste is to a large extent dispensed with. Handling substances containing nitro-glycerine for the first time frequently produce most distressing symptoms, due to the absorption of the nitro-glycerine by the skin, the operator being seized with violent headache, or often with vomiting; these symptoms, however, rapidly disappear in the course of a day or two. The complexion of those employed is much improved, and on this account there is a great competition for employment among the young women of the district, it being considered a sure road to matrimony.

The last portion of the work is devoted, more or less, to the description of the apparatus used in the examination of explosives; some of the instruments belonging, let us hope, to a bygone age, are of the most crude description, but there are included some of the more refined instruments employed at the present time. Very little, indeed, is said about the results obtained from ordinary powder, or from the modern explosives; and to those who are interested in the new powders as propelling agents, the question of the energy that can be developed by them, and the conditions under which such energy can be efficiently and satisfactorily utilised, is of the highest importance. So far as we know, the most complete and extensive series of experiments on this subject, and on certain kindred researches, has been made in this country principally at Elswick, and some interesting results have been obtained.

Should a new edition of the work be called for, no doubt some of the debatable points would receive revision: and we would also recommend the author not to make the same indiscriminate use of the Centigrade and Fahrenheit thermometric scales which appears in the present edition; both volumes, however, show very conclusively the large amount of engineering skill Mr. Guttmann has brought to bear in their production.

H.

ENTOMOLOGY AND EVOLUTION.

Handbuch der paläarktischen Gross-Schmetterlinge für Forscher und Sammler. Von Dr. M. Standfuss. Pp. xii + 392; eight plates. (Jena: Gustav Fischer, 1896.)

IT has long been recognised that the class of insects is particularly rich in good material for the elucidation of many important biological problems; and in the hands of Bates, Wallace, Meldola, Poulton, Merrifield, Fritz Müller, Weismann and others both in this country and abroad, to say nothing of Darwin himself, the lepidoptera, and especially the butterflies, have been largely turned to account in elaborating the details of the picture of organic evolution. Notwithstanding all that has been done both by way of observation and experiment in this direction, it can hardly be questioned that the author of the book before us is right in asserting that the work of systematic entomologists has not been made so profitable to science as it might have been; and that entomological literature has hitherto been overlooked, with some justice, by scientific zoologists. In re-editing with large additions his former useful "Handbuch für Sammler der europäischen Gross-Schmetterlinge," Dr. Standfuss has proposed to himself the laudable aim of raising the "Cinderella of the Sciences" to a position more worthy of her intrinsic merit; and his method of so doing is to combine a full account of his own experiments and speculations on various points of biological interest with the practical directions of a manual for collectors. The result is the substantial volume before us, which the author hopes will serve as a stimulus to the "mere collector" to direct some of his energies into channels which may lead to really important scientific results. There can be no doubt that Dr. Standfuss has thrown himself into his task with great vigour and enthusiasm. The experiments recorded in this book were conducted on a very large scale, and must have laid a severe tax on the industry and perseverance of their originator. Any one with experience in this direction will have some idea of what is involved in the rearing of more than 7000 lepidopterous larvæ through their various stages, under varying conditions, and in keeping full records of the results. Whether the ordinary collector will be stirred into emulation of these achievements is perhaps doubtful, but Dr. Standfuss has certainly done his best to show him how much interest may attach to the study of butterflies and moths when conducted with a definite scientific object.

The practical part of the book needs little comment. It treats of the usual topics to be found in works of the kind in a plain and serviceable manner. The advice given is sound and sensible, and bears evidence of being the fruit of the author's own experience. We note that

the diseases of larvæ and pupæ are dealt with at greater length than is often the case in similar manuals. With regard to the section on the care of a collection, our own opinion would be in favour of considerably amplifying the suggestions here thrown out as to labelling and register-keeping.

It is, however, to the experimental and speculative part of the work that the scientific reader will turn with most interest. Here he will find a large mass of valuable material; consisting in the chief place of elaborate records of the author's own experiments. The first subjects dealt with are those of hybridisation, the respective influence of the male and female parent on the structure and appearance of the hybrid progeny, the fertility of crosses, the production or suppression of intermediate forms. The value of well-planned and systematic experiments on these points cannot be easily overestimated. The importance of the subject has been fully recognised by Darwin, Wallace, Galton and Weismann amongst others, but the comparative absence of quantitative results such as Dr. Standfuss gives us, and the consequent impossibility of applying any measurement to the forces at work, has hitherto prevented the facts of hybridisation, their relation to fertility, and their bearing on questions of heredity and species-formation, from having their due weight in the discussion of biological problems. Another large and most interesting group of experiments centres round the question of the effect of abnormal external conditions, during the immature stages, upon the form of the perfect insect. The author has here taken as his model the well-known temperature experiments of Dorfmeister, Weismann and W. H. Edwards upon lepidopterous pupæ, elaborating the conditions and extending his investigations over a wider range of material. It is remarkable that the species selected by him as the subjects of experiment were in very many cases the same as those used by Merrifield, who had already been working quite independently on similar lines, and most of whose results, published before those of our author saw the light, are in close agreement with the latter. The work of each experimenter thus receives independent confirmation from that of the other

While there can be no question of the remarkable interest attaching to the effects obtained by these temperature-experiments upon pupæ, and while it will be generally allowed that much gratitude is due to Dr. Standfuss for his assiduity in conducting and recording the large number of experiments here referred to, and in accurately describing their results, there will be much difference of opinion as to the value of his interpretations. Dr. Standfuss's own views on the subject of evolution may be shortly stated. He believes in the hereditary transmissibility of acquired characters; and without enunciating any definite theory of the nature of pangenesis, he argues in favour of a centripetal mode of germ-formation. Variations are, according to him, produced by the direct effect of the environment on the parent organism, and the principle of natural selection is limited in operation, many species having become established without its aid. The theory of mimicry, he thinks, has certainly to be reckoned with, but great caution must be used in applying it to the explanation of any given case. Of Fritz Müller's development of the mimicry theory, in consideration of which many of his objections would lose their force, he takes no notice. From all this it may be seen that our author is a pronounced Neo-Lamarckian Space would not allow us to follow him in all his speculative arguments, which, though often far-fetched and sometimes demonstrably erroneous, are always ingenious and interesting. Recognising the extreme value of facts in reference to such a question as that of the true nature of heredity, we have carefully searched the whole volume for any unequivocal instance of the genuine transmission of an acquired character, and we are bound to say that we have not found one, unless n the sense admitted by Weismann ("The Germ-Plasm," 1893, p. 401), which, strictly speaking, is not a matter of heredity at all. The author has evidently convinced himself that several of his results are to be interpreted in the former, viz. the Lamarckian way. For our own part, we can only say that they seem to us to be all capable of other explanations; and that in spite of the difficulty he alleges (p. 292), the only means of attempting a satisfactory solution of this question, as it appears to us, would be a careful experimental inquiry pursued through several generations. For this purpose some species should be sought for which is at the same time capable of partial domestication, and possesses distinctive features of colour and pattern which are fairly sensitive to external influences. An argument against Dr. Standfuss's view of species-formation is afforded by the curious reversionary character of many of the changes produced by exposure of the pupa to abnormal conditions of temperature. The ancestral features thus revived are sometimes of so very distinct and special a kind, that it seems scarcely adequate to regard them, as he does, simply as the direct effect of temperature conditions similar to those under which the ancestral form came into existence. But our author practically ignores the possible influence of sexual selection and of the necessity for recognition in the production of characteristic external markings, and with him "adaptation" as applied to these markings means little else than protective resemblance. Hence, probably, his limited view of the action of natural selection, and his readiness to attribute the distinct aspects of the various species of *Vanessa* and other groups to direct climatic influences, *plus* isolation. Still, whatever may be the omissions and shortcomings of the book from the theoretical point of view, of which much more could be said, its value as a great quarry of facts is undeniable, and the author makes no attempt to present his experimental results in any but the most fair and impartial manner.

The value of the descriptions is greatly increased by the excellent plates, which are very well executed and really illustrative of the text. The book is well printed; we have only discovered a very few misprints in the text, and one small inaccuracy in one of the plates. The want of a general index is a serious drawback. Taking the work as a whole, we are bound to say that it is one that challenges the serious attention of biologists, and that whatever may be thought of the author's speculations and arguments, the facts that he has collected are of unquestionable interest and importance.

F. A. DIXEY.

A PHILOSOPHY OF MAN.

Die Schöpfung des Menschen und seiner Ideale. Ein Versuch zur Versöhnung Zwischen Religion und Wissenschaft. Von Dr. Wilhelm Haacke. Mit 62 Abbildungen im Text. Pp. x + 487. (Williams and Norgate, 1895.)

An author who claims for his book that it is, "in its aim and substance, entirely new and original," does not prepossess a reader in his favour; nor do the contents of Dr. Haacke's book remove the prejudice. He seeks to prove that the mechanical conception of nature leaves room for faith in a moral order of nature, by showing that natural bodies and organisms, and human ideals alike follow a great law of tendency to equilibrium. The book is popular in character, and it has the merit of being very readable. It is partly and mainly biological, partly philosophical, and throughout speculative. Dr. Haacke will have nothing to do with Darwin or Prof. Weismann—not merely that he rejects pangenesis or the continuity of the germ-plasm, but natural selection as well. He substitutes an epigenetic theory of *gemmæ* or crystals of the germ-plasm, which have polarity and are united into a *gemmarium* (or collection of *gemmæ*) whose configuration seems to be determined by every influence which affects the organism. The theory, which is explained in full in the author's work "Gestaltung und Vererbung," is based on the assumed transmission of acquired characters. How unclearly he conceives the problem is shown by his description of an ideal test of that transmission (p. 344), which is no test at all, and by the confused treatment of inherited memory. Dr. Haacke thinks that in consequence of the organic connection of every part of the body, acquired characters may affec the configuration of the gemmarium, but he does no explain how the male gemmarium, when it passes rom the parent body, should retain this configuration. The philosophical portion of the book is purely hypothetical. Each atom has sensation, and therefore, according to the sensori-motor law, also motion, which it exhibits in the tendency to equilibrium with other atoms. Schopenhauer's "will to live" is replaced by the "will to equilibrate." It is not clear whether the author supposes each brain-cell to have consciousness (which is psychological atomism with a vengeance). The most interesting portion of the book, from a philosophical point of view, is the slight sketch in which it is shown that art, morality, and religion exhibit the tendency to unite various elements into an equilibrium, that is, in simpler language, into an organic system. It is not, however, quite original, nor is it adequate. The author hopes to reconcile religion with the materialistic conception of nature in half a page, in which he declares the ideal of religion to be the equilibrium of all other ideals, and God to reveal himself everywhere as the tendency to equilibrium. From a purely speculative point of view, the author's doctrine is open to a grave objection. That every organic form which can maintain itself exhibits internal equilibrium is undoubted, and if Dr. Haacke had expounded this truth in its application to morality and knowledge with anything approaching adequacy, he might have done service. But it is quite another thing to assume a "tendency to equilibrium." How much truer is the simple doctrine of Spinoza, that everything tends to "persist in its being"—*in suo esse perseverare*—a real tendency of which equilibrium is the result. Such a view is perfectly compatible with natural selection, which is the process by which bodies that cannot be in equilibrium under their conditions are eliminated. But Dr. Haacke apparently takes natural selection to be a force instead of a mere process according to which forces act, dismisses it for this reason, and sets up in its place an unreal striving after equilibrium, which equilibrium is only an effect. Of his purely philosophical quality the sample which the author gives in the concluding portion of his book does not induce us to recommend the book to the study of philosophers.

OUR BOOK SHELF.

Roads and Pavements in France. By A. P. Rockwell, A.M., Ph.B. Pp. 107. (New York: John Wiley and Sons. London: Chapman and Hall, Ltd., 1896.)

The title of this book is hardly broad enough to do justice to the contents, which include general descriptions of construction and maintenance of roads, and of other points to be considered when building a new road or improving one already built. At the same time, all who have to do with road-making know that they can learn something from an account of the methods adopted by the highly-educated and able engineers whose work has resulted in the excellent roads of France to-day, and whose experience as to the best and most economical systems extend over more than a hundred years. The author has brought together the results of this instructive experience, and has thereby produced a work which will be of great service to road contractors and engineers in every country.

Single-Salt Analysis. By B. P. Lascelles, M.A. (London: Swan Sonnenschein and Co., Ltd., 1896.)

This addition to the already too numerous sets of tables for use in chemical laboratories, consists of fourteen cards containing instructions what to look for, and what to conclude, when conducting the various operations involved in the analysis of a simple salt. Five cards are devoted to stating dry tests, and the remainder are taken up with wet tests for a simple salt, soluble in water or acids. The cards will be useful in elementary chemical laboratories, where test-tubing is the order of the day; but we hope for a time when their use will be limited to students who intend to become analysts, for work conducted upon the lines laid down in these and similar analytical tables are of no educational value whatever.

The West Indies and the Spanish Main. By James Rodway. Pp. xxiv + 371. 48 illustrations. (London: Fisher Unwin, 1896.)

The stirring events described in this latest addition to the "Story of the Nations" series are sufficient to furnish material upon which a score of romances might be built, even though Marryat, Kingsley, Stevenson, and other writers innumerable have made the Indies the arena of all the incidents attractive to adventurous spirits. So full of incident is the history of the West Indian Islands, that Mr. Rodway has had a difficulty in compressing his story within reasonable limits, and he has only been able to do so by giving preference to facts referring to the islands as a whole, and omitting events of interest chiefly to the communities of particular islands and provinces. Little is said about the islands from the scientific point of view, but as a contribution to historical geography the book is undoubtedly valuable; for few persons are better acquainted with the history of the progress and development of the Indies than the author.

LETTERS TO THE EDITOR.

Velocity of Propagation of Electrostatic Force.

As we may have to wait some time for the experimental solution of Lord Kelvin's very instructive and suggestive problem concerning two pairs of spheres charged with electricity (see NATURE of February 6, p. 316), it may be interesting to see what the solution would be from the standpoint of existing electrical theories.

In applying Maxwell's theory to the problem, it will be convenient to suppose the dimensions of both pairs of spheres very small in comparison with the unit of length, and the distance between the two pairs very great in comparison with the same unit. These conditions, which greatly simplify the equations which represent the phenomena, will hardly be regarded as affecting the essential nature of the question proposed.

Let us first consider what would happen on the discharge of (A, B), if the system (c, d) were absent.

Let m_0 be the initial value of the *moment* of the charge of the system (A, B), (this term being used in a sense analogous to that in which we speak of the *moment* of a magnet), and m the value of the moment at any instant. If we set

$$m = \mathrm{F}(t), \quad \ldots \ldots \ldots \ldots \quad (1)$$

and suppose the discharge to commence when $t = 0$, and to be completed when $t = h$, we shall have

$$\mathrm{F}(t) = m_0 \qquad \text{when} \qquad t < 0, \quad \ldots \quad (2)$$

and

$$\mathrm{F}(t) = 0 \qquad \text{when} \qquad t > h, \quad \ldots \quad (3)$$

Let us set the origin of coordinates at the centre of the system (A, B), and the axis of χ in the direction of the centre of the positively charged sphere. A unit vector in this direction we shall call i, and the vector from the origin to the point considered ρ. At any point outside of a sphere of unit radius about the origin, the electrical displacement ($\mathfrak{D}$) is given by the vector equation

$$4\pi\mathfrak{D} = [3r^{-5}\mathrm{F}(t - cr) + 3cr^{-4}\mathrm{F}'(t - cr) + c^2r^{-3}\mathrm{F}''(t - cr)]\chi\rho$$
$$-[r^{-3}\mathrm{F}(t - cr) + cr^{-2}\mathrm{F}'(t - cr) + c^2r^{-1}\mathrm{F}''(t - cr)]i, \quad . \ (4)$$

where F denotes the function determined by equation (1), F′ and F″ its derivatives, and c the ratio of the electrostatic and electromagnetic units of electricity, or the reciprocal of the velocity of light. For this satisfies the general equation

$$-\nabla^2\mathfrak{D} = c^2d^2\mathfrak{D}/dt^2, \quad \ldots \ldots \ldots \quad (5)$$

as well as the so-called "equation of continuity," and also satisfies the special conditions that when $t < 0$

$$4\pi\mathfrak{D} = m_0(3r^{-5}\chi\rho - r^{-3}i)$$

outside of the unit sphere, and that at any time at the surface of this sphere

$$4\pi\mathfrak{D} = m(3\chi\rho - i),$$

if we consider the terms containing the factor c as negligible, when not compensated by large values of r. That equation (4) satisfies the general conditions is easily verified, if we set

$$u = r^{-1}\,\mathrm{F}(t - cr), \quad \ldots \ldots \ldots \quad (6)$$

and observe that

$$-\nabla^2 u = c^2d^2u/dt^2, \quad \ldots \ldots \ldots \quad (7)$$

and that the three components of $\mathfrak{D}$ are given by the equations

$$\left.\begin{aligned} 4\pi f &= -d^2u/dy^2 - d^2u/dz^2 \quad \ldots \\ 4\pi g &= d^2u/dxdy \quad \ldots \ldots \ldots \\ 4\pi h &= d^2u/dxdz \quad \ldots \ldots \ldots \end{aligned}\right\} (8)$$

Equation (4) shows that the changes of the electrical displacement are represented by three systems of spherical waves, of forms determined by the rapidity of the discharge of the system (A, B), which expand with the velocity of light with amplitudes diminishing as r^{-3}, r^{-2}, and r^{-1}, respectively. Outside of these waves, the electrical displacement is unchanged, inside of them it is zero.

If we write (with Maxwell) $-d\mathfrak{A}/dt$ for the force of electrodynamic induction at any point, and suppose its rectangular components calculated from those of $-d^2\mathfrak{D}/dt^2$ by the formula used in calculating the potential of a mass from its density, we shall have by Poisson's theorem

$$\nabla^2(d\mathfrak{A}/dt) = 4\pi d^2\mathfrak{D}/dt^2,$$

or by (5),

$$\nabla^2(d\mathfrak{A}/dt) = -4\pi c^{-2}\nabla^2\mathfrak{D},$$

whence

$$d\mathfrak{A}/dt = -4\pi c^{-2}\mathfrak{D} \quad \ldots \ldots \ldots \quad (9)$$

From this, with (4), and the general equation

$$d\mathfrak{A}/dt + 4\pi c^{-2}\mathfrak{D} + \nabla\mathrm{V} = 0,$$

we see that during the discharge of the system (A, B) the electrostatic force $-\nabla\mathrm{V}$ vanishes throughout all space, while its place is taken by a precisely equal electrodynamic force $-d\mathfrak{A}/dt$.

This electrodynamic force remains unchanged at every point until the passage of the waves, after which the electrostatic force, the electrodynamic force, and the displacement, have the permanent value zero.

If we write *Curl* for the differentiating vector operator which Maxwell calls by that name, equations (8) may be put in the form

$$4\pi\mathfrak{D} = \text{Curl Curl }(iu),$$

whence

$$d\mathfrak{D}/dt = (4\pi)^{-1}\text{ Curl Curl }(idu/dt).$$

From $d\mathfrak{D}/dt$ we may calculate the magnetic induction $\mathfrak{B}$ by an operation which is the inverse of $(4\pi)^{-1}$ Curl. We have therefore

$$\mathfrak{B} = \text{Curl }(idu/dt),$$

or

$$\mathfrak{B} = [r^{-3}\mathrm{F}'(t - cr) + cr^{-2}\mathrm{F}''(t - cr)](yk - zj).$$

The magnetic induction is therefore zero except in the waves.

Equations (4) and (9) give the value of $d\mathfrak{A}/dt$ as function of (t and r). By integration, we may find the value of $\mathfrak{A}$, Maxwell's "vector potential." This will be of the form of the second member of (4) multipled by $-c^{-2}$, if we should give each F one accent less, and for an unaccented F should write $\mathrm{F}_{\prime}$, to denote the primitive of F which vanishes for the argument ∞.

That which seems most worthy of notice is that although simultaneously with the discharge of the system (A, B) the values of what we call the electric potential, the electrodynamic force of induction, and the "vector potential," are changed throughout all space, this does not appear connected with any physical change outside of the waves, which advance with the velocity of light.

If we now suppose that there is a second pair of charged spheres (c, d), as in the original problem, the discharge of this pair will evidently occur when the relaxation of electrical displacement reaches it. The time between the discharges is, therefore, by Maxwell's theory, the time required for light to pass from one pair to the other.

It may also be interesting to observe that in the axis of χ, on both sides of the origin, $\chi\rho = r^2i$, and equation (4) reduces to

$$4\pi\mathfrak{D} = [2r^{-3}\mathrm{F}(t - cr) + 2cr^{-2}\mathrm{F}'(t - cr)]i.$$

Here, therefore, the oscillations are normal to the wave-surfaces. This might seem to imply that plane waves of normal oscillations may be propagated, since we are accustomed to regard a part of an infinite sphere as equivalent to a part of an infinite plane. Of course, such a result would be contrary to Maxwell's theory. The paradox is explained if we consider that the parts of the wave-motion, expressed by F and F′, diminish more rapidly than those expressed by F″, so that it is unsafe to take the displacements in the axis of χ as approximately representing those at a moderate distance from it. In fact, if we consider the displacements not merely in the axis of χ, but within a cylinder about that axis, and follow the waves to an infinite distance from the origin, we find no approximation to what is usually meant by plane waves with normal oscillations.

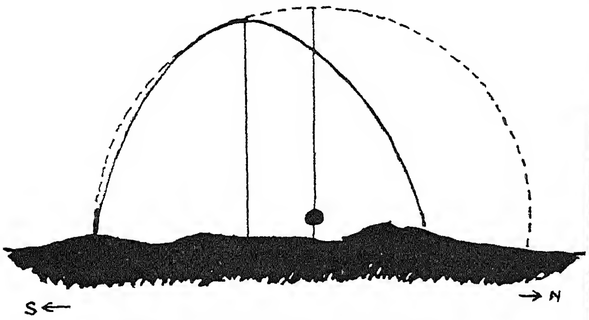
An Unusual Solar-Halo.

ON March 17, at Göttingen, a curious solar halo was observed by a friend and myself towards the time of sunset. The weather that day had been beautifully fine, but towards 5h. p.m. (Mean European Time) thin light clouds began to form, which covered the heavens with a thin white raiment. When the sun was

about a few degrees from the horizon (the horizon at the place of observation was not the true one, for a large but not very distant hill intervenes towards the west), there seemed to be suddenly formed a halo of peculiar shape. Its form may be described as nearly, if not quite, parabolic, the axis of the parabola being vertical. Curiously enough, this parabolic form was not symmetrical with regard to the position of the sun, but the latter was situated some distance to the north of the axis. The above phenomenon was observed at about 5h. 50m.–5h. 55m. p.m.

A few minutes afterwards (6h. 5m.), this parobolic form slowly underwent a change, and after a minute or two a circular



Halo at sunset, February 17, 1896, Göttingen.

halo concentric about the sun was distinctly visible. While the concentric halo was in the act of being formed, that portion of the parabolic halo towards the south seemed to maintain its position, but the northern end moved distinctly more north until the position of the sun was half-way between the two. The parabolic form *may* have been caused by the positions of the light fleecy clouds, apparently distorting the halo on the northern side and making the whole appear parabolic; but the change of shape was so considerable, that this explanation seems hardly satisfactory. WILLIAM J. S. LOCKYER.

Remarkable Sounds.

MR. GODWIN-AUSTEN'S letter in NATURE of January 16, reminds me of similar sounds heard at Java in the year 1881. I was then building a railway tunnel through the Gunung Kendang, a range of hills about 100 metres high, situated between the towns of Sukabumi and Tjiandjor, Preanger Regencies, a district where more seismic disturbances take place than in almost any other district of Java.

One morning at about six o'clock, when at breakfast, I was startled by a very loud detonation which made me fear that one of our small vertical boilers at the other side of the works had exploded. I at once sent a man over the hill to ask for information, and received a note from my European assistant stating that no accident had taken place, but that he also heard the detonation and took it for an accidental explosion of some cases of dynamite at Tjiperda, a kampong about six miles from the tunnel, the headquarters of one of the European railway contractors. He at once went thither to see whether any assistance might be wanted, but found that nothing unusual had happened. The contractor, however, told him that at the very moment that we had heard the detonation he had felt a very severe vertical shock of earthquake, but had heard no sound.

In this same tunnel I experienced twice a very severe horizontal shock of earthquake which made a creaking sound in the timbering from end to end in the adits, causing some of the horizontal timbers which had not yet been spiked to fall down. The first time that this happened the coolies bolted, but the second time I managed to keep them in the works to watch the timbering. TH. DELPRAT.

Malang, Java, February 18.

An Excellent View of the Retinal Circulation.

ON a cycling tour recently, after riding some forty miles, with much hill-climbing and against a strong wind, I lay down on a grassy bank facing the east, towards sunset. Viewing the clear eastern sky, I obtained a most remarkable view of my own retinal circulation. A companion also got an excellent view of his own blood corpuscles. The apparent circulation occupied a considerable portion of the visual field, and a most vivid conception was obtained of the relative slowness of movement in the capillaries. It occurred to me afterwards that the reason of the phenomenon was the hyperæsthesia of the retina, caused by the dilatation of the arterioles, which is a characteristic of excessive cycling. It would be interesting to learn whether others have obtained similar experiences. JAMES W. BARRETT.

Melbourne, Australia.

Butterflies and Hybernation.

SOME time late in last autumn, a tortoiseshell butterfly took refuge in a small bath-room in this house, established itself on the ceiling, and there remained, immovable, throughout the winter. On the 10th of this month it shifted its position, and on the 12th flew out of the open window. On the 19th, and again to-day, I have seen a tortoiseshell butterfly fluttering about the garden, and should not be surprised if this early rover were the same individual as that which has undoubtedly wintered here. Half a dozen gauzy-winged green flies also hybernated in close company with the butterfly, but they woke up and flew a fortnight or so before the tortoiseshell butterfly stirred. DAN. PIDGEON.

Children's Drawings.

AS supplementary to the interesting note in NATURE of February 20, on children's drawings, I may mention that some children of my acquaintance show what seems a strong native tendency to reverse right and left in drawing such letters as L and J, making them ⅃ and ⅂. It is possible this confusion is akin to that confusion of right and left which one first feels on using a mirror for toilet purposes, as shaving, &c.

Lake Forest, Illinois, March 16. HIRAM M. STANLEY.

"Testacella haliotidea."

ON addressing you some time ago on the subject of Worcestershire being a habitat of what I regard as this mollusc, some of your contributors applied for specimens. I have now six to give away. One of your contributors doubted whether the specimen I then had was Haliotidea, on account of alleged rarity. The same doubt applies now.

Worcester Museum, March 23. J. LLOYD BOZWARD.

An Early Swarm of Bees.

A SWARM of bees on March 23 is, I think, so unusual, that you may perhaps like to be informed that one was taken here yesterday. A. PAGE.

Tendring, Essex, March 24.

THE MANAGEMENT AND PROTECTION OF FORESTS.[1]

I.

PROF. SCHLICH'S important work is approaching completion. The two first volumes were noticed in December 1889 and July 1891.[2] Of these, it is understood, a new edition will soon be necessary. The third volume, which deals with forest management, is about to appear in a Spanish translation. Vol. iv. is an English adaptation of an excellent German book on forest protection, by Dr. Richard Hess, Professor of Forestry at the University of Giessen. It is the work of Mr. Fisher, formerly Conservator of Forests and Director of the Imperial Forest School at Dèhra Dùn in North-Western India. The last volume will deal with forest utilisation. In the present article, we propose to deal with the subjects of the third and fourth volumes, viz. the management and the protection of forests.

[1] "A Manual of Forestry," by William Schlich, C.I.E., Ph.D. Vol. iii. (pp. xix + 397). "Forest Management," by William Schlich. Vol. iv. (pp. xix + 593). "Forest Protection," by W. R. Fisher, B.A. (London: Bradbury, Agnew, and Co., 1895.)

[2] NATURE, vol. xli. p. 121; vol. xliv. p. 265.

The management of forests depends upon the objects which the proprietor desires to realise. These objects may be of two kinds: they are either indirect, such as landscape beauty, protection against erosion, landslips, avalanches; or they are direct, the production of timber or other forest produce, so as to yield the largest possible permanent income to the proprietor. Dr. Schlich deals with the attainment of the direct objects, that is, with the economic working of forests; but he justly observes, that a forest under good economic management, as a rule, is capable of yielding all those indirect advantages that may reasonably be expected from it.

As explained on a previous occasion, Dr. Schlich's manual is, in the first instance, intended for the instruction of students preparing for the Indian Forest Service at Coopers Hill College. At the same time, there seems good ground for hoping that eventually it may also be useful to proprietors, land-agents, and wood-managers in Great Britain, as well as in the Colonies and the United States of North America. The third volume of the manual has a special value for persons interested in the management of woodlands in Great Britain; it is the first really comprehensive work upon this subject that has been published in English, and those who may take the trouble to work through its pages, will find that it will enable them to strike out a new line in the management of their woodlands. In 1883, another Indian forest officer, who had received his professional education in Germany, Mr. J. L. Laird MacGregor, now Conservator of Forests in the Bombay Presidency, attempted to place portions of the subject before English readers, under the title "Organisation and Valuation of Forests." (London: Wyman and Sons.)

At the outset, it will be necessary clearly to understand what the author intends by the term "forest management." Forestry, like medicine, engineering, or agriculture, originally commenced as an empirical routine; but its operations are now built upon the results obtained by researches in numerous branches of pure science. The most important of these are mathematics, botany, zoology, chemistry, geology, law, and political economy. Apart from these auxiliary sciences, forestry proper deals with the following subjects: (1) the raising and maintenance of woods, or sylviculture; (2) the protection of forests against damage; (3) the utilisation of forest produce; (4) forest management; (5) forest law.

The last-named subject has been dealt with in a separate work,[1] which, though not published as part of Dr. Schlich's manual, essentially belongs to this series of forest publications. The author, Mr. B. H. Baden-Powell, in 1868 was Small Cause Court Judge at Lahore, and consented to be employed during a series of years in the Indian Forest Service, then a small and humble concern, the progress of which was not generally regarded with favour. The main object of this measure was to secure his assistance in the matter of forest legislation. After doing excellent work as Conservator of Forests in the Punjab, and as Inspector General of Forests to the Government of India, Mr. Baden-Powell resumed his judicial work, and closed his Indian career as Judge in the Chief Court of the Punjab.

The first volume of Dr. Schlich's manual is introductory, the second deals with sylviculture, the third with forest management, the fourth with forest protection, while the fifth will teach utilisation of forest produce. Forest management is built upon the other branches, and under a strictly logical arrangement it ought to be the last volume of the series. This, however, would have delayed its publication. It may be objected that the term "forest management" has a wider meaning in English than that attributed to it by Dr. Schlich, that it comprises all operations of forestry, including sylviculture protection and utilisation of forest produce. In his manual the author uses it in a somewhat restricted sense, but this restriction is justified; it is convenient, and cannot lead to misconception. In French this branch of forestry is called *aménagement des forêts*, in German the usual term is *Forsteinrichtung*. MacGregor, in the work quoted, designates a portion of it as *Forest Organisation*. The term selected by Dr. Schlich seems the most suitable.

Forest management, as here understood, comprises three main subjects: mensuration, valuation, and working plans. Forest mensuration deals with the instruments used, the measurement of timber, standing and felled, it determines the volume of entire woods, the age of trees and woods, as well as the increment of woods. It appears necessary here to draw attention to another technical term, which, though English, is used in a definite sense. Dr. Schlich employs the term "wood" to designate what in German is called *Bestand*, meaning part of a forest forming a unit of fairly the same description. It might be objected that a "wood" is generally understood to mean an isolated small forest block, surrounded by clearings or by prominent natural boundaries. It will be a great convenience if Dr. Schlich's use of the term "wood" is accepted. The volume of a wood standing, say, on one acre of ground, is the product of two factors, the number of trees per acre and the mean volume of those trees. Again, the volume of a tree is the cylinder, height × sectional area, multiplied by a coefficient, called the form factor, which is different for each species, and in each species varies according to age and size of the tree. By a most elaborate system of measurements of many hundred thousand trees of all ages grown in different localities, form factors have now been established in Germany for most of the principal species. These form factors are governed by laws peculiar to each species. Thus, for trees 50 and 100 feet high of Scotch pine and Beech, the following factors are used to calculate the volume of timber down to three inches diameter:

	50 ft.	100 ft.
Scotch Pine	0·48	0·45
Beech	0·40	0·51

It must be distinctly understood that these form factors are only applicable to forests managed upon proper economic principles, where the trees, while young, are allowed to grow up crowded in compact masses, so as to form straight well-shaped stems, free from knots and branches, and are afterwards thinned out methodically, with the object of leaving in the final crop only well-shaped sound trees, likely to yield the most valuable timber. To trees grown in open park-like woods, these form factors would not be applicable.

Hand in hand with the determination of form factors, yield tables have been prepared in Germany for the principal species. These yield tables give the volume of timber in completely stocked woods of the different species standing on a given area at different ages, and in localities of the different quality classes. The work of examining the data, upon which these yield tables have been based, has led to an important result, viz. that the mean height of a wood as a rule indicates the quality of the locality. On good soil and under conditions otherwise favourable, the mean height of a wood is much greater than one of the same age which has grown up under less favourable conditions. Indeed, it is possible, with the help of yield tables to ascertain the volume of an even aged wood, the age of which is known, by determining the mean height of the trees composing it. The following extract from the yield table for Scotch pine in Germany, mainly taken from the figures given by Dr. Schlich, may serve to explain this.

[1] "Forest Law," by B. H. Baden-Powell, C.I.E., late of the Bengal Civil Service. (London: Bradbury, Agnew, and Co., 1893.)

Volume and Volume-increment of Timber down to 3 inches diam. Net value and Value-increment. All on one Acre, stocked with Scotch Pine of middling quality.

Age, years	60	70	80	90	100
Number of trees per acre ...	516	393	316	266	230
Mean height, feet	51	57	63	67	71
Volume, cubic feet, solid ...	3713	4183	4587	4902	5158
Current annual increment, cubic feet, solid	47·0	40·4	31·5	25·6	
Volume increment, per cent.	1·2	0·93	0·60	0·51	
Net value of stock (shillings)	1186	1683	2225	2789	3376
Volume- and value-increment, per cent.	3·76	2·83	2·29	1·93	

If two woods, known to be 60 and 100 years old, have a mean height of 51 and 71 feet respectively, it follows that they belong to the class, of which an extract is here given, which is known as the third or middling class, and, if completely stocked, the volume standing on one acre would be 3713 cubic feet in the one, and 5158 cubic feet in the other case. Other Scotch pine woods of the same age, if their mean height were greater, would belong to a higher quality class, and if fully stocked, their volume would be that recorded in the yield tables under their class. It stands to reason that in woods not fully stocked the timber per acre is less in inverse proportion to the degree of completeness.

The great practical importance of height-growth will perhaps be better understood by reference to matters which, many years ago, have exercised considerable influence upon the development of regular forest management in India. The writer of these lines, on taking charge, in January 1856, of the Pegu teak forests, made it his first duty to ascertain which were the most valuable forest tracts in that country. The number of teak trees of the different age classes on the square mile, he ascertained by a system of linear valuation surveys, laid through the forests in all directions. At the same time he measured the height of trees in all districts. The data thus obtained, the timber standing on the ground, and the height of the trees, particularly of the younger classes, enabled him to classify the forests, and to pick out those which were the most valuable. The measures which he had introduced, had gained him the confidence and goodwill of the Karen and other inhabitants of the forests, for those measures gave to the people profitable employment in timber operations, and this made them allies, instead of enemies, in regard to forest protection. The merchants of Rangoon, on the other hand, naturally desired to get the forests into their own hands, and, backed by the influence of the powerful mercantile firms of Calcutta, they induced the Government of India to order the Pegu forests to be thrown open to private enterprise. These orders had to be carried out; but, fortunately, they did not require that the whole of the forests should be thrown open at once. Those districts, therefore, in which the growing stock of teak timber, in regard to height and otherwise, was most promising, were for a time retained under control of the Forest Department, while the rest were thrown open to private enterprise, in accordance with the orders received. This was in 1861. Subsequently a different view of the question was taken by Government; the arrangements which had been made could not, however, be cancelled. The mischief had been done; but, fortunately, it had been limited to the less valuable districts. The really valuable forests, which had been reserved in 1861, had been saved, and this made it possible to maintain a profitable system of regular management.

The little table, entered on page 511, illustrates the growth of a Scotch pine wood of middling quality between the ages of sixty and a hundred years. As the wood advances in age, the number of trees diminishes, but the remaining trees are taller and heavier, and hence the total volume increases. During these 40 years no less than 286 trees have died or been thinned out, and the skill of the forester consists in this, that the final crop is composed of sound and well-shaped trees, so that their timber may fetch the highest price obtainable. These figures show further, that, while in the first period of 10 years, between 60 and 70, the timber produced per acre amounted to 470 cubic feet, or 47 cubic feet a year, only 256 cubic feet, or 25·6 cubic feet annually, were produced from the 90th to the 100th year.

The current annual increment is greatest while the forest is young, in the case of Scotch pine between the ages of 30 and 40, after which it diminishes steadily. The annual increment may be regarded as a percentage of the growing forest capital. Between the years 60 and 70 the increment per cent. (p) would be determined by the formula: $4183 = 3713 \times 1{\cdot}0p^{10}$, which makes $p = 1{\cdot}2$. Between the years 90 and 100 the increment per cent. is only 0·51. The maintenance of a forest, which increases at a rate so slow and so steadily diminishing, at first sight appears to be a most unprofitable undertaking. Fortunately the market value of the timber up to a certain point increases with the age of the wood. The net value of the growing stock (less the cost of cutting, carriage, and other expenses) of the wood exhibited in the table at the age of 60 years is 1186 shillings, rising to 1683 shillings at the age of 70. During this period the value- and volume-increment per cent. is 3·76, but it falls steadily to 1·93 per cent. between the years 90 and 100. Obviously, from a purely financial point of view, it is best to cut the wood when it is between 80 and 90 years old, and to invest the proceeds in Consols at 2½ per cent., for its maintenance beyond that age entails a loss of interest. The increment, that is the interest on the growing capital of the forest, is less than can otherwise be obtained on perfect security.

It is also evident that the value- and volume-increment per cent. may be used to aid in determining the most profitable rotation to adopt in the management of a forest. In the vicinity of coal- or other large mines, where pit-props find a ready sale, a rotation between 60 and 70 years, and even lower, would be most profitable. Where, however, the chief demand is for building timber, or there is a risk lest an over-production of smaller wood might lower prices, the rotation should be higher, 70 to 80 or 80 to 100 years. The value- and volume-increment per cent. does not, however, correctly express the rate at which the forest capital works. For this purpose the formula must be completed by inserting the annual expenses for taxes, administration, &c., as well as the rent of the soil. The result is called the *forest per cent.* To discuss this part of the subject would, however, lead too far on the present occasion.

Part ii. deals with forest valuation. Obviously it is often necessary, when a forest is to be divided, or assessed or sold, to determine its capital value. The English reader may be disposed to think this an extremely simple matter. The value of a piece of property is either its selling value or its productive value, and these can readily be ascertained by the prices paid for forest land in the open market, or by the rent derived from forest land. Sales of forest land, however, do not often occur, and when a sale takes place, the price realised for one piece of forest does not give the value of another piece. Soil, aspect, elevation, and the other factors which influence the annual timber production and the rate at which the timber can be sold, must be considered, and more than these, the actual condition of the growing stock depending upon species, age, and previous treatment.

Nor does the rental of forests come to our aid; forest lands, as a matter of fact, are not often leased out, the difficulty being to make sure that the capital value of a forest has been maintained unimpaired during the lease. The rent obtainable from a field, or from a piece of grass-

land, whether let as a sheep-walk or for shooting, is known or can readily be ascertained. The same holds good in the case of osier-beds, which are cut over annually or every second year, and, in the case of coppice woods, which are worked on a short rotation. In all these cases the yield is approximately the same every year, and so is the annual outlay for labour and manure. Matters are complicated where standards are held over in the coppice, and more complicated in the case of high forest. A piece of high forest consists of trees which require eighty or hundred years, or even longer, to come to maturity. It consists of woods of all ages, and in the same wood trees of different species and of different ages are often found mixed. Under good management, a piece of high forest, if of sufficient extent, ought to yield, year after year, approximately the same quantity of timber, and hence a forest under a good system of management, in accordance with a well-considered working plan, is analogous to a field or meadow. When this, however, is not the case, it obviously is not a simple operation to determine the annual yield and the capital value of a forest. The annual yield is derived, in the shape of thinnings and final cuttings, from certain compartments this year, and from other compartments another year. Data extending over a long series of years would be needed to ascertain its average amount.

It may be objected that the capital value of a forest consists of two items, the value of the land and the value of the growing stock; that the former can generally be estimated within narrow limits, and that the latter should be calculated by adding up the market value of the timber standing in each compartment. This method, however, would leave out of account all young woods, which do not yet contain marketable timber; it would, in fact, treat them as blanks. The result of such a proceeding would be misleading, for obviously the capital value of a forest depends upon the yield which may in future be expected from it. And the future yield depends quite as much upon the condition of the young woods, which eventually are to furnish thinnings and the final crop, as upon the timber which at the present time happens to be marketable.

On the assumption that a forest is worked in accordance with a system settled beforehand, its capital value and its rental can obviously be calculated with the aid of yield tables. All net income, that is, the amounts expected to be realised by the sale of timber, less the cost of cutting, carriage, and other expenses, is discounted to the present time, and from the present value of all income is deducted the present net value of all expenses expected to be incurred upon the property. The result thus obtained is called the expectation value. Starting from an area not stocked, the *soil expectation value* is obtained. Thus, on the assumption that Scotch pine is to be planted, the soil expectation value of an acre of land of middling quality, such as that to which the data given on page 512 relate, will be as follows:—

Under a rotation of		With a net rental of
60 years	196*s*.	4·90*s*.
70 ,,	236*s*.	5·91*s*.
80 ,,	250*s*.	6·25*s*.
90 ,,	245*s*.	6·14*s*.
100 ,,	229*s*.	5·73*s*.

In calculating these values, the question had to be settled which rate of interest should be employed. As regards security, forest property has the drawback of possible damage by fire, storms, snowbreak, and insects. On the other hand, once placed under systematic management, a forest yields approximately equal returns annually, while those of fields and grass-lands vary according to the seasons. Once established, a forest requires less labour, and can be left alone for a time without much risk, for the timber continues to grow all the same. Lastly, the yield of several years may be anticipated, if money is wanted, or if it is desired to take advantage of a temporary rise in timber prices. These are substantial advantages of forest property, which make it a desirable investment, and therefore justify a low rate of interest. In these calculations, as well as in all others in this portion of his manual, the author has employed the interest of British Consols, that is, 2½ per cent. The calculation of the soil expectation value will be understood at a glance by stating the formula for a rotation of 80 years:

$$S_e = \frac{Y_{80} + T_{30}\cdot 1{\cdot}025^{50} + \ldots + T_{70}\cdot 1{\cdot}025^{10} - c\ 1{\cdot}025^{80}}{1{\cdot}025^{80} - 1} - \frac{e}{0{\cdot}025}$$

Y_{80}, the final yield at the end of the rotation is, according to the table given, worth 2225 shillings; the thinnings at the ages of 30, 40, 50, 60 and 70 years are worth $T_{30}=4$, $T_{40}=36$, $T_{50}=67$, $T_{60}=86$, $T_{70}=91$ shillings. These values are all prolonged to the end of the rotation, and the same is done with c, the cost of formation, here assumed to amount to 60 shillings, which is deducted from the sum of final and intermediate yields. The difference is the rent yielded by the forest every 80 years, that is, at the end of each rotation, and the present value $\frac{r}{1{\cdot}0p^{80}-1}$ of this perpetual rent, after deducting the capital value of c, the annual expenses for administration, taxes, &c., ($e=3s.$), represents the soil expectation value.

All other data remaining the same, the value of S_e varies with the length of the rotation adopted, and in the present case its value culminates for a rotation of 80 years. Obviously this is financially the most profitable rotation which yields the highest net rental, 6·25 shillings per acre. Under this rotation the capital value of the growing stock is utilised to its full extent; if the wood is allowed to grow older, both soil expectation value and net rental diminish. It will be understood that on the data here assumed, it will pay to plant Scotch pine on land of middling quality, if that land can be purchased at 250 shillings (£12 10*s*.), or less, an acre.

The method here explained can be employed to determine the expectation value, not only of land, on the assumption that it is to be planted up with Scotch pine or other trees, but also of existing forests. The expectation value of a normal forest, for instance, consisting of 80 compartments of one acre each, all of the same middling quality, completely stocked with Scotch pine, in a regular succession of ages, the wood on the youngest compartment being 1, that on the oldest 80 years old, would stand as follows:—

	£		£	*s*.	*d*.
Growing stock ...	3418	or, per acre ...	42	14	6
Soil	1000	,, ...	12	10	0
	4418	,, ...	55	4	6

It must be distinctly understood that these calculations are based upon assumptions, which may not in all cases be realised. The first assumption is that the plan adopted, upon which the formula is based, will be strictly carried out, that thinnings and other operations will not be interfered with by fires, storms, snowbreak, insects, or other damage, and that the areas will always be fully stocked with even aged timber. The second is, that the data of the yield tables will actually hold good in the case in point. The third assumption is, that the prices realised by sale of the timber, that wages and other circumstances which govern the value of c and e, will be, and remain, as entered in the calculations.

There is some analogy with engineering formulæ. These the practical engineer uses as his guide, not blindly, but with circumspection and with due consideration of all circumstances which may affect the result. The difference is this, that the forester attempts to express by a mathematical formula the growth of trees,

of organised beings, the development of which is governed by a multitude of influences, varying incessantly. Nevertheless, if used with due caution, these mathematical formulæ, elaborated with praiseworthy perseverance by foresters in Germany, will be found most useful aids in considering the difficult problems which forestry presents in all countries. Some of these problems can, others cannot, in the present state of our knowledge, be solved by the use of mathematical formulæ. Space forbids a further discussion of this subject.

In the kingdom of Saxony the State owns a forest area of 430,000 acres, which, after deducting all expenses, yields a mean annual net revenue of £390,000, or 18*s.* per acre. For many years it has been an established practice to determine, at intervals of ten years, the capital value of each forest range, soil and growing stock, and to calculate the rate of interest which, under existing management, that capital yields. The total area consists of 107 forest ranges or executive charges, and authentic statements, giving the financial result of forest management in each range, are published annually. During the five years ending with 1892 the average capital value of the entire area (soil and growing stock) amounted to 15 millions, or about £36 an acre. During this period, therefore, these forests have yielded interest on the capital involved at the rate of 2·6 per cent. Many of the 107 forest ranges have yielded less than 2 per cent., but a large number regularly yield more than 3 per cent. Compared with the State forests in other countries of Germany, those of Saxony have great advantages. The country is densely inhabited, up to the edge of the forests, factories and other industrial establishments are numerous, and there is a complete system of roads and railways. The consequence is, that timber, even of moderate dimensions, commands high prices, and that the produce of thinnings finds a ready market. Under these favourable circumstances, most of these forests are worked on a short rotation, which, it will be evident from the preceding remarks, is always more likely to lead to good financial results, than if the woods were permitted to attain a great age. A large portion of this area has gradually been converted into pure spruce forests, managed on a rotation of eighty years. On other grounds, it may, perhaps, not have been wise to rely upon pure spruce forests. Up to the present time, however, there has been no serious damage from insects or fungi.

In most other countries of Germany the public forests—that is, those which belong to the State, to towns, village communities, and other public corporations, and most of the larger private forests—are managed on rotations considerably longer, and the consequence is, that the capital involved (soil and growing stock) does not yield as high interest as in the State forests of Saxony. The Spessart, for instance, an extensive forest area belonging to the State in the kingdom of Bavaria, contains a large growing stock of old oak timber, 250 to 450 years old, which, if cut and sold at the present time, would fetch about £1,500,000. The existing working plan governs operations during a period of 120 years, from 1888 to 2007, and particularly prescribes the manner in which the old standing oak timber shall be utilised. About 60 per cent. of the quantity alluded to consists of trees 300 to 450 years old, with hardly any volume- or value-increment. These it is proposed to cut during the next forty years. If they were cut now, and the proceeds were used to redeem part of the State debt, upwards of £27,000 a year would be saved in interest. The remaining 40 per cent. consists of trees now about 250 years old. These will furnish the yield in oak timber from 1936 to 1983, and when they are cut the volume will be greater, and the timber, being larger, will fetch much higher prices. Nevertheless, in the case of this portion, also, there will be considerable loss of interest. This sacrifice of interest is made deliberately by the Government of Bavaria, with the full consent of the Parliament at Munich, because it is considered desirable to maintain a regular supply of oak timber from this source, upon which numerous industrial establishments in the large villages all round the Spessart to a great extent depend.

And there are many other forest tracts in Germany of large extent, both public and private, which still contain enormous stores of old-growing timber, the inheritance of several centuries. In such cases it is right on many grounds to spread the removal of the old timber over a long series of years, and rather to work the forests on conservative than on purely financial principles. In Great Britain, however, circumstances are more similar to those which exist in Saxony, and hence, in the management of its woodlands, financial considerations will probably preponderate.

Part iii. deals with working plans; and this portion of the book cannot be sufficiently recommended to forest proprietors in Great Britain. In the first volume of his manual, Dr. Schlich justly drew attention to the large importation into the United Kingdom of timber and other forest produce, and he estimated that £12,000,000 a year represented the value of oak, birch, coniferous and other woods imported from abroad, that might be produced in Great Britain. This was in 1889; it was a cautious estimate, and since it was made, the imports into the United Kingdom have increased steadily.

Landed proprietors in Great Britain have fortunately not yet suffered to the same extent by the decline in the price of wheat and other agricultural produce, as proprietors in some parts of Germany. Yet their income has diminished, and in many cases it doubtless would be desirable to increase that income. Much might be done in this direction, if the management of existing woodlands were improved, and if land which it does not pay to keep under the plough, or to convert into grass land, were planted up and converted into forest. One objection commonly raised to this proposal is, that timber traders prefer imported to home-grown timber. That this is the case there is no doubt, and in the preface to the present volume Dr. Schlich explains the reason. Home-grown timber cannot, as a rule, compete with imported timber, because it has not grown up in dense compact masses. The woods are open, hence the bole is short, branched, and knotty. There are exceptions, but open park-like woods are the rule, and these cannot be expected to yield timber of good quality. A different system of sylviculture must be adopted. Of greater importance still is the adoption of regular systems of management. Timber of different kinds and of the exact qualities required by the market is imported regularly in sufficient quantities at the principal ports of the United Kingdom; the timber trader is able to make the needful arrangements to supply his customers, because he is certain that whatever he may require to meet their demands, will be available at the right time. Home-grown timber, on the other hand, is thrown upon the market in an irregular fashion. All at once heavy cuttings are made at one place, to provide money, or for other reasons, and then perhaps nothing is cut in the same district for years to come. The necessary consequence of such a system, or rather want of system, is that the timber is not sold at its full value. And when a calamity occurs, such as the storm of 1894, the timber blown down cannot be sold, except at ruinously low rates. The only remedy is the adoption of methodically arranged working plans in all forest tracts throughout the country. Among other things, such working plans determine the annual yield of each forest district. It does not follow that the yield once fixed must be pedantically maintained. A good working plan is elastic, and permits deviations to suit the interests of the proprietor. But if a methodical system of working is the rule in all forest districts, these deviations will generally compensate each

other, and the market will nevertheless be regularly supplied.

What, then, is a working plan? The German term is Wirthschafts plan, and the English term (working plan) was first used in 1856, when the writer of these lines commenced to work the Pegu teak forests on a regular system. The number of teak trees of the different age classes was approximately determined by an elaborate system of valuation surveys. It was found that the trees of the second class were sufficiently numerous to take the place of the first class trees, and that the same was the case with the younger classes. It was also ascertained, that twenty-four years on an average would be required for the trees of the second class to attain first class size. The result was that the removal of the first class trees, those which were fit to yield marketable timber, must be spread over at least twenty-four years; and upon this very simple principle, a working plan, intended to provide, in the first instance, for six years only, was established for the different forest districts. After the expiration of the first six years, this plan was renewed, and subsequently modified and elaborated in detail. The principle, however, has been maintained to the present day. These are the bare outlines of the scheme, which has not only ensured a sustained yield, but, and that is very important, has been readily intelligible to all.

(*To be continued.*)

THE NEW PROCESS FOR THE LIQUEFACTION OF AIR AND OTHER GASES.

THE liquefaction of air, and the rest of the so-called permanent gases, is an achievement which belongs to quite recent times. Faraday cooled and compressed gases by such means as were at his disposal, with results which are well known; but it was the experiments of Andrews, published in 1869, which taught physicists the fact that until the cooling has been effectual no amount of pressure will liquefy the gas; in fact, that every gas has a critical point below which its temperature must be reduced before pressure can bring about liquefaction. The critical points of oxygen and the components of air are very low. Hence it was not till 1877 that these gases were liquefied by Pictet and by Cailletet. The former reached the necessary temperature by two stages, using first liquid sulphur dioxide, then liquid carbon dioxide, both boiling under reduced pressure. Cailletet used the principle of cooling by sudden release from higher to lower pressure. The introduction of liquid ethylene as a cooling agent enabled experimenters to make another step forward; for, with the help of liquid ethylene, Wroblewski and Olszewski first obtained liquid oxygen in quantity far larger than would be possible in any form of Cailletet's apparatus, and without the complicated machinery of Pictet. Liquid oxygen itself thus became available as a refrigerating agent, and afforded the means of cooling a tube containing any other gas to a temperature lower than ever; namely, about 211° below zero Centigrade. With this cooling agent, and with the further cooling produced by expansion of the confined gas from a pressure of 150 atmospheres to 20 atmospheres, hydrogen has been liquefied by Olszewski. Suggestions have from time to time been made as to the possibility of applying the reduction of temperature, consequent upon the expansion of a gas when released from a high pressure, to the further cooling of the compressed gas; but no practical steps had been taken in this direction till the publication, in October last, of Herr Linde's successful liquefaction of air by the application of this principle. It now appears, however, that Linde has not only been anticipated in the application of the principle, but that a more effective apparatus than his has been devised. On Saturday, March 21, a demonstration was given, at Brin's Oxygen Works, of the construction and use of a new apparatus, the subject of an English patent, dated May 23, 1895, standing in the name of Dr. William Hampson. The apparatus consists of three coils of narrow copper tubing, arranged concentrically in a metal case, and connected successively together, as shown in the accompanying diagram (Fig. 1), which displays a vertical section of the apparatus. The gas, say oxygen, enters the outer coil under a pressure of 120 atmospheres, passing from this into the second, and from this into the central coil, which is surrounded by a

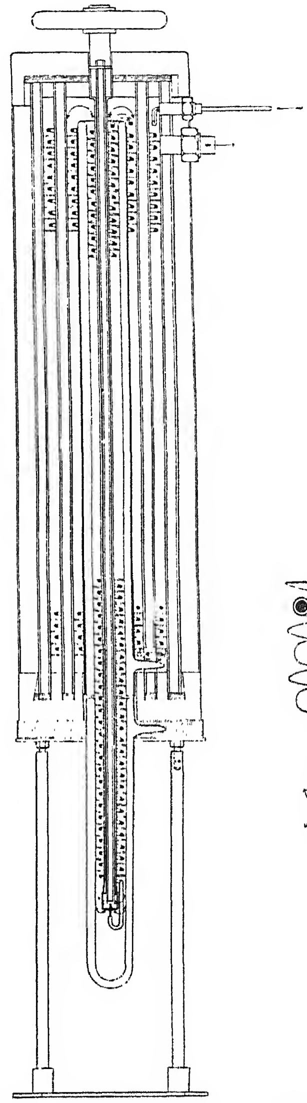

FIG. 1.—Sectional elevation.

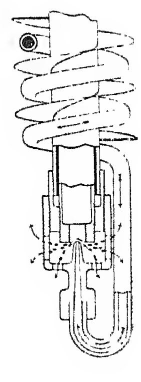

FIG. 2.—Detail of valve.

cylindrical glass vacuum-jacketed vessel as devised by Prof. Dewar. The two outer coils are separated from each other by vertical divisions of the case, and the spiral of the central coil is followed by a flat spiral of sheet copper. When the gas reaches the extremity of the central coil, it escapes through a fine orifice of peculiar construction, formed by bringing two knife-edges closely together (shown in Fig. 2). The size of the orifice can be regulated by means of an ebonite rod, which passes up the axis of the apparatus, and terminates in a handle at the top. After its escape the whole of the gas cooled by

expansion passes through the spaces surrounding the pipe through which the compressed gas is passing to the point of expansion, and so makes this gas, still under pressure, cooler than it was itself while under compression. The compressed gas consequently becomes at the point of expansion cooler than that which preceded it, and in its turn follows backwards the course of the still compressed gas, and so makes the latter cooler than before expansion, and therefore also cooler than ever after expansion. This intensification of cooling (always assuming sufficient protection against access of heat from the outside) is only limited by the liquefaction of the gas, the temperature of liquefaction being in the case of oxygen $-180°$ C. The apparatus exhibited measures 28 inches deep by 7 inches in diameter, and when once cooled down, that is, in about half an hour, it yields liquid oxygen at the rate of about seven cubic centimetres in four minutes. No carbonic acid, nitrous oxide, or other artificial cooling agent is employed either inside or outside the apparatus. With the liquid oxygen obtained, a series of interesting experiments were shown, which, however, were not in themselves new, such as the freezing of ether and alcohol, and the pulverisation of india-rubber after cooling. The expanded gas, after leaving the apparatus by the wide tube shown in the diagram, was led back to the suction pipe from which the pump was drawing. The impulse of the pump thus caused rhythmical variation in the pressure of the expanded gas over the surface of the liquid which had collected, and this in its turn produced a rhythmical variation in the small amount of ebullition visible in the liquid. Dr. Hampson's experiments, performed in the presence of a considerable number of representative men, constitute the first complete demonstration in England of the efficiency of the process of self-intensification of cold produced by expansion alone without the aid of extraneous artificial refrigeration.

It is obvious that the model exhibited admits of modification, both as to size and in some details of arrangement; but this ingenious adaptation of a well-known principle cannot fail to receive important practical applications. In the meantime the results already attained have the highest scientific interest. Among the more immediate consequences, we may look for the liquefaction of hydrogen in such quantities as to admit of the more exact study of the physical properties of this element in the liquid, and perhaps even in the solid state; while following upon this, the attainment of, or approximation to, the absolute zero of temperature cannot be far off.

ANIANUS JEDLIK.

On the 12th of last December, a month before having completed his ninety-sixth year, Anianus Jedlik, who had for half a century been an active labourer in the field of experimental physics, ended his lengthy career at the cloister of the Benedictine Order, in Györ.

It was a strange sort of an investigator's life that came to a close with Jedlik's death. We scarcely meet with his name in the international literature of natural sciences, and yet he worked a great deal and wrote a great deal; but he totally lacked the ambition to obtain the appreciation of foreign fellow-labourers in his branch of learning, for the results attained by him. To him, his researches in the world of physical phenomena afforded in themselves sufficient enjoyment; and his laboratory work thoroughly satisfied his unpretending nature, which was free from all desire for fame.

Stephen Jedlik, who as Benedictine monk adopted for his monastic name that of Anianus, was born on January 11, 1800, at Szimö, in the county of Komárom (Hungary). He frequented the Latin schools at Nagy Szombat and Pozsony. In 1817 he entered the bonds of the Benedictine Order at Pannonhalma, in 1822 he became Doctor of Philosophy, and in 1825 was consecrated officiating priest.

The talented young priest was intended by his Order for a professor, and so he was employed in teaching natural philosophy successively at Pannonhalma, Györ, and Pozsony. In 1840 he was appointed Professor of Natural Philosophy at the University of Pest.

Jedlik's scientific researches extended to various branches of natural philosophy; nevertheless he turned his attention principally to those physical phenomena which chiefly absorbed the learned men of the time at which he started upon his career, namely, those connected with galvanism and electro-magnetism.

Within the sphere of these, Jedlik succeeded in making two important discoveries, as we can prove with total certainty. But these discoveries now bear the names of others, who happened to make them independently of Jedlik, and hastened to make the scientific world acquainted with them, while he merely laid them before his own pupils.

It was in the first years of his professorship—in 1827–1828—that, upon reading about electro-magnetism in the German periodicals to which he had access, he modified Schweigger's multiplicator in the following manner. He put in the place of the magnetic needle an electro-magnet, and thus, with the aid of a current-commutator, produced permanent rotation.

Jedlik relates, in his modest manner, that he never came upon any mention of such electro-magnetic rotatory apparatus in any of the periodicals or works with which he was acquainted, so that he could not but believe that he was their discoverer. But he kept it to himself, as he had repeatedly experienced that descriptions of apparatus constructed by him after his own original ideas, already existed elsewhere; and so he never thought of sending descriptions of the above to any of the foreign scientific periodicals of which he knew.

Jedlik's other discovery had reference to the fundamental principle of the dynamo-electric machine. In the collection of the physical department of the University of Budapest, there is a machine of very primitive construction, dating, as it appears, from somewhere about the year 1860, and probably the work of some mechanician of Pest, to which are joined directions as to its use in Jedlik's own handwriting.

In the fourth point of these instructions we find clearly defined the fundamental principle of the dynamo-electric engine, which principle Werner Siemens brought before the Academy of Berlin in 1867, and according to which the magneto-electric currents of augmenting force may be developed by means of mechanical force, with the aid of the slight amount of magnetism contained in ordinary soft iron.

Jedlik discoursed with great zest upon his investigations at the meetings of natural philosophers and physicians, in whose publications his dissertations are to be found. Several of his treatises appeared in the publications of the Hungarian Academy of Sciences, which elected him its regular member in 1858.

The topics of some of his more important treatises are as follows: "The Deflection of Beams" (1845); "The Application of the Electro-Magnet in Electro-Dynamic Rotations" (1856); "A Modification of Grove and Bunsen's Battery" (1857); "The Magneto-Motor" (1857); "Concatenation of Leyden Jars" (1863), through which peculiar modification he attained a remarkable degree of effect; "Modification of Fresnel and Pouillet's Interference Apparatus" (1865); "Tubular Electric Collectors" (1867); "Electro-magnetic Undulation Machine" (1868).

With Jedlik there expired one of the typical figures of

the old school of physical experimenters who lacked that most important helper to their investigations—the knowledge of mathematics, but made up for this deficiency through a sort of intuitive perception when, led by a certain imaginative or creative faculty, they were able, with a sure hand, to grasp the very essence of a physical phenomenon.

With the present tendency of physical researches, this class of learned men could scarcely hold their ground; but, on the other hand, we must not disdain these mere experimenters, for they count among their number no less a man than the great Faraday.

Augustus Heller.

NOTES.

The adoption of the metric system by the United States seems to have received a notable impulse during the present week by the action of the Committee of Congress, which has reported in favour of its use by the United States Government in all its affairs except the completion of land surveys now in progress, on and after July 1, 1898, and its general use throughout the country on the first day of the twentieth century, January 1, 1901. The report is the outcome of a movement very early in this Session of Congress.

In accordance with a resolution of the House of Assembly of Cape Colony, carried last year, a Commission, consisting of the Hon. J. X. Merriman, Dr. Thomas Muir, Dr. David Gill, F.R.S., Mr. Thomas Stewart, and Mr. Charles Currey, has been appointed for the purpose of organising, controlling, and directing the work of geological exploration and survey in the colony. We are informed that the Commission has now appointed the under-mentioned gentlemen to begin the work of surveying and mapping the country:—Geologist, Dr. G. S. Corstorphine; Assistant Geologists, A. W. Rogers and E. H. L. Schwarz. As early as possible the Commission will publish and distribute a bibliography of South African geology.

It has been decided by the Huxley Memorial Committee to strike a medal for award by the Royal College of Science, London, and possibly for other purposes. The Committee desire to obtain the design for the medal, if possible, by competition. Further particulars will be furnished on application, which must be sent in before May 1 to the Honorary Secretary of the Huxley Memorial Committee, Prof. G. B. Howes, Royal College of Science, South Kensington, S.W.

We regret to see the announcement of the death of Mr. Charles Chambers, F.R.S., Director of the Colába Observatory. For the following particulars of his career, we are indebted to a long notice in the *Times* of India. Mr. Chambers was born at Leeds, Yorkshire, on May 30, 1834, and was consequently at the time of his demise in his sixty-second year. After finishing his education in his native place, he secured an appointment in the Kew Observatory, which he left in October 1863, to take up the post of assistant to the Director and Chief Superintendent and Electrician of the Indo-European Telegraph Department, Persian Gulf Section. In October 1865, he was temporarily appointed Superintendent of the Government Observatory, Bombay. After acting in that capacity for over two years he was confirmed in the appointment in January 1868, and continued to hold that office till November 1886, when he was given the appointment of Director of the Colába Observatory, which office he was holding at the time of his death. He was elected a Fellow of the Royal Society in 1869. He was also appointed a Fellow of the Bombay University in 1872, and a member of the Syndicate of the same University from 1879 to 1890. His contributions to scientific literature were very numerous, most of them being records and discussions of meteorological and magnetic observations in relation to solar changes.

Prof. N. A. Moos, of the Elphinstone College, Bombay, has been selected for the post of Director of the Government Observatory at Colaba, in succession to the late Mr. Charles Chambers.

The Annual Congress of the British Institute of Public Health will be held in Glasgow, from July 23 to July 28.

Dr. Samuel Wilks, F.R.S., was elected President of the Royal College of hysicians of London, at a meeting held on Monday.

Prof. Wyndham R. Dunstan, F.R.S., has been appointed Director of the Scientific Department of the Imperial Institute, which has hitherto been under the direction of Sir Frederick Abel. The principal work of this Department is to investigate new or little-known products from India and the Colonies, and to advise in reference to their commercial utilisation. Already much valuable work has been accomplished in this direction. With the aid of an increased grant from the Royal Commissioners of the 1851 Exhibition further additions to the staff of the Department will be made, and the Laboratory, which was fitted up in 1894 with the assistance of a grant from the Goldsmiths' Company, will now be considerably extended.

The College of New Jersey at Princeton is preparing to send an expedition to Patagonia for the purpose of securing fossils and large game. At a recent meeting of the Board of Trustees of the College, it was decided to change the charter name to Princeton University.

A few days ago M. Eugéne Fariot, an engineer of some repute and a worker in aeronautics, one of the siege aeronauts who escaped from Paris in the *Louis Blanc*, died at the age of sixty-eight. e has bequeathed a sum of £4000 to the Société française de Navigation Aerienne, of which he was a member. One half of this sum is to pay the expenses of experiments, and the other half to be funded in the name of the Society; the interest to be expended yearly on its behalf. Consequently, it is expected that an end will be put to the long stagnation in scientific aeronautics in France, owing to the indifference of the public authorities for an art so popular in that country.

For more than twenty years, the Sunday Society has been working "to obtain the opening of museums, art galleries, libraries, and gardens on Sundays." As already noted in these columns, the House of Commons on March 10 passed, without a division, a resolution in favour of this object. We are glad now to record that in the House of Commons on Monday, in answer to Mr. Massey-Mainwaring, Mr. Balfour said: "The Government are prepared to open South Kensington and Bethnal Green at a very early date—indeed, almost immediately. Those are museums under the control of the President of the Council. The National Gallery, the National Portrait Gallery, and the British Museum are in the hands of trustees, and correspondence is still going on between the Government and the trustees, though I have no reason to believe that any difficulty need be apprehended as to the final conclusion of a satisfactory arrangement." In fulfilment of this promise, it was announced yesterday that the South Kensington Museum, including the India Museum and Science Collections in the Galleries on the west of Exhibition Road, as well as the Bethna Green Branch Museum, will be open on Sunday next at 2 p.m. and will remain open till dusk.

An instructive case for the consideration of anti-vaccinationists is reported in Wednesday's *Times*. It appears that the guardians

of the Gloucester Union have for some years persistently neglected to perform their statutory duty under the Vaccination Acts, with the result that they now find themselves responsible for one of the most appalling outbreaks of smallpox which has for a long series of years visited any provincial town in England. During the last seven weeks, the notifications of fresh cases of smallpox in the cathedral city of Gloucester have enormously increased, the number of new cases during the past week being no less than 154, and the disease is still rapidly spreading. The guardians are now endeavouring to stem the disastrous torrent they have let into Gloucester by their non compliance with the laws of vaccination. About a week since they decided to attempt to undo the mischief of past years by passing a resolution deciding to enforce the compulsory clauses of the Vaccination Acts. It may be stated that the Town Council of Gloucester from the first have done their utmost by isolating the sick in hospital, by disinfecting houses, burning clothes and bedding, and placing relatives of sick in practical quarantine to stay the outbreak. Finding the outbreak gaining, they built extra hospitals, and have now hospitals for 120 patients, but the disease has continued to spread with such virulence that it is quite beyond their power to cope with it. A significant fact is that out of 90 deaths that have occurred in hospital up to March 27, 74 are among unvaccinated persons.

Individual enterprise is not often lacking in British commercial circles. Mr. R. K. Douglas gives an instance of this in the *Times*. He states that the Blackburn Chamber of Commerce have inaugurated a subscription, which now amounts to between £2000 and £3000, to provide sums for the purpose of sending out a commercial expedition to China, whose duty it will be to report on the state of trade in the interior of the country, the price of foreign goods in the native markets, the kinds of goods in demand, and the products and capabilities for trade of the inland districts. So far no assistance has been asked from the Government, and none has been given. But a point has now been reached when that modicum of official support which is necessary to the success of the expedition should be confidently asked for and promptly granted. Mr. Douglas is undoubtedly right in pointing out that if the expedition is not to prove a failure, the Foreign Office should supplement the efforts of the Blackburn Chamber of Commerce by giving it tangible support, and by appointing a member of the Consular Service in China to accompany the expedition on its travels. There should be no difficulty in doing this, and we hope with Mr. Douglas that the Government will give support to an undertaking which has for its important object the further promotion of British trade in the Far East.

Writing with reference to the aurora of March 4, it was suggested by Dr. M. F. O'Reilly, in our issue of March 12, that possibly Röntgen effects might be produced by auroral light. Mr. Donald S. Munro sends us a cutting from the Glasgow *Evening News*, in which he describes an experiment made to test this point. He says: "I put a rapid isochromatic plate in a camera slide, and covered the slide with black paper wrapped round several times, in case of any possible want of tightness in the slide. Several circular and triangular pieces of sheet-iron were placed beneath the paper, and next the lid of the dark slide. On developing, the result was no image. Perhaps, however, some one trying again with a brighter display and a longer exposure might get a result. I did not think of the experiment until the northern lights were beginning to fade, so my plate had only half an hour's exposure."

Statistics relating to the harvest gathered in from the sea around the coasts of the United Kingdom during 1895, are given in a return made to the Board of Trade, and published as a Parliamentary Paper. The statistics relate mainly to fish landed on the coasts of England and Wales, but summarised statements are also given of fish landed on the Scotch and Irish coasts. For purposes of comparison the statistics are given of the sea fisheries of Norway, Holland, France, and Canada. As regards England and Wales, the total value of the fish landed was £5,438,000. The corresponding values for 1893 and 1894 were £5,171,000 and £5,291,000 respectively. For Scotland the total value was £1,830,000, and for Ireland £269,000. In Scotland, during the year 1895, there has been a slight decrease in the quantity and an increase in the value of the fish landed as compared with 1894. In Ireland there was a decrease, both in quantity and value. The aggregate value for the United Kingdom during the year 1895 is £7,537,000, as compared with a total value of £7,260,000 in 1894. The figures for other countries during 1895 are not to hand, but for 1894 the values were:—Norway, £1,272,000; Holland, not accurately known, but probably less than Norway; France, £4,681,000; and Canadian Dominion, £4,317,000.

The report of the Departmental Committee appointed by the Board of Agriculture to inquire into the etiology, pathology, and morbid anatomy of swine fever has been issued as a Blue-book. The following conclusions are stated therein: (1) Bacteriological investigations prove that the cause of swine fever is a specific microbe. (2) Experience and observation prove that swine fever (both in its acute and chronic forms) is communicable from diseased to healthy swine by contact, and also by the agency of persons, animals, and substances which are capable of conveying the infective matter. (3) It has been shown that the pronounced symptoms which have hitherto been looked upon as essential to a correct diagnosis are not always present in the early stage of swine fever, and are almost constantly absent in the chronic form of disease. (4) The Committee regard it as an important outcome of the study of the morbid anatomy of the disease that some animals undoubtedly infected with swine fever presented only minute erosions in the intestinal canal, and that other animals, which had been suffering from either the acute or the chronic form of the malady, but which had recovered, showed only depressed scars which were apt to be overlooked at any but a very thorough *post-mortem* inspection. (5) From the experimental evidence it is concluded that a condition of plugging of the crypts on the ileo-cæcal valve cannot be accepted as an indication of swine fever.

The current number of *Weidemann's Annalen* contains an interesting paper by Herr Lang on the determination of the wave-length of Hertz electric waves. The method employed is similar to Quincke's method of measuring the wave-length of a musical note by arranging the lengths of two tubes which, starting from near the source of sound, are at their other ends brought together, so that the sound which has travelled along one tube interferes with that which has travelled along the other. Herr Lang uses an oscillator of Righi's form, consisting of two spheres. The tubes along which the electric waves have to pass are made of paper lined with tinfoil, and have a diameter of about 6 c.m. In order to detect the electric oscillations, a Branly tube (coherer) was employed. By placing a paraffin cylinder in one of the tubes the wave-length of the electric oscillation in paraffin, and hence the refractive index of paraffin, can also be measured.

The "Handbook of Jamaica" for 1896 is filled with historical, statistical, and general information concerning the island. This present issue contains in an appendix a useful article by Mr. W. Fawcett, Director of Public Gardens and Plantations in Jamaica on the planting and care of woodlands.

A SENSIBLE little pamphlet, entitled "Health Notes for the Seaside" (Whitby: Horne and Son), in which some of the salient facts of the science of hygiene are applied practically to every-day life and holiday seeking, has been written by Mr. A. C. Dutt. The "Notes" contain much good advice on how to make the best use of a brief holiday.

MESSRS. G. PHILIP AND SON have sent us a copy of the special map they have had prepared to illustrate the British and Italian operations in the Eastern Soudan and Red Sea littoral. The map shows the entire course of the Nile from the great lakes to the sea, and the approaches to Khartum from the east coast. Another map published by the same firm, shows on a large scale the present scene of operations in Egypt.

THE fifth part of the second volume of the *Proceedings* of the Imperial University College of Agriculture, Tōkyō, is occupied by two papers, both in German, on Japanese trees in the winter state, illustrated by thirteen plates, and on the shrinking (*Klemmen*) of the Japanese timbers which are most useful for practical purposes.

THE "Hand-list of Coniferæ grown in the Royal Gardens, Kew," just issued, comprises 227 species, with 340 varieties. It has been drawn up with the assistance of Dr. M. T. Masters, and is preceded by a very valuable historical sketch of the nomenclature and classification of the *Abietineæ*, from the pen of Sir Joseph D. Hooker.

A KIND of German *Kew Bulletin* is announced, with the title *Notizblatt des königlichen botanischen Gartens und Museums zu Berlin*, under the direction of the staff of the Royal Garden and Museum at Berlin. It is to be devoted to the botanical interests of the German colonies, to the presentation of results which it is desirable to place promptly before those interested, and to the publication of new species.

WITH the view of bringing together the opinions of persons interested in reptiles, and with the laudable intention of educating people to a kinder feeling for these interesting creatures, *The Vivarium* has been started. The first number has been produced by a lithographic process, but the promoters hope to elevate the contributions to the dignity of print in the near future. The periodical is intended to be the organ of the newly-formed Reptilian Society, and copies can be obtained from the Secretary, Rand Rectory, Wragby, Lincolnshire.

A SIXTH revised edition of Prof. C. Gegenbaur's "Lehrbuch der Anatomie des Menschen" has been published by Engelmann, of Leipzig, in two ponderous volumes. The work was originally published in 1883, and took its place in the first rank among reference books of anatomy. The revisions ensure that the new edition will maintain the high position earned by the original. Another new edition, received during the past few days, is the seconds of "Geology and Scenery of Sutherland" (Edinburgh: D. Douglas), by Mr. H. M. Cadell. The book is a worthy example of a guide-book which has nature for its subject, and is a desirable companion for visitors to the rocky wilds of Sutherland. Would there were similar volumes for every county in the British Isles. Many instructive diagrams and full-page illustrations are distributed through the pages of the book.

THE Royal Agricultural and Commercial Society of British Guiana may not be progressing so much as it deserves, if progress is counted by an increased roll; but its admirable journal, *Timehri*, the December number of which (vol. ix. part 2) has come to hand, testifies to the existence of a healthy spirit of inquiry, which assists in the progress and development of the great colony with the affairs of which it is chiefly concerned. Among the subjects of papers in the present number are: "Food Adulteration," by Mr. L. M. Hill; "The Relation of Boiling Temperatures in Multiple Evaporation," by Mr. F. I. Scard; "Ethnological Notes from Pirari," by Mr. C. A. Lloyd; "The Materials of the Urali Poison," by Mr. J. J. Quelch; "Some Guiana Parrots," by Mr. C. A. Lloyd; and two articles by the editor, Mr. James Rodway—one on the future of the Negro, and the other on the old boundary of Essequibo. In view of the fact that Venezuela lays claim to the whole of Guiana west of the Essequibo, it is well to call attention to this article, in which Mr. Rodway shows the baselessness of such a claim. The London agent of *Timehri* is Mr. E. Stanford.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. S. C. Fisher; a Silver-backed Fox (*Canis chama*) from South Africa, presented by Mr. C. W. Southey; a Leadbeater's Cockatoo (*Cacatua leadbeateri*) from Australia, presented by Miss E. S. Young; two Crowned Dricker-Boks (*Cophalophus coronatus*, ♂ ♀) from West Africa, received in exchange.

OUR ASTRONOMICAL COLUMN.

NEW VARIABLE STARS.—The *Harvard College Observatory Circular*, No. 6, announces that an examination of the Henry Draper Memorial photographs of stellar spectra by Mrs. Fleming has led to the discovery of fourteen new variable stars of long period, in addition to those previously announced. The spectrum of the fifth star in the following list is of the fourth type. All of the others have spectra of the third type, having also the hydrogen lines bright, and it was this peculiarity which led to their discovery. The variability has been shown by comparison of a large number of photographs, and the variation has been confirmed in each case by Prof. Pickering.

COMET PERRINE-LAMP.—The following is a continuation of Dr. Lamp's ephemeris of Comet Perrine-Lamp for Berlin midnight (*Ast. Nach.*, 3341):—

		R.A.		Decl.		Brightness.
		h. m. s.		° ′		
April 3	...	4 19 25	...	+42 4·7	...	0·023
6	...	24 49	...	41 36		
9	...	29 45	...	41 10·6		
12	...	34 21	...	40 48·3		
15	...	38 39	...	40 28·4	..	0·012
18	...	42 45	...	40 10·8		
21	...	46 39	...	39 55·3		
24	...	50 23	...	39 41·4		
27	...	53 59	...	39 29·0	...	0·007
30	...	4 57 28	...	+39 18·0		

Mr. Joseph Lunt reports that on March 1, 2 and 3, the comet appeared as a circular nebulosity without tail, but with a bright central condensation, which very gradually faded away outwards. It was as bright as the nucleus of the great nebula in Andromeda, which it somewhat resembled, and was easily seen with a telescope of one-inch aperture. On March 9 the aspect of the comet was greatly changed, a bright stellar nucleus having developed; this was not centrally placed, and gave the comet a fan-shaped appearance.

During April the comet passes from near 58 Persei to a little south of η Aurigæ. In the latitude of London it is circumpolar throughout the month.

SEARCH EPHEMERIS FOR COMET 1889 V.—The following search ephemeris for the expected return of Comet 1889 V (Brooks) is given by Dr. Bauschinger (*Ast. Nach.*, 3334):—

	R.A. h. m. s.	Decl. ° ′	Brightness.
April 2	20 40 24	−24 9	0·17
6	47 3	23 50	0·18
10	53 35	23 31	0·19
14	21 0 3	23 12	0·20
18	6 24	22 52	0·22
22	12 39	22 32	0·23
26	18 47	22 12	0·25
30	24 47	21 53	0·27
May 4	30 40	21 33	0·28
8	21 36 25	−21 14	0·29

The ephemeris is for Berlin midnight, and the unit of theoretical brightness is that on 1889 July 8, the date of the first accurate observation. When last seen in January 1891 by Prof. Barnard at the Lick Observatory, the calculated brightness was 0·08, so that the comet should even now be brighter than when it was last observed; it is, however, not very favourably situated for European observers. During April the motion of the comet is a little north of the line from ψ to ζ Capricornii.

INSTITUTION OF NAVAL ARCHITECTS.

THE annual spring meeting of the Institution of Naval Architects was held last week, commencing Wednesday, the 25th ult., and being carried over Thursday and Friday, the two following days. The new President, the Earl of Hopetoun, who has succeeded Lord Brassey, occupied the chair throughout the meeting.

There was a long list of papers to be read, the following being on the agenda:—

(1) "Watertight Doors, and their Danger to modern fighting Ships," by Captain the Right Hon. Lord Charles Beresford, C.B., R.N.

(2) "Watertight Doors," by Colonel Nabor Soliani, Director of Naval Construction, Royal Italian Navy.

(3) "Some Geometry in Connection with the Stability of Ships," by J. G. Bruhn.

(4) "The Causes of Mysterious Fractures in the Steel used by Marine Engineers as revealed by the Microscope," by A. E. Seaton.

(5) "The Measurement of Feed and Circulating Water, &c., by Chemical Means," by C. E. Stromeyer.

(6) "Salvage Appliances," by J. G. Kinghorn.

(7) "Compound Marine Boilers," by Colonel Nabor Soliani, Director of Naval Construction, Royal Italian Navy.

(8) "Water-tube Boilers," by J. Watt.

(9) "Circulation in Water-tube Boilers," by Prof. W. H. Watkinson.

(10) "The Non-uniform Rolling of Ships," by R. E. Froude, F.R.S.

(11) "A New Theory of the Pitching Motion of Ships on Waves, and of the Stresses produced by this Motion," by Captain A. Kriloff, Professor at the Naval Academy of St. Petersburg.

(12) "Notes on the Carriage of Grain Cargoes," by George Herbert Little.

The paper by Lord Charles Beresford set forth the views of a naval officer on the question of watertight doors. It may be said generally that the piercing of bulkheads has been done at the request, or perhaps more correctly speaking, the insistence of naval officers, who have found it difficult to work their ships with partitions in them not allowing means of ingress and egress from one compartment to the other. Lord Charles Beresford, however, differs from the majority of naval captains, and considers that bulkheads are too much pierced. He would do away with a large number of openings in a ship. He tells us that in the *Magnificent* and *Majestic*, which are the most powerful battleships in the service, and, therefore, in the world, there are 150 compartments in each ship, and 208 doors. Many of these of course are not in positions which are of vital importance, so far as flooding of the ship would be concerned in case of accident. He proposes to do away with nineteen of these doors in the most important part of the ship, and twenty-three would be made smaller, or modified so as to give additional safety in accordance with his proposals. This would undoubtedly add to the safety of the ship, and equally without doubt it would detract from the convenience of those inhabiting it. The latter may seem at first a small matter, but, as was pointed out during the discussion which followed the reading of the paper, convenience is to a large extent a measure of efficiency in action. In fighting a ship it is necessary for the men to move from part to part with great rapidity. This naturally means openings in bulkheads; for if a man, say the chief engineer, in order to get from one part of the vessel to another, has to climb up on deck to surmount a bulkhead, and descend on the other side, time will be occupied in the transition. In the rapid handling of ammunition, also, it is absolutely necessary that direct access should be obtained to various compartments; whilst for bringing coal from the bunkers to the stokehole floors, divisions must have openings made in them. It is also necessary to consider the question of habitability. A ship requires ventilation, otherwise it is impossible to live in her; at present a good deal of space is given to steam fans and air conduits, for this purpose. If bulkheads are to be unpierced, the difficulty of ventilation becomes more pronounced. It will be seen, therefore, that the question of openings in bulkheads, whether fitted with water-tight doors or not, is not of so simple a character as might at first appear. In fact in this element of warship design, as in all others, "compromise" must be the watchword. It is necessary not only for naval officers but for naval architects as well to meet and discuss this matter. Up to the present it has been rather that the naval officer has demanded watertight doors, and the ship designer, or naval architect, has opposed the demand. It is evident, from the discussion which followed the reading of Lord Charles Beresford's and Colonel Soliani's papers, that opinions are divided. It is essential that the matter should be threshed out, and the best compromise, according to our lights, should be adopted.

Colonel Soliani's paper dealt with different forms of watertight door. It was very fully illustrated, and will be a valuable source of reference to shipbuilders and naval architects.

In Mr. Bruhn's paper the question of stability of ships was treated, both in an historical and a mathematical manner. This contribution was read in brief abstract, and there was practically no discussion upon it. It is not one that would bear condensation very readily, and in any case could not be understood without the use of the diagrams which accompanied it. It dealt with the problem of constructing geometrically a set of cross curves of stability for inclinations from 90° to 180°, the corresponding curves from zero to 90° being known. Another section dealt with the determination of the direction in which the centre of buoyancy moves when a ship is inclined in a given direction. Lines of curvature and geodetic lines as curves of buoyancy, relations between the surfaces of buoyancy and flotation, and an extension of Leclert's theorem were subjects also dealt with; whilst the paper concluded with a geometrical construction for finding the length n, or the radius of curvature of the curve of flotation, from the usual information given on metacentric diagrams.

Mr. Seaton's paper was an extremely interesting one, and will prove of great practical value to engineers. As is well-known, the author is the managing director of Earle's Shipbuilding and Engineering Works at Hull. Some time ago part of the shafting of a screw steamer with which he had to do suddenly gave way. This shaft was made of steel containing from 0·2 per cent. to 0·25 per cent. of carbon, and its ultimate tensile strength was guaranteed to be not more than 30 tons, with an elongation of 25 per cent. in 5 inches. Mr. Seaton determined to make an inquiry into the composition of this shaft, and for that purpose it was subjected to chemical analysis. We need not repeat this analysis; it will be sufficient to state that it showed a very high proportion of undesirable elements in the steel. The most interesting part of the investigation was that carried out by Prof. J. O. Arnold, of Sheffield, who prepared micro-sections in the usual way. The chief point of the paper consists in the fact that chemical analysis is shown to be insufficient to give the engineer information as to the value of a given steel used for structural purposes. For instance, sulphur which is objectionable under certain conditions may be present to a considerable extent in a steel casting or forging, but though it may be of no serious moment if in one form, will be conducive to most disastrous results in another form. The chemist, as Mr. Seaton pointed out,

is only able to state the quantity of sulphur present; but whether in a dangerous or non-dangerous form, he is unable to say. Mr. Seaton concludes, therefore, that chemical analysis alone is sufficient neither for steel nor for any other combined metal used by the engineer; while, on the other hand, the microscope reveals the actual structure of the material, and shows most distinctly whether it is a safe or an unsafe one. It appears, therefore, that the use of the microscope is likely to be of the utmost advantage to the marine engineer. We have not space to give the details by which Mr. Seaton supports his contention. The subject, however, is one well worthy of attention on the part of engineers, and scientific experts who work for them.

Mr. Stromeyer's paper was also one of interest. He proposes to measure the quantity of water either fed into a boiler, or passing through the condenser, by chemical means. A measured quantity of salt water is slowly injected, say into the condenser of an engine while at work; subsequently a chemical analysis for salt is carried out, both on a sample of sea-water and on a sample of the water to be measured. Their relative salinities would then give the quantity of water pumped, or the amount of steam condensed for any given period. The method is one which will probably be useful for estimating the quantity of circulating water used by the marine engineer, as it is capable of being applied to large quantities of flowing water with comparative facility. For the smaller volumes of water used for feed, which can be passed through pipes of moderate dimensions, the water-metre would, we think, be preferred by the majority of engineers; although, perhaps, the measuring-tank would command the greater confidence than either.

Mr. Kinghorn's paper, on salvage appliances, was of considerable practical interest. It referred to a new system of wreck-raising which has been evolved by certain salvage agents and marine engineers of Liverpool. This country is lamentably deficient in wreck-raising facilities, a fact which has been proved by the resource that has been had to foreign "wrecking" companies, when vessels of exceptionally large size have had to be raised. The case of the battleship *Howe*, at Ferrol, which was lifted by a Scandinavian company, and of the Atlantic liner *Eider*, wrecked on our own coast, and lifted by the same company, are instances in point.

The only evening sitting of the meeting, which was held on Thursday, the 26th ult., was devoted to the great water-tube boiler question, which is now agitating the marine engineering world. Of the three papers set down for reading, that of Prof. Watkinson was by far the most important. Colonel Soliani proposed a combination of fire-tube and water-tube boiler, which did not meet with universal approval during the discussion. Mr. Watt described certain experiments that he had made many years ago, and which could hardly be described as crucial. Prof. Watkinson attacked the great problem of circulation, the vital question certainly in water-tube boilers, and also to a far greater extent than has been supposed, in boilers of the shell, or fire-tube class. The circulation of water and steam in a water-tube boiler involves some very nice questions in physics. Its study affords a good opportunity for those highly skilled in physical science to assist the engineer in arriving at definite conclusions as to what causes govern the flow of water and steam in pipes subjected to heat. There were three types of boiler chiefly dealt with by Prof. Watkinson. The Belleville boiler, a French invention, which has now been in use for a number of years. It consists of a series of pipes of comparatively large diameter, say four inches to five inches; these are arranged in a continuous zigzag form, and subjected to the heat of the furnace; the water flows upward through this serpentine course, steam being generated in its course, and that water which is not converted into steam flows down external pipes, and then again passes into the bottom of the steam-generating pipes. In this way a continuous circulation is kept up. The distance the water has to travel through, from one end of the serpentine to the other, is considerable. The various lengths of pipe are not much inclined from the horizontal, and the sudden bends at the ends of each pipe tend to check the flow. It is believed that for this reason the Belleville boiler will not stand forcing—that is to say, only moderate quantities of coal can be burned to each unit of grate surface. For if rapid evaporation be attempted, the tubes are apt to be denuded of water. Judging by the recent trials of H.M.S. *Sharpshooter*, there would appear to be some truth in this contention. How far it applies, however, is a matter which experiment alone can reveal, and the results of such experiments, even if made, are not yet available so far as we are aware.

The other two kinds of boiler dealt with were of what is known as the "express" type—that is to say, they are boilers which will bear forcing, so that large quantities of fuel can be burned in a given time, and the rate of evaporation thus made very high. These are the well-known Thornycroft and Yarrow types of boiler, which have been so successfully applied to the torpedo-boat destroyers, which have given such remarkable results of late, in the matter of quick steaming. Although both the Yarrow and Thornycroft boiler have small tubes, say about one inch in diameter, which are comparatively short in length, each tube connecting directly with the top and bottom vessel, yet the two types have fundamental points of difference. The Thornycroft boiler has outside down-comers and bent tubes which discharge into the top drum above water. The Yarrow boiler has straight "drowned" tubes. These expressions require some further explanation. Each boiler consists essentially of a top drum or steam vessel, and two bottom drums or wing cylinders. Looked at in sectional elevation, these three drums form the points of a triangle standing on its base. The sides of the triangle are composed of the steam-generating tubes; the base is composed of the fire-grate. The products of combustion ascend from the grate amongst the tubes, and pass off to the furnace. In the Thornycroft boiler the outline formed by the three cylindrical vessels, and the connecting steam-generating tubes, is not strictly triangular, as the tubes are bent, as already stated. This bending enables them to be inserted into the top drum above the water-level carried into the latter. In the Yarrow boiler, the straight tubes pass in a direct line from the bottom vessels to the top drum, and therefore enter the bottom part of the latter, and, consequently, are below the water-level.

We will first trace the course of circulation of water in the Yarrow boiler. As there are several rows of tubes on each side of the furnace, those on the inside are naturally subjected to the greater heat. In them, as steam is first generated, the bubbles of steam rise, and water flows with them. To make up the deficiency thus caused in the content of the tube, water flows down the back tubes furthest from the fire, into the bottom vessel, which is common to all tubes on that side of the furnace, and then ascends those tubes where steam has been generated. In this way a continuous circulation is kept up. In the Thornycroft boiler this cycle cannot exist, as the tubes deliver above water, therefore special down-comer tubes have to be fitted; these enter the top drum below the water-level. Circulation takes place as follows. When the hot gases ascend among the bent steam-generating tubes, steam is generated. The tubes being small, it forces upward a certain quantity of water, which then falls into the top drum, and flowing down the downcomers, is able to rise again in the generating tubes to make up the deficiency. Circulation is, of course, due to the difference in specific gravity of the upward and downward columns of water in the generating tubes, and the down-comers, respectively. For some time past controversy has ranged between two schools—one favouring drowned tubes and anti-down-comers, the other undrowned tubes and down-comers, each maintaining that boilers constructed according to their views have most efficient circulation. Prof. Watkinson's paper dealt with this question, but no final opinion was expressed as to the respective values of the two types of boiler. The Professor had brought from Glasgow the glass model boilers with which he had made a number of experiments. Unfortunately, when he attempted to repeat these at the meeting, the breakage of tubes prevented him from carrying out his full programme. This is much to be regretted, as the experiments are of a very interesting nature. It is to be hoped that at no distant date Prof. Watkinson will have an opportunity of repeating them.

The last day of the meeting was devoted to two papers on pitching and rolling of ships. Mr. Froude's paper was practically a reply to one recently contributed by M. Émile Bertin, the eminent French naval architect, at the last meeting of the Institution; which in turn was a continuation of a paper by the said author read at a previous meeting. Without referring at length to these two papers it would be useless to attempt to give the substance of Mr. Froude's contribution, even if we had space to do so. It may be said, however, that Mr. Froude does not agree generally with M. Bertin. What the points of disagreement are, it would be impossible to explain without the aid of many diagrams, upon which the author relied for making his explanation clear. We must therefore refer our readers to the

Transactions of the Institution for information upon this intricate but extremely interesting subject.

Captain Kriloff's paper was of a completely mathematical character, and indeed was of far too abstruse a nature to follow during the reading. It depended on an appendix of many pages containing columns of figures which would require carefu study to master.

Mr. Little's paper was of practical interest to those concerned in the carriage of grain.

The proceedings were brought to a close by the usual votes of thanks.

The summer meeting this year is to be held in Hamburg during the early part of June. Extensive preparations have been made for the reception of members, and there is no doubt the meeting will be of quite an international character. The success of last year's meeting in Paris has encouraged the Council to go abroad again.

It may be added that the Institution is increasing in numbers at a rapid rate, there being a greater addition to the roll of membership at this meeting than has ever before taken place.

RECENT WORK WITH RÖNTGEN RAYS.

SEVERAL important communications referring to work upon Röntgen rays have come before our notice during the past week. While some experimenters are perfecting the methods so as to develop the capabilities of the rays, others are investigating the physical characteristics pertaining to them, and in both directions of work clear advances have been made since our last eclectic statement of the contributions to the subject founded by Röntgen's discovery.

Prof. Alfred M. Mayer, of the Stevens Institute of Technology, has sent us the following account of experiments carried out by him on the polarisation of Röntgen rays.

"Of the remarkable properties of the Röntgen rays, the one of the greatest interest is that these rays are not polarisable; for this property shows that these rays, unlike those of light, are not propagated by vibrations transverse to the direction of their progress. To decide conclusively this point certain properties, shown by Röntgen's experiments, must be possessed by the substance which is to act on the Röntgen rays, viz. (1) a low density; (2) the substance must be very thin, and yet give complete polarisation to transmitted light. These two properties are eminently peculiar to herapathite, an iodo-sulphate of quinine. Its density is only 1·8, and crystals of herapathite of only 0·05 mm. in thickness, with their axes crossed at 90°, entirely obstruct the incident light, so that their crossed portions appear intensely black.

"Six discs of glass, 0·15 mm. thick and 25 mm. in diameter, were covered with crystal-plates of herapathite crossing one another at various angles. Where they crossed at right angles they gave a black field. These discs were fastened to the surface of a screen of compressed brown paper, which was found to be impervious to the actinic action of a powerful arc light acting during two hours, and placed 1 foot in front of the screen; the latter covering a sensitive photographic plate. On this screen were also placed three discs of the same glass, overlapping one another, so that 1, 2, and 3 thicknesses of the glass had to be traversed by the X-rays before they reached the photographic plate. These discs served as standards with which to compare the action of the X-rays on the discs covered with herapathite. On the same screen was also placed a square of yellow blotting-paper, $\frac{3}{4}$ mm. in thickness, having on its surface superposed herapathite crystals from two to four layers deep.

"This screen so prepared, and covering a sensitive plate, was exposed to the radiations of the Crookes' tube; in the first experiment for half an hour, in the second for one hour, and in the third for two and a half hours. On developing these plates there was not the slightest trace of the presence of the herapathites. The photographs of the glass discs had not the slightest mottling on their surfaces. Their surfaces appeared throughout to the unaided eye, and also when examined with a magnifying glass, with a uniform illumination and grain throughout. The herapathite, of the thickness used in these experiments, does not appear to screen at all the X-rays; for all the discs carrying it appeared exactly alike, in illumination and in grain, to the photograph of a similar disc having nothing on its surface. But the action of the rays on the square of blotting-paper carrying the herapathites showed this in a more conclusive manner; for where this paper covered the photographic plate nothing was visible, except by the most careful scrutiny, and with the most favourable illumination, and then a mere ghost of the paper could be detected, but with no traces whatever of the herapathites.

"These experiments appear to have shown conclusively what Röntgen found by his experiments; viz. that the X-rays are not polarised by passing through doubly-refracting media."

At a recent meeting (March 3) of the Dublin University Experimental Science Association, Dr. J. Joly, F.R.S., described experiments made by him on the "Lenard-Röntgen" rays. He has found that the rays are reflected at the surface of mercury, lead, glass and wood. A photographic plate was enclosed in a light-tight carrier of millboard, upon the outside of which a copper ring was attached. This was exposed in the geometrical shadow of a thick lead plate to rays which entering a slot in the plate were reflected at the surface of mercury. An exposure of over an hour gave the shadowgraph of the ring. The position of this upon the plate indicated that the rays had approached from the direction of the reflecting mercury surface. Removing the dish of mercury, a much fainter image was obtained apparently from rays reflected from the wood beneath.

If the rays are received upon the carrier after passage between two parallel lead plates, the dark band formed upon the sensitive plate will be found to be bordered by heavy black lines. This was traced to a very complete reflection at grazing incidence to the lead plates, corresponding to the manner in which light is reflected at grazing incidence. A photographic plate exposed to light passing between the lead plates shows, in fact, a similar dark border; substituting glass plates for the lead, similar effects were obtained. This marked grazing reflection rendered it possible to concentrate the rays to an imperfect focus by causing them to pass through a conical tube of lead open at both ends, when a strengthening of the effects was formed on exposing at the narrow end of the cone.

Before the Royal Society on March 19, Lord Blythswood described some experiments which indicate that the X-rays can be reflected. He placed a vacuum-tube, A (Figs. 1–2), behind a lead screen, B B, 18 in. × 12 and $\frac{1}{8}$ thick. The screen had a 2-in. hole in it with a 2-in. pipe attached; 4 in. from the vacuum-tube was placed a speculum-metal mirror D, 4 in. × $2\frac{1}{2}$, at an angle of 45° with the lead screen; 4 in. from the mirror was a light-tight zinc box, E, with aluminium window, F; inside came first the objects, G, stuck on to a black cardboard, H, then I, the photographic plate. The following objects were photographed in about twenty minutes: (1) Some brass clock wheels. (2) A screw-cutting gauge. (3) Two lead discs. (4) The mirrors, being two pieces of speculum-metal used by Lord Blythswood to divide upon.

Two other papers were read before the Royal Society at the same meeting. In one of these, Mr. R. Erskine Murray described experiments made in the Cavendish Laboratory of the University of Cambridge, at Prof. J. J. Thomson's suggestion, in order to find whether the contact potential of a pair of plates of different metals is in any way affected by the passage of the Röntgen X-rays between the plates.

The vacuum bulb and induction coil for the production of the rays were enclosed in a box lined with metal, so that the plates and the apparatus used in measuring their contact potential difference should be screened from any direct electrical disturbances. At one side of the box there was a circular hole of about 3 cm. in diameter. The vacuum bulb was placed just inside this hole, and directed so that the rays should stream out through it in a direction perpendicular to the side of the box. In some experiments this hole was closed by a tinfoil screen, which allowed a large proportion of the rays to pass out while shutting in ordinary electrical disturbances. The plates whose contact potential difference was to be measured were placed at a short distance outside the box, in such a position that the rays could fall on them.

To measure their contact potential, Mr. Murray used the null method described by Lord Kelvin in his paper given to the British Association in 1880. In this method the value of the contact potential is found by measuring the amount of the counter potential which has to be applied to the pair of plates to reduce the potential difference between their opposing surfaces to zero. The counter potential introduced to effect this annulment must obviously be equal and opposite to their contact potential difference. Hence the numerical value of the latter is simply

that of the applied counter potential, but is of opposite sign. The plates were of zinc and tinfoil, the latter being mounted on thin ebonite to keep it flat. They were placed parallel to one another at a small distance apart, so that the rays fell perpendicularly on the back of the tinfoil plate, passed through it and the air space between them, and were absorbed by the zinc. The tinfoil plate was insulated and connected to the insulated quadrants of a Kelvin quadrant electrometer. The zinc was uninsulated, and was connected to the uninsulated quadrants of the electrometer. This plate was movable in a direction perpendicular to its plane, and could thus be drawn away from the tinfoil. If there was any electric potential difference between the opposing surfaces of the two plates, further separation caused a change in it which, reacting on the electrometer, deflected it.

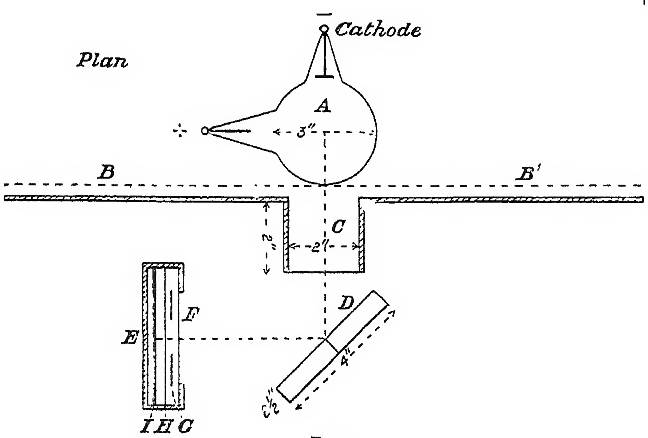

FIG. 1.

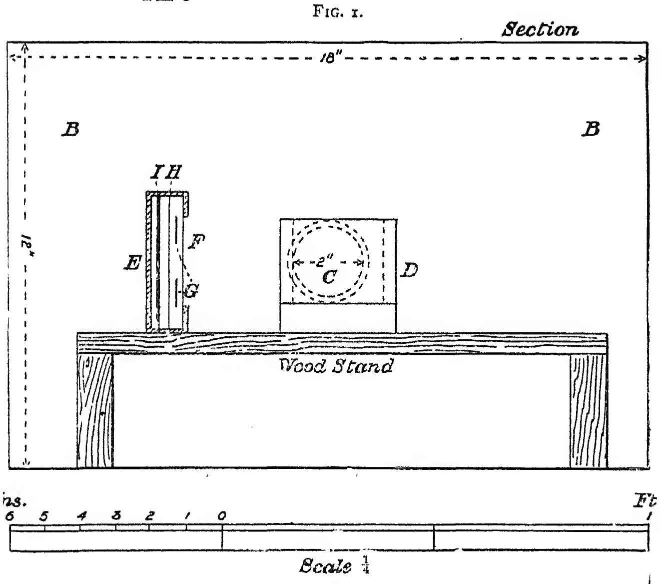

FIG. 2.—A, vacuum tube; BB', lead plate, 18 in. × 12 in. ⅛ in. thick; C, hole 2 in. diameter. Pipes 2 in. diameter × ½ in.; D, speculum-metal mirrors; E, zinc box, 4 in. × 4 in., 1 in. deep; F, aluminium window; G, objects; H, black cardboard; I, photographic plate.

Experiments conducted with this arrangement led Mr. Murray to conclude that (1) the influence of the rays on the zinc and tinfoil plates does not cause any direct or sudden change in their contact potential, but that (2) the air through which the rays pass is temporarily converted into an electrolyte, and when in this condition forms a connection between the plates which has the same properties as a drop of acidulated water, namely, it rapidly reduces the potential between the opposing surfaces of the plates to zero, and may even reverse it to a small extent.

It is pointed out that this electrolytic property was found by Lord Kelvin ("Electrostatics and Magnetism," Art. xxiii, §§ 412—414) to be possessed by the fumes from a burning spirit lamp. In both cases its cause is probably the same. It is, no doubt, due to a want of electrical equilibrium among, and a partial dissociation of, the molecules of the gas.

In the third of the Royal Society papers referred to in the foregoing, Mr. C. T. R. Wilson gave an account of experiments made to determine the effect of Röntgen rays on cloudy condensation. The author has previously shown that cloudy condensation takes place in the absence of dust when saturated air suffers sudden expansion exceeding a certain critical amount. He now finds that air exposed to the action of Röntgen rays requires to be expanded just as much as ordinary air in order that condensation may take place, but these rays have the effect of greatly increasing the number of drops formed when the expansion is beyond that necessary to produce condensation. It is concluded that when the Röntgen rays pass through moist air they produce a supply of nuclei of the same kind as those which are always present in small numbers, or at any rate of exactly equal efficiency in promoting condensation.

At the Royal Dublin Society, on March 18, Mr. Richard J. Moss read a paper on the Röntgen X-rays. The mixed gases obtained by the electrolysis of hydrochloric acid were submitted to the action of X-rays. The apparatus employed was similar to that devised by Bunsen and Roscoe for their "Photo-Chemical Researches" (*Phil. Trans.*, vol. cccxlvii. p. 355). Every precaution was taken to ensure that the hydrogen and chlorine were in atomic proportions, and free from impurity. It was found that the X-rays, at a distance of 5 centimetres from the Crookes' tube, caused no combination of the hydrogen and chlorine. The combination of 0·1 per cent. of the volume of gas operated upon could not have escaped detection. The X-rays from the Crookes' tube employed were sufficient to produce fluorescence in a crystal of lithium rubidium platinocyanide at a distance of 2 metres. The examination of a series of crystalline platinocyanides showed that lithium rubidium platinocyanide emitted the brightest light under the influence of the X-rays. The same order of luminosity was observed with ultra-violet light as with X-rays; and the colour of the fluorescence is similar whether excited by X-rays or by ultra-violet. Crystals of platinocyanides which exhibited yellow and green fluorescence under the influence of the X-rays, behave as bodies opaque to those rays when photographed. Potassium platinocyanide exhibits blue fluorescence, and if a crystal of this salt, separated from the sensitive plate by a sheet of white paper, be submitted to the action of the X-rays, it behaves as a luminous body and does not throw a shadow. The fluorescent light excited by the X-rays in this salt, acts more powerfully upon the sensitive plate than the direct X-rays.

Dr. John Macintyre has sent us an account of a further study and comparison of fluorescent screens. He says:

"I have tried several screens of calcium tungstate as recommended by Mr. Edison. The insoluble amorphous precipitate is fluorescent, but I have had it prepared in the crystalline form from two different sources; in both cases the screens gave much better fluorescence, and consequently better images. Messrs. Baird and Tatlock prepared the one form of crystalline salt, which was larger in the crystals than that prepared for me by Mr. I. Frank Bottomley. As there seems to be some difficulty in obtaining the crystalline form, it may be of interest to say tha the latter gentleman prepared it according to the method of N. S. Manross ("Liebig's Annalen," vols. 81–82). The method consisted in fusing together the anhydrous sodium tungstate and calcium chloride, the latter in excess The sodium chloride and excess of calcium chloride are dissolved out, and crystalline calcium tungstate is left behind to be filtered off and dried. The crystals are a mixture of needles and octahedra, the latter only recognisable through the microscope.

"As far as I have been able to judge from the preparations given to me, potassium-platino-cyanide is the best salt. Of course, Mr. Edison may have a better method of preparing the crystals. With greater experience in screens, I am inclined to think that success depends very largely upon the way in which they are prepared. The paper or glass covering must be thickly and evenly coated. I have had an excellent screen prepared with the barium salt as well.

"My experiments have mainly been with the human skeleton; I have now seen shadows of all the bones and joints of the extremities, and what is more important, by placing the tube in the proper position I have seen distinct shadows of the spinal column and ribs of a man. The head is easily penetrated, and for surgical purposes all we now require in order to obtain greater

definition in any part of the skeleton, is a more powerful source of X-rays; in other words, a step further in the preparation of Crookes' tubes. Even now the shadows obtained are good enough for many surgical purposes."

One of the most important discoveries in the new field of investigation is that certain phosphorescent substances emit rays capable of penetrating opaque materials and producing photographic effects. M. Henri Becquerel's experiments in connection with this matter have formed the subject of several valuable communications to the Paris Academy of Sciences, and have been referred to in our abstracts of the *Comptes rendus*, as well as in a brief note. We propose to give a full account of his work in a subsequent number of NATURE.

Mr. A. Hutchinson has sent us, under date March 23, the following account of experiments carried out by him in the Mineralogical Museum, Cambridge:—

"During the past few weeks I have found that quite a number of inorganic substances fluoresce when exposed to the action of the Röntgen rays; thus the following minerals all become more or less luminous, viz. diamond fluor-spar, apatite, autunite, scheelite, and a number of lead compounds, including cerussite, matlockite, anglesite, lanartrite, phosgenite; also lead chloride, lead iodide, lead glass, uranium nitrate and uranium glass. The fluorescence produced in most of these substances is very weak, but autunite, uranium nitrate and uranium glass, cerrussite, some specimens of fluor spar, and some diamonds become fairly bright. The most effective substance which I have so far examined is, however, scheelite, the native tungstate of calcium. Colourless crystals of this mineral phosphoresce brilliantly under the action of the X-rays, the glow continuing for some seconds after the current is switched off, and when powdered they afford a screen which is at least as bright, if not brighter, than one prepared with barium platinum cyanide. It seems very possible that this substance may be 'the properly-crystallised' calcium tungstate of Edison's telegram, quoted in NATURE of March 19.

"It is, perhaps, interesting to note also that uranium nitrate, uranium glass, and the minerals autunite and torbernite are all capable of producing the remarkable effects discovered by M. Becquerel. Thus I have found that the radiations given out by uranium nitrate, when exposed to daylight, in an ordinary room are capable in twenty-four hours of penetrating sheets of aluminium 0·5 mm. thick, and I have obtained a shadow photograph of a coin by placing it on a plate, thoroughly protected from sunlight by light-tight envelopes, and covering it with a slab of uranium glass. This arrangement was allowed to stand near a window for a day; on developing the plate a distinct outline of the coin was found."

A decided step in advance in the application of Röntgen photography to medical science is marked by illustrations in the current issues of the *British Medical Journal* and the *Lancet*. The former journal contains a striking double-page plate of the skeleton of an infant, reproduced from a photograph by Mr. Sydney Rowland, and demonstrates at once the ability to portray the deep visceral region of the body by means of Röntgen rays. Mr. Rowland remarks that although no disease was present in the body of the child, the picture is none the less interesting from a scientific and medical point of view as being the first step towards the application of the method to the diagnosis of spinal and other deep affections. The photograph was obtained in fourteen minutes, and the age of the child was three months. The tube employed was the new focus tube, and it was placed some eight inches from the surface of the body so as to obtain sufficient spreading to cover the plate. It is pointed out that the positions of some of the soft organs are indicated on the picture; thus the heart and lungs are clearly silhouetted, and curiously enough the coils of intestine; while a clear space above them exhibits the place occupied by the stomach. A striking feature is that only the ossified portions of the bones in the arm and hand produce definite shadows, the undeveloped parts of the bones being but faintly visible.

The *Lancet* referred in the issue of March 21 to a photograph obtained through the body of a dead monkey, into whose kidney a biliary and uric acid calculus had been previously inserted. The current issue contains a plate reproduced from this photograph, and showing the spinal column and ribs with great clearness. The biliary calculus can hardly be distinguished from the kidney substance, but the uric acid calculus shows very clearly. The kidney itself is almost transparent to the rays, though not absolutely so.

In a letter communicated to the *Electrician*, Prof. G. M. Minchin gives a summary of the conclusions to which he has been led with reference to the discharge of electrified bodies by the X-rays. The generally accepted opinion is that the X-rays discharge negative electricity from all bodies with great rapidity, and positive more slowly, leaving every body finally with a positive charge. Prof. Minchin, however, finds that "the X-rays charge some bodies positively and some negatively, and whatever charge a body may receive by other means, the X-rays charge it, both in magnitude and sign, to the charge which they independently give to the body." While gold, silver, copper, platinum and iron are all charged positively by the X-radiation, sodium, magnesium, tin, lead and zinc are charged negatively, the effect being in the case of some of these metals much more marked than in the case of the metals that become positively charged. Antimony appears to be almost neutral. Prof. Minchin considers that these observations tend to support the view that the X-rays are undulatory in character, and not of the nature of kathode rays.

Prof. Oliver Lodge writes to the *Times*:—"It may be worth just putting on record that during the past week I have seen fluorescence excited by Röntgen rays after they had penetrated the bodies of two men standing one behind the other in their clothes. Also, that we have succeeding in radiographing the details of a damaged vertebra in the spine of an adult patient at the Northern Hospital, Liverpool, with an exposure of half an hour; and have found a 'Murphy-button' in the intestine of another adult at the Liverpool Royal Infirmary with an exposure of ten minutes. A 'focus-tube' and a powerful ordinary induction coil were the means used."

Six good photographic reproductions accompany an article on Röntgen photography contributed by Mr. J. W. Gifford to *Knowledge*. One of the pictures of a mouse, and another of a sparrow, obtained on February 28, clearly locate the internal organs.

Finally, a number of important papers are referred to in the abstract of the *Comptes rendus* which appears in another column.

REPORT ON THE USE OF ANTITOXIN IN DIPHTHERIA.

A DETAILED report on the use of antitoxic serum in diphtheria, at the hospitals of the Metropolitan Asylums Board, has just been issued. It exhibits the results obtained during the year 1895 in all the six hospitals in which cases of diphtheria were treated, and is a most valuable testimony to the efficacy of the new treatment. From the summary of the report given in the *Times* we derive the subjoined general statistical results and conclusions.

Antitoxin was administered in rather more than three-fifths of the total number of cases admitted into the hospitals, and those for the most part representing the severer types of disease. The value of results obtained will be seen by taking the whole of the figures for 1895 and contrasting them with those of 1894, or rather with the first ten months of that year, previous to the introduction of antitoxin. This gives the following results:

Year.	Cases.	Deaths.	Mortality per cent.
1894	3042	902	29·6
1895	3529	796	22·5

The reduction in mortality of 7·1 per cent. below that of 1894—the lowest previously recorded in any year—must be fairly attributed to antitoxin, because nothing else was changed in the treatment; the average severity of the disease was about equal in the two years, and the proportion of juvenile, that is unfavourable, patients was somewhat larger in 1895 than in 1894. It may be added that diphtheria in both years alike means diphtheria as clinically, not bacteriologically, diagnosed. The essential conditions, therefore, were the same in the two periods. Had antitoxin been used in all cases in 1895, instead of in three-fifths only, the comparison would have been more symmetrical, but the numbers are sufficiently large to make it quite valid; and in this connection it is worth noting that those individual hospitals which made least use of the drug show the highest rate of mortality and the smallest reduction on their previous records. The broad conclusion reached is that in the year 1895 antitoxin saved 250 lives in London.

A complete examination and discussion of the statistics, leads to the following conclusions:—

The improved results in the diphtheria cases treated during the year 1895, which are indicated by the foregoing statistics and clinical observations, are:—

(1) A great reduction in the mortality of cases brought under treatment on the first and second day of illness.

(2) The lowering of the combined general mortality to a point below that of any former year.

(3) The still more remarkable reduction in the mortality of the laryngeal cases.

(4) The uniform improvement in the results of tracheotomy at each separate hospital.

(5) The beneficial effect produced on the clinical course of the disease.

A consideration of the foregoing statistical tables and clinical observations, covering a period of twelve months and embracing a large number of cases, sufficiently demonstrates the value of antitoxin in the treatment of diphtheria.

It must be clearly understood, however, that to obtain the largest measure of success with antitoxin it is essential that the patient be brought under its influence at a comparatively early date—if possible not later than the second day of disease. From this time onwards the chance of a successful issue will diminish in proportion to the length of time which has elapsed before treatment is commenced. This, though, doubtless, true of other methods, is of still greater moment in the case of treatment by antitoxin.

Certain secondary effects not infrequently arise as a direct result of the injection of antitoxin in the form in which it has at present to be administered, and, even assuming that the incidence of the normal complications of diphtheria is greater than can be accounted for by the increased number of recoveries, we have no hesitation in expressing the opinion that these drawbacks are insignificant when taken in conjunction with the lessened fatality which has been associated with the use of this remedy.

We are further of the opinion that in antitoxin serum we possess a remedy of distinctly greater value in the treatment of diphtheria than any other with which we are acquainted.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The next examination for the diploma in agricultural science and practice will begin on July 6, 1896. Names of candidates should be sent to the Registrary of the University on or before Monday, June 22, 1896. The examination is open to persons who are not members of the University as well as to members.

We learn from *Science* that the Bill establishing a National University of the United States has been reported favourably by the Senate Committee. It grants a charter to the University, provides for its government, grants it the ground in the city of Washington designated by President Washington as a site for a national university, and appropriates 15,000 dols. for the fiscal year ending on June 30, 1897, and 25,000 dols. for the year following.

We offer our best wishes to *Education, Secondary and Technical*, the new weekly journal of combined educational interests, which has taken the place of the *Technical World* and *Science and Art*. There is much for such a periodical to do, and the combination of technical and secondary interests in education is certainly one that makes for advancement. As the journal is the official organ of the Incorporated Association of Head Masters, the Association of Directors and Organising Secretaries of County Councils, the National Association of Manual Training Teachers, and the Recreative Evening Schools Association, it should not lack support.

At a meeting of the Technical Education Board of the Stourbridge district, held on Tuesday, March 17, the Chairman announced that promises amounting to £540 had already been received towards the building fund for the proposed new technical schools in that town. Other promises, where the actual amount has not been specified, will materially increase this total. The sum at present assured enables the Committee to claim a grant of £600 from the Worcestershire County Council. It is not intended that a site should be chosen and active steps taken until the sum of £2000 is in hand.

At the meeting of the Association of Chambers of Commerce, held at the Hôtel Métropole, London, on Wednesday, the 25th ult., the following resolution, proposed by the London Chamber, was agreed to :—"That this association views with interest the report of the Royal Commission on Secondary Education, and, while it regrets the exclusion of commercial representation from its membership, suggests that its recommendations be carefully considered, and, so far as they commend themselves, put into practice at an early a date as possible. That the Executive Council be recommended to take an early opportunity of urging upon Chambers of Commerce the necessity of keeping in touch with their local County Councils, in order that such Chambers may secure representation upon any local educational authority which may be called into existence by legislation, and thus obtain the due consideration and provision of industrial and commercial education recognised by the Royal Commission as falling under secondary education."

The Paris correspondent of the *British Medical Journal* reports that the French Senate is about to name a Commission to examine the New University Law, which has been voted unanimously by the Lower Chamber. In the last bulletin of the Minister of Public Instruction of grants, receipts, and register of students in the French faculties during the ten years 1884 to 1895, it is stated that in 1884 a total of 14,000 students were registered in the different faculties, and in 1895 24,000. In 1884 Government granted to the faculties £460,000. In ten years £104,000 has been added, making a total of £564,000. The faculties received from students' fees ten years ago very nearly £160,000, and last year a little more than £260,000. In 1884 each university student cost £21 18*s*. 4*d*. In consequence of the considerable afflux of pupils, the cost to the university for each student is now £11 0*s*. 10*d*. The French universities consider that Government does not treat them with sufficient liberality. In support of their plea the grants to the German universities are quoted; these are £400,000 more than the amount granted by the French Government. No hope is entertained that by Government help the French universities will rival the German universities in organisation of laboratories, libraries, and general excellence.

A strong Committee has been formed to organise some permanent memorial to perpetuate the memory of the late Rev. William Rogers, who did good pioneer work for education. It is proposed that the funds obtained should be used in connection with the St. Thomas, Charterhouse Schools, where Mr. Rogers worked to improve middle-class education, and assisted to develop the present system of elementary education. The introduction into primary schools of the practical study of science and art was commenced there. Dr. Gladstone, F.R.S., in giving evidence before a Special Committee of the London School Board, once said :—"Prof. Sylvanus Thompson told me that the only elementary school in London from which the Finsbury College could draw youths qualified for technical classes, was that of St. Thomas, Charterhouse, where a good deal of scientific instruction is given, and the boys are encouraged to make their own apparatus." The great aim has been to make the institution self-supporting, and this to a great extent has been accomplished; but the providing of special and costly science apparatus—of effecting expensive structural alterations—render it necessary to occasionally apply for extraneous aid, so that Mr. Rogers' work may not be allowed to languish. The late founder, before his serious accident, was intent upon helping the School Committtee to raise funds by means of which the building could be modernised, and a playground added, and additional science accommodation provided. Subscriptions for these purposes, made payable to the account of the Rogers Memorial Fund, will be gladly received by either of the Hon. Secretaries, St. Thomas, Charterhouse Schools, Goswell Road, London, E.C.

Sir John Gorst introduced the Education Bill of the Government into the House of Commons on Tuesday. The Bill is a great measure of educational decentralisation. It provides for the establishment of a paramount educational authority in every county and county borough. This is to be the channel through which public money is to reach the schools. It is to supplement and not to supersede existing educational effort, and it is to be a sort of separate Education Department for each county and county borough. Sir John Gorst also proposes that the education authority shall be the county council acting through a statutory educational committee, and the number and composition of this committee is to be left entirely in the discretion of the county council, subject only to the condition that the majority of its members must be also members of the council. The in-

tention is to decentralise the administration of school grants by the Education Department, and to throw upon those bodies the duty of administering the Parliamentary grant. Should the Bill become law, the general inspection of schools will be undertaken by the county authority, and the Committee of Council—the central government—will only have inspectors who will visit the schools from time to time in order to see that the county education authority is properly fulfilling its duties, and that the education is up to the proper standard. It is proposed to hand over to this committee the powers of the county council under the Technical Instruction Act, 1889. The money received under the Local Taxation Act, 1890, will be specially applicable to secondary education, and will be administered by the education authority, and may be accumulated. It is hoped that the Bill will create a system under which all those parts of a county in which there are public schools will be connected with and under the authority of the county education authority, and will be maintained out of the general county rate. As regards secondary education, the new authority will be able to aid schools out of the money at its disposal and to establish them; and with the assent of the Education Department it may take a transfer from the School Boards of their higher grade schools. The Bill contains numerous proposals which will revolutionise the system of elementary education in this country, and greatly change the positions of Board Schools and voluntary schools.

SCIENTIFIC SERIALS.

Symons's Monthly Meteorological Magazine, March.—Extreme heat in Australia in January 1896. Mr. Russell, Government Astronomer of New South Wales, writes: "We are having a very hot summer. . . . Those who hold that icebergs cool the weather will have a nut to crack with the icebergs on one hand, and these excessive heats on the other." On January 13 the temperature in the shade at Sydney rose to 108°·5. This is the greatest heat recorded there since 1859; the highest previously registered there was 106°·9 in January 1863. A temperature of 108° was also registered in Melbourne, but this temperature had been exceeded on three occasions: in January 1862, the shade temperature reached 111°·1; in 1876, 110°·7, and in the summer of 1882, 110°·5. In some inland parts of Victoria, even higher temperatures were recorded.—Severe frost in North America. Unprecedentedly severe weather has been experienced over the Eastern States of America, and in Newfoundland. On February 17 the thermometer registered 39° of frost at New York, a lower reading than has been recorded so late in the year since observations were begun. In the interior of the State of New York a record of 49° below zero was obtained. In Newfoundland the winter is said to be more severe than has been known for forty years. Snow was lying on the ground to a depth of fifteen feet at St. John's. At Fortune Bay the entire failure of the herring fishery has brought the people to the verge of starvation.

Wiedemann's Annalen der Physik und Chemie, No. 3.—Influence of light upon the form of discharge of an influence machine, by J. Elster and E. Geitel. The brushes and sparks from a Holtz machine passing between a kathode plate of amalgamated zinc and an anode sphere of any metal, are replaced by a glow discharge when the kathode is illuminated with short-wave light. A smaller quantity of electricity passes by this glow discharge than by the brushes and sparks in the dark.—Change of resistance due to electric radiation, by E. Aschkinass. Gratings made of strips of tinfoil have their series-resistance lowered by electric rays. The original resistance is restored by shock or heating. It is most likely that the strips are bridged by free metallic particles, but certain experiments tend to show that the process is molecular rather than purely mechanical.—Interference of electric waves, by Viktor von Lang. This was shown by an apparatus constructed on the plan of that used by Quincke for sound waves. The electric waves enter a tube which divides into two branches, and then recombines. The length of the branches can be adjusted. After recombination the waves impinge upon a Lodge "coherer" which indicates interference by changes of resistance. Well-defined maxima and minima were obtained, and the apparatus was used for obtaining the velocity of the waves in paraffin and in sulphur. The electrical index of refraction was thus found to be 1·648 for paraffin, and 2·333 for sulphur. These values are higher than those hitherto obtained.—Fluorescence of sodium and potassium vapour, by E. Wiedemann and G. C. Schmidt. The vapours of these metals show bright fluorescence when illuminated with bright sunlight. Sodium vapour shows a continuous band in the red, a fluted band in the green, and the bright sodium line in the yellow. Potassium vapour shows an intense red band. These vapours also show electro-luminescence. These results are of importance to astrophysics. The vapours in the solar atmosphere probably owe part of their luminosity to fluorescence, and this kind of radiation would not obey Kirchhoff's law.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 19.—"On the new Gas obtained from Uraninite. (Seventh Note.) Remarks on Messrs. Runge and Paschen's Diffusion Experiment." By J. Norman Lockyer, C.B., F.R.S.

I pointed out in a previous communication (*Roy. Soc. Proc.*, vol. lviii. p. 193) that, from evidence afforded by the behaviour of the lines under different conditions of the spark, the gas obtained from clèveite is in all probability compound.

Some time afterwards (July 11, 1895) Messrs. Runge and Paschen published (*Sitz. der K. Preus. Akad. der Wiss. zu Berlin*, vol. xxxiv., 1895) the same conclusion, and, as a result of a diffusion experiment (Nature, vol. lii. p. 321) described in their paper, they came to the conclusion that the gas giving the line D_3 was heavier than the gas giving the line 5015·7. As they themselves, however, pointed out, the result was not final, because the pressures were not the same. As it is important for stellar classification to settle this matter, I have recently made some experiments in which the pressures remain the same. The experiments are not yet finished, but the first, which was made on January 22, 1896, seems to leave no doubt on one point of the investigation.

An U-tube was taken, and at the bend was fixed a plaster of Paris plug about 1·5 cm. thick; in one of the limbs two platinum wires were inserted. The plug was saturated with hydrogen to free it from air; the tube was then plunged into a mercury trough, and fixed upright with the limbs full of mercury. Into the leg (A) with the platinum wires a small quantity of hydrogen was passed, and as soon after as possible another small quantity of a mixture of helium and hydrogen from samarskite was put up the other limb (B) of the U-tube.

Immediately after the helium was passed into the limb (B), spectroscopic observations were made of the gas in the limb (A); D_3 was already visible, and there was no trace of 5015·7. This result seems to clearly indicate that if a true diffusion of one constituent takes place, the component which gives D_3 is lighter than the one which gives the line at wave-length 5015·7.

Athough this result is opposed to the statement made by Runge and Paschen, it is entirely in harmony with the solar and stellar results. In support of this I may instance that of the clèveite lines associated with hydrogen in the chromosphere, and the stars of Group IIIγ, those allied to D_3 are much stronger than those belonging to the series of which 5015·7 forms part.

Physical Society, March 27.—Prof. Carey Foster, Vice-president, in the chair.—Prof. J. A. Fleming read a paper on the Edison effect. The Edison effect alluded to in the title of the paper is that if a metal plate is placed inside the loop of an incandescent lamp, then a galvanometer of which one terminal is connected to this metal plate, and the other to the positive lead of the lamp, will indicate a current passing from the lead to the plate. If, however, the galvanometer is connected to the plate and the negative lead, no current passes. Prof. Fleming, by connecting the poles of a condenser, firstly to the two leads, secondly to the plate and positive lead, and thirdly to the plate and negative lead, and in each case discharging the condenser through a galvanometer, has shown that after the lapse of a certain time, depending on the position of the plate, if the lamp is working at about four watts per candle, the potential of the plate falls to that of the negative lead. If the plate, instead of being inside the loop of the filament, is outside, then the time taken by the plate to acquire the potential of the negative lead is considerably longer. The space between the plate and the negative lead exhibits a kind of unilateral conductivity, for a battery having a low voltage is able to send a current from the plate to the negative lead, but not in the opposite direction. If instead of using a cold metal plate a second filament, maintained

in a state of incandescence by an insulated battery, is used, then a current can be obtained between this filament and both the positive and negative leads. If the voltage on the lamp is raised considerably above that required to give one candle-power for four watts, then a current can be passed from the plate to the negative lead, while a galvanometer connected to the positive lead and the plate will indicate the passage of a current from the positive lead to the plate. When the lamp is in this condition, the space between the plate and the negative lead is very sensitive to the effects of a transverse magnetic field, such a magnetic field causing a large increase in the resistance. The curve showing the connection between the current passing from the positive lead to the plate and the volts between the terminals of the lamp is found to be discontinuous. As the volts are raised the current suddenly increases about ten-fold, and it is while the lamp is in the condition corresponding to this upper portion of the curve that it is sensitive to the influence of the transverse magnetic field. By using a movable plate it has been found that the minimum current is obtained when the plate is nearer the positive than the negative lead. When an alternating current is used to supply the lamp, a continuous current can be obtained passing from the plate to either of the leads. If a small platinum cylinder is placed surrounding each of the leads, then a current can be obtained between each of the cylinders and the positive lead, but no current between the two cylinders. The largest effect occurs when a cylinder near the end of the negative lead is connected to the positive lead. The author considers that his experiments show that the resistance of a vacuum tube to the passage of a discharge would be greatly reduced if the kathode were made incandescent. Prof. S. P. Thompson said he would like to have some information as to the state of exhaustion of the lamps; whether this was such as is found in ordinary commercial lamps, or whether it more nearly approached that used by Crookes. A great change in the conductivity, &c., took place at an exhaustion slightly greater than that ordinarily found in incandescent lamps. It would be of interest to vary the size of the kathode and to investigate whether the magnitude of the effects observed depended on the fall of potential per unit length along the filament. Another point was whether the position of the plate, for which the effect was a minimum, was the same for all lamps, or whether it changed with the volts and the length of the filament employed. Again, did the minimum occur at a certain fraction of the distance between the positive and negative leads, or, as was the case in some of the phenomena observed by Crookes, at a definite distance from either of the leads. These points might be investigated by means of a lamp with a straight filament where the fall of potential per unit length along the filament might be the same as with the loop-shaped filament, but the fall of potential per unit length in the vacuum would be different. The author's proposed experiment of heating the kathode by concentrating on it the rays of a lamp, did not seem to him (Prof. Thompson) to differ materially from Crookes' experiment in which an incandescent wire, heated by a current, was used as the kathode. Mr. Skinner said that the heating of the kathode by means of a "burning-glass" could easily be carried out. Mr. Blakesley pointed out that it would be quite possible to produce an increase of the current by means of a magnet. Mr. Serle said that Prof. J. J. Thomson had shown that a magnet affected the conductivity of a gas. Prof. Fleming, in his reply, said that no doubt the effects were largely dependent on the vacuum in the lamps. The lamps employed were exhausted to the ordinary commercial vacuum. Since it was found that the "treating" was more worn off the negative leg of the filament, and that a screen placed between the legs of the filament was more blackened on the side turned towards the negative leg, it would appear that the particles of carbon were shot off from the negative leg, and hence perhaps the charge was carried by these carbon molecules.—A paper of a purely mathematical character, entitled "Notes on the electro-magnetic effect of moving charges," by Mr. W. E. Morton, was read by Mr. Serle, who also made some remarks on his own investigations dealing with this subject. The Society then adjourned till April 24.

Geological Society, March 11.—Dr. Henry Hicks, F.R.S., President, in the chair.—On an Alpine nickel-bearing serpentine with fulgurites, by Miss E. Aston, with petrographical notes by Prof. T. G. Bonney., F.R.S. The specimens described were collected on the summit of the Riffelhorn (near Zermatt) by Prof. W. Ramsay, F.R.S., and Mr. J. Eccles, and they showed some very well-marked "lightning-tubes." The rock was a serpentine, somewhat schistose from pressure, which had been formed by the alteration of a rock chiefly composed of olivine and augite. One of the analyses gave 4·92 per cent. of nickel oxide and hardly any lime. Prof. Bonney detected some awaruite under the microscope, but not nearly enough to account for the analysis. Reasons were given to show that the nickel oxide probably replaced lime in the pyroxenic constituent of the rock. The tubes, about $\frac{1}{10}$ inch in diameter, were round in section, cleanly drilled, and lined with a very thin film of dark brown or black glass.—The Pliocene glaciation, pre-glacial valleys, and lake-basins of subalpine Switzerland: with a note on the microscopic structure of Tavayanaz diabasic tufa, by Dr. C. S. Du Riche Preller. The main object of this paper, which was the sequel to one read last session, was to solve the problem whether the Pliocene glacio-fluviatile conglomerates of the Swiss lowlands were deposited on a plateau or in already existing valleys. For the purpose of this inquiry, the author examined last summer a large additional number of glacial high- and low-level deposits throughout the Zürich Valley over an area more than 40 miles in length; and his investigations further led him to important conclusions with respect to the combination of causes which determined the formation of the lake-basins lying in the same zone at the foot of the Alps. He showed that the Lake of Zürich owes its origin, in the first instance, to a zonal subsidence (probably between the first and second glaciation) of about 1000 feet, as evidenced by the reversed dip of the disturbed molasse-strata between the lakes of Zürich and Zug. During the second and third Ice-periods, the original lake-basin was gradually filled with glacial and fluviatile deposits at both ends, and was finally restricted to its present dimensions by a post-glacial bar deposited at its lower end by a tributary river. In the author's view, the other subalpine lakes, extending from the Lake of Constance to Lac Bourget in Savoy, owe their origin and present limits, in the main, to the operation of similar causes. With regard to the main question, he averred that the Lower and Middle Pliocene period was, in Switzerland, entirely one of erosion and denudation on a prodigious scale. Irrespective of the evidence he had adduced, he was therefore driven to the conclusion that at the advent of the first Ice-period in Upper Pliocene times the principal subalpine valleys must have been already excavated approximately to their present depth, and that ever since then the action of the great Alpine and subalpine rivers had been, as it is still in our own day, mainly directed to regaining the old valley-floors by removing those enormous accumulations of glacial and glacio-fluviatile material, which are respectively the direct and indirect products of three successive and general glaciations.—Notes concerning certain linear marks in a sedimentary rock, by Prof. J. E. Talmage. The marks described in the paper occur in a fine-grained argillaceous sandstone referred by the U.S. Geological Survey to the Triassic or Jura-Trias period, which is found on a low tableland within two miles of the bluffs overlooking Glen Canyon. The marks commonly appear as straight lines intersecting at right angles, but some have a pinnate distribution, suggesting engravings of frost-flowers. A description of the markings was given, and various experiments made in the laboratory to illustrate the effects of formation of crystals formed over sediment were described.

Paris.

Academy of Sciences, March 23.—M. A. Cornu in the chair.—On the invisible radiations emitted by the salts of uranium, by M. H. Becquerel. A confirmation and extension of previous experiments upon potassium uranyl sulphate. Uranium salts appear to be unique in the length of time during which they give off photographically active rays in the dark. On comparing the rate of discharge of a gold leaf electroscope by the radiations from a crystal of potassium-uranyl sulphate and a Crookes' tube respectively, the effect of the tube was found to be over one hundred times greater than that of the crystal.—Observations on the preceding communication, by M. L. Troost.—Observations relating to a note of M. C. Henry, entitled "On the principle of an accumulator of light," by M. H. Becquerel. An account of some earlier work on the same subject overlooked by M. Henry.—Application of the X-rays to the diagnosis of surgical diseases, by M. Lannelongue. A description of the results obtained in two cases, in the second of which a supposed exostosis was shown not to exist, the pain and muscular atrophy being due to hysteria.—Researches on the earths contained in the monazite sands, by MM. P. Schützenberger and O. Boudouard.—On the quantities of nitric acid contained

in the waters of the Seine and its principal tributaries, by M. Th. Schlœsing. The amount of nitric acid reaches its minimum about August, and its maximum in February. – Study of the stability of ships by the method of small models, by M. J. Leflaive.—A new property of the surface of a wave, by A. Mannheim.—On groups of operations, by M. Levavasseur.—On a means of communicating to the X-rays the property of being deviated by the magnet, by M. A. Lafay. A bundle of rays from a Crookes' tube was allowed to imprint on a sensitive plate the shadow of a platinum wire supported on a very thin sheet of silver. When the whole was placed in a powerful magnetic field (400 C.G.S. units), the reversal of the current produced a sensible deflection of the image, if the needle was strongly electrified by being placed in connection with the negative pole of the induction coil. If the needle was not electrified, no sensible deflection of the image could be produced.—On the mechanical action proceeding from a Crookes' tube, by M. J. R. Rydberg. On repeating the experiments of MM. Gossart and Chevallier, it was found that the actions observed on the radiometer had their origin in the well-known layer of positive electricity with which the external antikathodic surface of the Crookes' tube is covered during the discharge. By covering the radiometer with a metallic gauze screen, it is possible to take Röntgen photographs through it, without any rotation or mechanical effect being observable.—Origin of the Röntgen rays, by M. Jean Perrin. From the experiments described, the conclusion is drawn that the Röntgen rays are developed only at those points where the kathode rays are arrested, and that this is true whatever material may be used for the tube.—Researches concerning the properties of the X-rays, by MM. Prince B. Galitzine and A. de Karnojitzky. By taking photographs with the rays of tourmalines superposed at various angles, results were obtained showing clearly that with crossed plates the photo-chemical action was reduced. From this the authors draw the conclusion that the X-rays correspond to transversal vibrations.—On the reduction of the time of exposure in Röntgen photographs, by M. G. Meslin. A magnet is used to create a magnetic field perpendicular to the kathode rays inside the tube. A good print of the hand was obtained after twenty-five seconds' exposure.—On the same, by M. Basilewski. A sheet of paper coated with a fluorescent substance is placed between the plate and the object. A photograph of the hand was obtained in ten minutes.—On the same, by MM. A. Imbert and H. Bertin-Sans. A magnet is used to deviate the kathode rays within the tube. Good results were obtained for the hand with exposures varying from one to five minutes.—On the X-rays, by M. Piltschikoff.—On the resistance to the passage of the Röntgen rays of some liquid and solid substances, by MM. Bleunard and Labesse. The study of the coefficients of absorption for saline solutions showed that the opacity increases with the atomic weight of both metal and non-metal.—Action of the X-rays on precious stones, by MM. A. Bugueit and A. Gascard.—Three cases of the surgical application of Röntgen photographs, by M. P. Delbet.—The Röntgen rays in the eye, by M. Wuillomenet.—On a new element contained in the rare earths, of samarium, by M. E. Demarçay. The new element is obtained by fractional crystallisation from fuming nitric acid of the portion of the rare earth rich in samarium.—Action of reducing agents upon the nitroso-compounds of ruthenium, by M. L. Brizard.—On the amalgams of molybdenum and some properties of metallic molybdenum, by M. J. Férée. Amalgams with compositions approximating to $MoHg_9$, $MoHg_2$, and Mo_2Hg_3 are described. The molybdenum obtained by distilling away the mercury from the amalgams is pyrophoric.—On the products of the distillation of wood, by M. E. Barillot.—On isomerism in the aromatic series, by M. O. de Coninck.—On rhodinol and its transformation into menthone, by MM. Ph. Barbier and L. Bouveault.—On the parasite of black-rot, by M. A. Prunet.—On the mode of formation of helicoidal coprolitlis, by M. Léon Vaillant.—On the attribution of the genus *Vertebraria*, by M. R. Zeiller.—On vegetation in an atmosphere vitiated by respiration, by M. L. Mangin.—On two new bacteria of the potato, by M. E. Roze.—On the optical isomorphism of the felspars, by M. F. Wallerant.—On the vegetable and mineral débris of the soundings from the *Caudan*, in the Bay of Biscay, by M. Bleicher.—Oceanographical observations made during the voyage of the *Caudan*, in the Bay of Biscay, by M. J. Thoulet.—On photography through opaque bodies, by M. A. Gassend.

DIARY OF SOCIETIES.

London.

THURSDAY, April 2.

Linnean Society, at 8.—Monograph of the Genus Stemona, Lour: C. H. Wright.—On African Algæ: W. and G. S. West.

Geologists' Association (Waterloo Station), at 4.55.—Excursion to Swanage. Corfe Castle, Kimeridge, &c., ending Tuesday, April 7.

Camera Club, at 8.15.—Cloud Forms and Tropical Weather: Captain Wilson Barker.

FRIDAY, April 3.

Quekett Microscopical Club, at 8.

FRIDAY, April 10.

Royal Astronomical Society, at 8.

Geologists' Association, at 8.

Malacological Society at 8.

CONTENTS.

THURSDAY, APRIL 9, 1896.

A LIFE OF LOUIS AGASSIZ.

Life, Letters, and Works of Louis Agassiz. By Jules Marcou. With illustrations. 2 vols. Pp. xxxii + 620. (London: Macmillan and Co., 1896.)

BIOGRAPHIES of Agassiz have not been wanting. In 1885 his widow published a "Life and Correspondence"; in 1893 Dr. F. Holder wrote a "Life and Work," a smaller book, which was reviewed in these pages (NATURE, vol. xlviii. p. 52); while biographical sketches, short and long, are numerous. But in M. Marcou's opinion, to quote from his preface,

"No true life of him has yet appeared: nearly all have been too eulogistic, while, on the other hand, some rather severe strictures and criticisms have incidentally appeared in articles purporting to give the life of some of his associates, or dealing with some special questions of natural history. . . . The true history of Agassiz has not yet been written."

So the task has been taken in hand by M. Marcou, who has executed it in the spirit of the "candid friend," and takes good care that the worshipper, while called upon to notice the gold, shall be in no danger of overlooking any spots of dross in the precious metal of the image. No illusion is any longer possible. We go away convinced that Agassiz was very far from faultless, a man of great strength, with a considerable share of human weaknesses, and that M. Marcou is a very superior person.

Which of the many pictures is the most true, only those who knew Agassiz intimately can judge. It may be permitted, however, to doubt whether his family will feel themselves under an overpowering debt of gratitude to M. Marcou. Granted that he does full justice to Agassiz' genius—his acuteness of observation, his extraordinary memory, his eloquence, perseverance, and powers of work—still he turns the search-light so full on his weaknesses, that they seem almost as prominent as his excellences. But does this serve any good purpose? Some of these weaknesses were inseparable from the nature of the man. Let us grant that he was unbusinesslike in his habits, that money passed through his fingers like water through a sieve, that he was always crying "give, give," even as "the daughters of the horseleech"—was this for his own enrichment, or to serve his own ends? No, it was for the sake of science; the great aim of his life was to procure abundant specimens for study, and, in America, to build up a splendid museum. Granted that he was injudicious in the selection of his assistants, and that his arrangements with them, or rather want of arrangements, sometimes led to trouble—surely the one was an error on the side of a generous trust, the other was pardonable, when the exigencies of the case are considered. How during the stress and poverty of his earlier life could Agassiz have obtained helpers had he not instituted a cœnobite establishment of some kind? How could he make very precise bargains with men to whom he could offer no stipends; who came more as fellow-workers than as assistants? Any one who has read one of the biographies already in existence can see that Agassiz sometimes made mistakes in dealing with his fellows, that he was not a good man of business, and was imprudent, we might say reckless, in matters of finance; but his imprudence was for the cause of science, not to minister to his own ease or luxury. The audacity with which he faced immense difficulties, ran risks that seemed hopeless, and almost courted ruin, if trying to relatives, friends, and even legislators, demands a lenient judgment from those who have profited by his efforts, and who recognise the greatness of his services to science.

There are of course occasions when the saying, *De mortuis nil nisi bonum*, must not be observed, when it is necessary to speak plainly of men whose work is ended. There are faults, about which a biographer cannot be silent—falsehood and treachery, gross selfishness or flagrant immorality. But of these no one can accuse Agassiz. There are times, too, when it is a duty to call attention even to the errors in science which the dead have committed; namely, when a school of this or that prophet is seeking by the glamour of their master's name to paralyse the honest worker and to check the progress of knowledge—but no one has done that wrong to the memory of Agassiz. Posterity, then, does not need that his mistakes should be proclaimed upon the housetops; it knows them already; it is content to be thankful for the good work which he did, and to say, in regard to the bad, "Which of us shall first cast a stone against him?"

But M. Marcou himself has views on scientific controversies, and where Agassiz takes the same side, is not parsimonious in praise. For instance, Agassiz held certain views as to the origin of species opposed to those of Darwin. No opportunity is lost of belittling the latter; a chapter is even devoted to this purpose. We are virtually told that both Darwin and his supporters were more prone to evolve theories out of their inner consciousness than to make careful observations. Here is a sample of M. Marcou's condemnation.

"The most enthusiastic propagators and apostles of the new gospel were not naturalists at all, with the exception of the systematic botanist, Asa Gray. Not one of them was a zoologist, in any sense of the word. Agassiz was too much a naturalist to accept a number of mere suggestions until they were scientifically proved by exact observations."

So we learn, among other pieces of interesting information, that the evidence obtained in the more recent deep-sea dredgings is adverse to Darwin's views as to the origin of species, that had he been right the transmutation of species ought by this time to have been demonstrated by experiment; nay, that even his hypothesis regarding the formation of atolls has been proved erroneous. As to the first, M. Marcou's remarks seem curiously inconclusive; as to the second, they indicate considerable misapprehension of Darwin's views; as to the third, perhaps room still remains for difference of opinion. Darwin's hypothesis as to the origin of species and the origin of atolls may not be "the whole truth and nothing but the truth," but we believe many authorities, quite as respectable as M. Marcou, continue to regard them as at least a long step in that direction. But nothing very good, our censor hints, could be expected from Darwin and his followers.

"Physically Cuvier and Agassiz resembled each other in possessing enormous heads and largely developed

brains, while neither Lamarck nor Darwin were abnormal as regards the size and development of the head. In a crowd Cuvier and Agassiz always attracted attention, and were distinguished at once as uncommonly fine-looking men, while Lamarck, Darwin, and Huxley passed unnoticed."

We will remember Mrs. Malaprop on comparisons, and content ourselves with observing that a crowd in which Darwin and Huxley would have passed unnoticed, must indeed have been composed of remarkable men.

To put the matter shortly, the history of personal squabbles, and the indications of M. Marcou's censorious disposition loom far too large in this book. He cannot let slip a chance of having a fling at somebody, and evidently our nation in some way or other has incurred his displeasure. This, for instance, is how he comments on Murchison's objections to the general applications of Agassiz' views on the extent of land ice: "Precisely what was to be expected from the English geologists, who are always strongly disinclined to accept any new truth, if discovered by foreigners." Considering that for not a little time prior to this date (1840) English geologists had been busily employed in combating mistaken notions—chaotic menstrua, sedimentary basalts, craters of elevation, *et hoc genus omne*—largely manufactured on and imported from the continent, they may be pardoned for some prejudice in favour of home-made scientific goods. Again, in 1846, we are told, as if it were a fault, that Agassiz saw plainly during his short stay in England that "although the English leaders of science were extremely courteous and friendly to him, it was absolutely useless to expect from them the offer of any scientific position." Were they to be blamed? Was not a man so improvident and reckless in money matters as M. Marcou depicts Agassiz, almost sure to be a failure among men with the business-like habits of the English? Would not his trick of occasionally talking brilliant scientific nonsense—we take this also on M. Marcou's authority—have raised doubts as to the solidity of his knowledge among the more phlegmatic British men of science? Was there any reason, at that time, why they should import teachers from the continent? In America things were different; there the study of science was almost inchoate; the workers were few; the generation of men who now can hold their own in every branch of science against the rest of the world, were then at school or unborn. But even an award of the Copley medal to Agassiz calls forth a covert sneer from his biographer—"It was certainly well placed this time"—as though that were not usual.

But enough—the book has its good points; it supplies some *lacunæ* in Agassiz' life, it contains some interesting letters, and it reprints one or two documents not easy of access; notably his *Discours de Neuchâtel* on the Ice-Age, which, however, would have been more fitly placed in an appendix; it gives a very full list of his writings, but—it leaves an unpleasant taste in the mouth. A critical history of Agassiz' work in science, and of his contributions to natural knowledge, would have been valuable. This book is too much occupied by the details of controversies and disputes which few desire to remember, and is too obviously affected by the spirit of a partisan, to fulfil adequately any such purpose.

T. G. BONNEY.

FERMENTATION STUDIES.

Practical Studies in Fermentation; being Contributions to the Life-history of Micro-organisms. By Prof. Emil Chr. Hansen, Ph.D. Translated by Dr. A. K. Miller, F.I.C., and revised by the author. Pp. xiv + 277. (London: E. and F. N. Spon, 1896.)

THE recondite researches of scientific men are usually of too abstruse a nature to tempt their authors to exhume them from the ponderous journals to which they have been committed, and present them to the general public.

With regard to bacteriological investigations, however, the case is different, and the eagerness with which such researches are followed, has justified the appearance of such special works as Prof. Hansen's "Practical Studies in Fermentation," in which a connected account is given of original investigations scattered through divers journals and periodicals.

The appearance for the first time of an English edition of this important work, is rendered additionally welcome by the fact that such an acknowledged authority on the subject as Dr. Miller has undertaken its translation. Hansen's name is now so universally associated with pure yeast culture, that it is difficult to realise that a little more than ten years ago he was fighting his way to obtain permission from Jacobsen, the owner of the Old Carlsberg Brewery, to carry out experiments which have now rendered this brewery famous throughout the world.

Step by step, however, in the teeth frequently of vigorous opposition, Hansen has revolutionised our conception of the practice of brewing, substituting a sound scientific basis for custom hitherto directed by empiricism and tradition.

His researches on yeasts and their systematic selection and classification, have enabled the brewer to guard himself against many of those maladies in beer, which Hansen was the first to show were not necessarily attributable to bacterial contamination, but were directly dependent upon the presence of so-called wild yeasts, whilst the substitution of pure yeasts for the heterogeneous mixture previously in use, has, in his own words "helped to raise the industry, a point of great interest to the intelligent brewer."

Naturally after the identification and classification of yeast species, the next step is their successful preservation. This Hansen has found is most effectually carried out in ten per cent. solutions of cane-sugar, and so-called "stock" yeasts can be retained in this manner for upwards of fourteen years without suffering any detriment, and can be propagated at will in beer wort, and sent all over the world. Ingenious methods have been devised for the transport of yeast, and so successful have been the results, that yeast samples have been sent by Jörgensen and others from Copenhagen to South America, Asia, Ecuador, and Australia, without any deleterious effect being produced.

It would not be within the scope of the present brief notice to enter into any detailed description of the numerous and varied problems in connection with yeast fermentation which Hansen has so patiently and successfully attacked; but to the bacteriologist the discussion of the diseases of beer produced by alcoholic ferments

will doubtless prove of special interest, giving, as it does, a concise account of the history of researches commenced over a hundred years ago, which prepared the way for the advent of Pasteur, and which have conducted Hansen on to his special line of investigation.

Of great importance in all bacteriological researches is the individuality of bacteria and the variations which may be introduced by suitable means in their morphological and biological character. But whilst the impressionable nature of bacteria renders their education so particularly attractive, it also complicates in divers ways their successful investigation. Now Hansen has been led to devote a great deal of attention to the variations which are inducible in yeasts, in consequence of the suggestion that the disease yeasts, so undesirable to the brewer, may in reality only be degenerate forms of the true brewery yeasts, and that, therefore, the introduction of pure cultures cannot ensure the absence of these malignant forms. But Hansen states that although he has studied for many years the cultivation of pure yeast on a large scale, he has never seen any signs of the brewery yeasts developing forms like those characteristic of disease yeasts, that on the contrary, under the conditions obtaining in the brewery, they always retained their specific character; and he concludes by saying, "the theories of the degeneration and transformation of yeast have thus, in this respect, proved to be quite untenable."

Yet irregularities do occur in the brewery yeast itself which cause great annoyance to the brewer, and in most cases there is no clue to their cause.

That yeasts, like bacteria, are capable of artificial modification, has been repeatedly shown by Hansen. Thus he found that yeast grown in aërated wort behaved normally in the brewery as regards clarification and attenuation, whilst that grown in non-aërated wort lost, for a time at least, these functions. Again, on submitting a yeast, *Sacch. Pastorianus I.*, to particular conditions, it completely lost its power of forming spores, whilst at the same time its capacity to produce films in old wort cultures disappeared.

It is obvious of what great importance is an intimate knowledge of the conditions which are able to modify the character of yeast cells, for, even with pure cultures, the brewer is yet unable to perfectly manipulate the working of his yeast, although the elimination of unfriendly varieties has materially lightened his difficulties.

Recently the old question has been revived by Juhler and Jörgensen as to the origin of yeast cells, and it is yet a question to which we have no final answer whether they are to be regarded as independent organisms, or only forms of development of the higher fungi. Fifty years ago the latter view was held by Bail, Hoffmann, and others, but at present Juhler's and Jörgensen's observations on the development of yeast cells from the *Aspergillus oryzæ* have not been confirmed, for Klöcker and Schiönning repeated their experiments, but failed to observe the development of yeast cells.

Until we shall be in a position to trace out the parentage of yeast cells, we cannot aspire to arrive at a complete understanding of the conditions which determine their individual characteristics. The same difficulty faces the student of bacteria; whether the differences, sometimes so slight, but, as far as our means of observation at present extend, apparently quite constant between otherwise such similar forms of bacteria, are fundamental or produced from the same form by conditions of which we have no knowledge, is still one of the problems of which we have no satisfactory solution.

Just as Hansen has been able to present us with a form of yeast from a spore-producing parent which will not form spores, so, for example, Roux has introduced us to sporeless anthrax; whilst in bacterial fermentations, Percy Frankland has shown that by suitable treatment the progeny of a fermenting organism can be made to yield up its power of fermenting particular solutions, and that only by resorting to special treatment can its fermentative powers be restored to it.

In the case of the sporeless yeast, and sporeless anthrax, and the non-fermenting bacteria, it would be impossible, on casually meeting with them without a previous acquaintance with the facts, to avoid regarding them as different species of yeast and bacteria from the familiar spore-producing yeast, and anthrax, and fermenting bacteria respectively, yet we know as a fact that they are in reality but variations from the parent form in each instance.

It is obvious, therefore, how important is a knowledge of the pedigree of these minute particles of living matter to enable us to rightly appreciate their character, reckon upon their conduct, and determine their claims to be regarded as separate species.

Prof. Hansen is at present engaged in preparing a special account of his researches on these variation phenomena in yeast, and the conditions which control them; and the work cannot fail to prove of great importance not only to the practical brewer, but to all interested in the study of micro-organisms.

PALÆONTOLOGY AT THE BRITISH MUSEUM.

Catalogue of the Mesozoic Plants in the Department of Geology, British Museum (Nat. Hist.). The Wealden Flora. Part II. *Gymnospermæ.* By A. C. Seward, M.A., F.G.S.. 8vo. Pp. xi + 259; pl. 20, and 9 illustrations in text. (London, 1895.)

Catalogue of the Fossil Fishes in the British Museum (Nat. Hist.). Part III. *Containing the Actinopterygian Teleostomi of the orders Chondrostei* (concluded), *Protospondyli, Ætheospondyli, and Isospondyli* (in part). By A. Smith Woodward, F.G.S. 8vo. Pp. xlii + 544; pl. 18, and 45 illustrations in text. (London, 1895.)

THESE two catalogues, the last additions to the long series of palæontological monographs published by the Geological Department of the British Museum, testify to the value of the work there done under the supervision of Dr. Woodward. The two volumes illustrate, moreover, the strikingly different points of view from which palæontological problems are regarded. Mr. Smith Woodward's catalogue is zoological in its aims and methods, while in Mr. Seward's, though the methods are biological, the most generally interesting results are geological.

The first volume of Mr. Seward's catalogue of the Wealden plants described the Algæ, Characeæ, Equisetinæ, and Filicinæ; the present volume concludes

the account of the flora of that period, by the description of the Cycads and Coniferæ. The complete absence of Angiosperms from the Wealden is disappointing and surprising, for it was unquestionably at that period that the higher flowering plants were evolved. Both in the Potomac beds of America and in rocks of the same age in Portugal, there are remains of monocotyledons and dicotyledons. Angiosperms have been also recorded from the Wealden; but Mr. Seward, after a careful consideration of the evidence, dismisses it as invalid. Mr. Seward's catalogue contains a full description of all the known plants from the Wealden series, and he is to be congratulated on having expanded his catalogue into a complete monograph of the whole flora, which numbers seventy-six species. The present volume contains the description of twenty-four Cycads and seventeen Conifers, of each of which as full an anatomical account is given as the material allowed; the genera are discussed in detail, and important additions made to the knowledge of their structure and affinities, as in the case of *Otozamites* and *Bennettites*. Mr. Seward gives a full bibliography. He discusses the relations of the British flora to their foreign representatives, their geological position, and their evidence as to the climatic conditions under which they lived. His conclusions on these subjects are of great interest. He says the climate was apparently tropical, and that the temperature must have been considerably warmer than that which rules in the Wealden district at the present day (p. 239). It is barely necessary to point out, that geologists have always included the Wealden deposits in the Cretaceous; but Mr. Seward tells us that "the evidence of palæobotany certainly favours the inclusion of the Wealden rocks in the Jurassic series." This conclusion is in accord with that of other lines of palæontological evidence, and it may be hoped that Mr. Seward's pronouncement will hasten the inevitable dismemberment of the Wealden series into two groups, the equivalents respectively of the Neocomian and Portlandian series.

If we miss in Mr. Smith Woodward's catalogue the geological conclusions which render Mr. Seward's so interesting, it is certainly superior to it in one respect; viz. the conciseness, and precision of the diagnosis of orders, families, genera, and species. In such catalogues we too often only have the synonymy and indefinite descriptions of specimens, instead of definite, accurate diagnoses. In this respect Mr Smith Woodward's work is a model. The arrangement is strictly zoological, and thus the volume will be mainly of interest to students of icthyology. The main task of the volume is to trace the gradual evolution in the Actinopterygi from the lower Chondœstrean type to that of fish which approximated to the Teleostei. Mr. Smith Woodward describes the successive modifications of the Mesozoic fish fauna, whereby this evolution has been effected. His classification therefore represents, not an *à priori* scheme as to the probable life-history of the fauna, but an actual life-history as revealed by the records of the rocks. In groups of animals where the fossil remains are sufficiently abundant to enable this to be done, this is the ideal system of classification. Mr. Smith Woodward introduces such revolutionary changes into the families and orders, that he has been obliged to abandon the attempt to show the relations of the divisions he accepts, to those of his predecessors, by synonymic tables. The author is greatly to be congratulated on his treatment of such genera as *Acipenser*, *Amia*, and *Lepidosteus*. As members of these genera still survive, they can be dissected and their anatomy studied in detail. Hence it has been the custom to take them as the types of the Chondrostei, Protospondyli, and Ætheospondyli respectively. But as these living genera are only degenerate, or at least remarkably specialised forms, they give a very misleading idea of the typical members of the Actinopterygi. Mr. Smith Woodward, therefore reduces them to their proper position, as aberrant offshoots from the main stem. This volume is a bulky one, and it is impossible in a brief abstract to give any idea of the amount of new information it contains. The anatomical structure of each genus is carefully worked out, so that the systematic conclusions are based on morphological characters. Many of the more important genera are also illustrated by restorations, while the series of diagrams of the cranial osteology are most instructive.

Reference must also be made to the thirty-eight clear and artistic plates, which have been drawn by Miss G. M. Woodward for the two catalogues.

OUR BOOK SHELF.

The Hymenoptera Aculeata of the British Islands. A Descriptive Account of the Families, Genera, and Species indigenous to Great Britain and Ireland, with Notes as to habits, localities, habitats, &c. By Edward Saunders, F.L.S. 8vo. Pp. viii + 391. (London: Reeve and Co., 1896.)

A GREAT number of books are published at presen relating to the more popular orders of insects, especially British butterflies and moths. Some entomologists, however, devote their attention to the more varied fauna of warmer climates, and publish valuable monographs on the insects of Central America, Asia, or Africa. We are glad to find that others make the less fashionable, if equally interesting, orders of British insects their study; and although there are still many groups, and even whole orders of British insects of which we do not at present possess any trustworthy monograph, their number is lessening year by year. Mr. Saunders deserves special praise for his labours in this direction. After publishing one or two useful works on foreign insects, he turned his attention exclusively to British entomology. He has given us a work on British *Hemiptera*, which is to be followed by one on British *Homoptera;* while the book before us relates to the British *Hymenoptera Aculeata*, the section of the vast order *Hymenoptera* which includes the bees, wasps, and ants, in which the ovipositor is usually modified into a sting in the females, though in some families, as in the first family of ants, the typical *Formicidæ*, the insects do not sting, though some of them bite very severely.

It is not the first time that Mr. Saunders has dealt with the *Hymenoptera*. Synopses of the British Aculeata were published in the *Transactions* of the Entomological Society of London some years ago, in addition to important papers on structure; and the former, enlarged and brought down to date, have formed the basis of the present work. He regards the *Hymenoptera* as entitled, both by their intelligence and structure, to stand at the head of the insect world; and they reach their highest development in the *Aculeata*, which, at present, number 374 British species. Full characters of species and genera are given, including elaborate tables of species. Three

plates of structural details have been added, two of which are devoted to the structure of the mouth in the principal genera of bees. The first, however, which includes details of general structure, very carefully indicated, will prove of the greatest value to entomologists taking up the study of the order *Hymenoptera*. There is a larger edition of the work, with coloured plates of the various species; but of these we cannot speak, as they are not before us while writing. We hope that Mr. Saunders' labours may induce many residents in the country to take up the study of the order *Hymenoptera*, and ultimately to extend their researches beyond *Aculeata* to the far larger and much more neglected, though hardly less interesting, section of *Terebrantia*, which includes the sawflies, gallflies, ichneumons, &c. The parasitic groups are so numerous as to render the *Hymenoptera* probably the largest of all the orders of insects, though they have hitherto received far too little attention from British entomologists.

Ostwald's Klassiker der exakten Wissenschaften, Nos. 67 to 75. (Leipzig: Wilhelm Engelmann, 1895–96.)

We have before us nine volumes recently added to Prof. Ostwald's very handy and useful series of reprints and German translations of classical papers. No. 67 is A. Göpel's "Theoriæ transcendentium Abelianarum primi ordinis adumbratio levis," published in 1847. This is edited by Dr. H. Weber, and translated into German by Dr. A. Witting. No. 68 should be of interest to chemists, for it contains papers by Lothar Meyer (1864–69) and Mendelejeff (1869–71) on the "Natürliche System der chemischen Elemente." This volume is edited by Dr. Karl Seubert, who adds to it some notes on Newland's work in connection with the discovery of the periodic law. A translation of Maxwell's papers on Faraday's lines of force, read before the Cambridge Philosophical Society in 1855–56, appears in No. 69 of the series, edited and annotated by Prof. Boltzmann. The following volume (No. 70) is taken up with Seebeck's papers (1822–23) on "Magnetische Polarisation der Metalle und Erze durch Temperatur-Differenz," its editor being Dr. A. J. v. Oettingen. No. 71 contains Abel's investigations of the series

$$1 + \frac{m}{1}x + \frac{m(m-1)}{1 \cdot 2}x^2 + \frac{m(m-1)(m-2)}{1 \cdot 2 \cdot 3}x^3 + \ldots$$

published in Crelle's *Journal* in 1826. In the volume entitled "Chemische Analyse durch Spectralbeobachtungen" (No. 72), Kirchhoff and Bunsen's contributions to spectrum analysis in 1860 are reprinted, with two coloured plates and seven figures in the text. The editor of this volume is Prof. Ostwald. Under the title "Zwei Abhandlungen über sphärische Trigonometrie" (No. 73), translations, by E. Hammer, are given of two papers by Euler—one on the outlines of spherical trigonometry (1753), and the other on general spherical trigonometry (1779). In No. 74, German readers have provided for them a translation of Berthollet's discussion of the laws of affinity (1801), edited by Prof. Ostwald. Finally, Prof. Groth edits a German edition of the work of the Finland mineralogist, Axel. Gadolin, on the "Herleitung aller krystallographischer Systeme mit ihren Unterabtheilungen aus einem einzigen Prinzipe," which forms No. 75 of this valuable series. Our only regret is that English readers have not a similar collection of edited reprints and translations of scientific classics.

The Metric System of Weights and Measures. By G. T. P. Streeter, B.A. Pp. 43. (London: Gee and Co., 1896.)

This short treatise is not only concerned with the metric system, but also contains "certain arithmetical principles, problems and formulæ, and an appendix on the common chemical reactions." The arithmetical contents may be useful as a supplement to ordinary books on arithmetic, but the statement of chemical reactions is "cram," pure and simple.

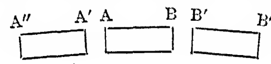
LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Stress in Magnetised Iron.

Mr. Wilberforce's letter (Nature p. 462) raises some points I ought to notice. In treating of the stress and strain, my phraseology has, I think, been extremely "unmaterialistic," in the sense that I have said little or nothing about a magnetic "ether," and have employed rather the language of action at a distance. Maxwell doubtless would have put things very differently, but my own experience has been that when one wishes to avoid confusing ordinary people on such questions as the sign of a stress or strain, the less one says about "ether" the better. My discussion of Maxwell's electrostatic medium (*Proceedings* Edinburgh Math. Soc., vol. xi. p. 107) will show, I hope, that his standpoint is not unfamiliar to me. The question really at issue is the existence and sign of certain strains in *iron* and other gross materials, and I judged Prof. Ewing's mode of presenting the case, which I practically followed, to be as clear as any. If strict Maxwellians object to the association of his name—which I did not originate—with stresses answering to the strains in question, by all means let us use another term, say "Q stresses," so long as their existence is queried.

In the accompanying figure—slightly modified from that on p. 270—suppose for the moment A'' A', AB, &c., to be straight lines. The conclusion I reached that the stress on the element AB of a uniformly magnetised bar, with air gaps AA', BB', is a *tension* meets, I am glad to see, with Mr. Wilberforce's support. This



implies his belief that the reasoning of Mr. Shelford Bidwell (*Phil. Trans.*, 1888, pp. 216, 217), Prof. Ewing ("Magnetic Induction," § 145), and Dr. More (*Phil. Mag.*, October 1895, pp. 349, 350)—who in the places cited have treated the existence of air gaps as immaterial—should have led them to the conclusion that "Q stresses" exist, and that they cause a *lengthening*, not a shortening, of magnetised iron.

Mr. Wilberforce's reconciliation of Prof. Ewing's present views with my own is based, I rather fear, on a fallacy. Let us consider the accompanying figure, still supposed to represent a straight uniformly magnetised bar.

When gaps AA', BB' exist, there must, as Mr. Wilberforce says, be forces at A'', B'' to balance the attractions exerted by AB. Let, however, A' move up to A, and B' to B, and equilibrium will still exist when the forces at A'', B'' are supposed to be reduced to zero. Hence, Mr. Wilberforce argues, in a continuous bar the "Q stresses" at A and B cease to exist. Let us push the argument a little further. Equilibrium will still exist when equal pressures of any magnitude are applied at A'' and B'', so that apparently the conclusion to be deduced is that the "Q stresses" are pressures *wholly arbitrary in magnitude*, which Euclid, I fear, would have declared to be absurd.

The explanation of the paradox is, I think, that when we treat A' A'', B' B'' as finite, we must suppose the conditions such as to maintain unaltered the state of uniform magnetisation originally postulated, and this does not leave the magnetic stresses at A'' and B'' arbitrary. We may of course use a magnetic bar for transmitting stresses other than the "Q stresses." For instance, if we employ two magnetising coils, carried by the bar itself, their mutual attraction or repulsion will introduce stress into the bar. (This is, I think, analogous to the case of glass and tinfoil introduced by Mr. Wilberforce.) All such stresses must be allowed for, but I think it is expedient when possible to avoid confusing them with the "Q stresses."

Mr. Wilberforce seems to me to attach too much importance to the criterion of equilibrium. The equilibrium of the element AB in the figure would be equally secured whether the stresses transmitted across the air gaps were pressures or tensions.

My illustration of the rotating anchor ring was introduced because Prof. Ewing seemed unable to realise the existence of a uniform stress—whether tension or pressure—in a simpler system than that composed of an outer hollow ring pushing or

pulling, and a connected inner ring pulling or pushing. I do not myself see that the existence of acceleration—in the strictly mathematical sense—in a ring rotating with uniform angular velocity is any real disadvantage; but if Mr. Wilberforce thinks it is, then as an accomplished and not too materialistic mathematician, he will, I hope, be satisfied with the case of a ring formed of matter repelling as, say, the inverse square of the distance.

Judging by what has passed, I think an attempt to put clearly the problem as it exists in a magnetised ring may be of service. Suppose the diagram on the preceding page to represent 3 out of, let us say, 360—or any larger number deemed requisite to justify treating arc and chord as practically identical—equal elements of a ring. When unmagnetised suppose each to be of length l, and to be separated from its neighbours by extremely small air gaps of width λ. The elements may be supposed to lie on a smooth horizontal table. When uniformly and equally magnetised each element will change in length, let us suppose lengthen, by the same amount δl. This lengthening is due presumably to several causes; of which one is the tension which experiments by Dr. Taylor Jones and others have shown to be nearly $B^2/8\pi$, so long as the permeability is large. For shortness, I shall treat this tension as actually $B^2/8\pi$ up to actual contact. The contribution to δl due to this stress may be taken as $B^2l/8\pi E$, where E is an elastic modulus, which, strictly speaking, varies with B. Suppose now B so chosen that $\delta l = \lambda$, so that the width of the air gaps reduces to zero. Then Mr. Wilberforce's view would seem to be that at the instant the gaps close the stress producing the lengthening $B^2l/8\pi E$ becomes zero, and comes into existence again only when the consequent shortening of the elements reopens the gaps; in this way a species of oscillation would ensue. Prof. Ewing, I rather fancy, would suppose the stress to exist until there is absolute continuity of matter. To deal with either view, suppose that at the first instant of contact, by some process of welding which leaves the material unaltered, the 360 elements transform into a solid ring. Call the state just before welding M, and that when equilibrium has ensued after welding N; then the following views seem to be or have been held:

(1) (By Mr. Shelford Bidwell, Dr. More, and Prof. Ewing [originally]) that the ring in N is shorter than my reasoning makes it in M by $2 \times (360\ B^2l/8\pi E)$.

(2) (By Prof. Ewing [now] and Mr. Wilberforce) that the ring in N is shorter than in M by $1 \times (360\ B^2l/8\pi E)$.

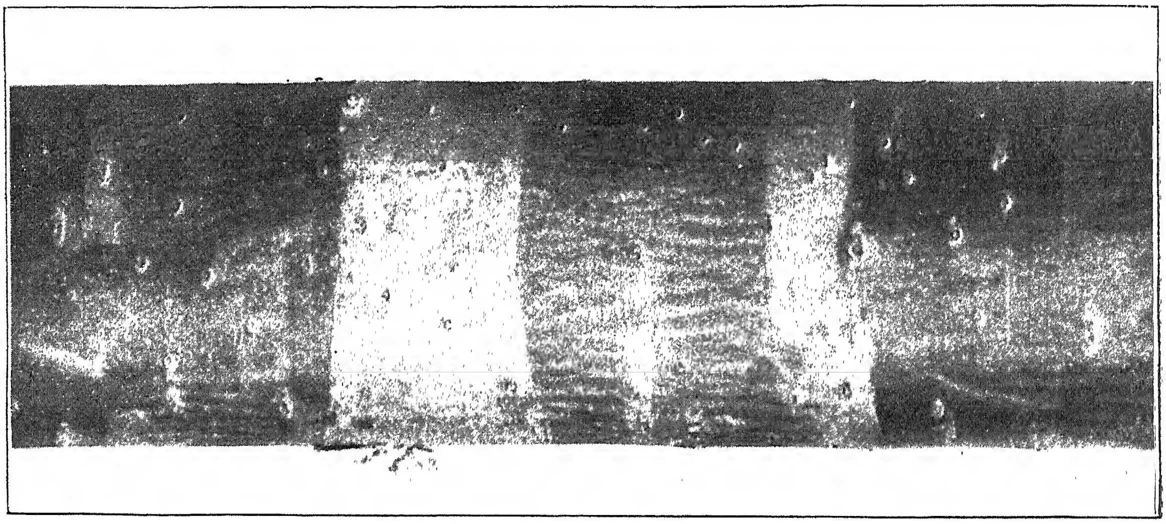
(3) (By, I believe, Prof. J. J. Thomson, Dr. Taylor Jones, and myself) that the ring in N, if shorter than in M, is so by a less amount than $1 \times (360\ B^2l/8\pi E)$. CHARLES CHREE.

March 23.

The Sacred Tree of Kum-Bum.

REFERRING to the letter of Mr. W. T. Thiselton-Dyer, you have published under the title "The Sacred Tree of Kum-Bum" (March 5, 1896, p. 412), I may add that Dr. Kanitz (as I am told by Dr. S. Bretschneider) identifies the tree as the *Ligustrina amurentis*. With the permission of the Vice-President of the Imperial Russian Geographical Society, I send you herewith a photograph (natural size, untouched) of about two-thirds of the piece of the stem of that tree in possession of the I.R.G.S., which received the piece from a lama who visited Kum-Bum late in the autumn of 1894.

The wood is very light, the bark thin (the diameter of the piece being 46 × 47 on one end, 45 × 46 millimetre on the other; the thickness of the back does not exceed 1 millimetre, being the third of it in some places of the circumference), its surface is somewhat rugged, as from desiccation (to be seen on the photo), the outer tissue is grey, translucent, the colour of the bark reddish, the signs *in* it of a golden hue, and can be discerned through the epiderm, but are best seen when the latter is pulled off.



Natural size in breadth, about two-thirds in length, of the piece in possession of the Imperial Russian Geographical Society, St. Petersburg.

A. GRIGORIEV,
Secretary of the Imperial Russian Geographical Society,
St. Petersburg.

A Jamaica Drift Fruit.

IN connection with the article by Dr. Morris on a Jamaica drift fruit, which appeared in NATURE of November 21, 1895, I am able to supplement it by a record of the tree in Trinidad. On March 10, after a personal visit to the vicinity, I despatched Mr. Lunt, my assistant—who may be remembered as being attached to Mr. Bent's expedition to the Hadramaut—to search for the tree or trees stated to have been seen by Messrs. Crueger and Devenish. I am glad to say that I have now Mr. Lunt's report on the trip before me, and still better, I have specimens taken from the trees, which show that *Saccoglottis amazonica* may still be regarded as one of our forest trees. Mr. Lunt followed as directed the course of one of the rivers, and found the tree in more than one place. He was able to bring fresh fruits, leaves and buds, but no flowers were to be had. Mr. Lunt notes that the specimens brought show that the fleshy outer layer or sarcocarp is not, as has been supposed, worn away by water, but owing to its palatable character forms the food of numerous fruit-eating animals, and that on falling to the ground it is further cleaned by ants.

It appears that after the sarcocarp is eaten away the seeds rest upon the ground until the occurrence of heavy floods, when they are washed away by the currents.

The sarcocarp is very pleasant to the taste, and is to be compared very closely with the exterior of many species of the genus Pyrus—as far as I could judge from the single specimen brought home in the green state.

Abundant fresh seeds deprived of the sarcocarp were procured, and a dissection of these shows how accurate are the drawings of Crueger, which were produced in Dr. Morris's article. We hope to secure full sets of herbarium specimens later.

Royal Botanic Gardens, Trinidad, B.W.I.

The Rotation-Period of Venus.

DURING the years 1876 and 1878 I paid some attention to Venus at the Kempshot Observatory, and although no distinct markings on the disc were seen in the very small equatorial, yet the following observation may prove valuable:—"1876 October 2, 6 a.m. The planet dichotomised, but the terminator is not straight; the S. horn projects, and the N. horn is rounded off."

By comparing the sketch then made with the drawing, Fig. 1, in the article in NATURE of February 20 (p. 367), there can be no doubt that the broader features in the curvature of the terminator are the same in both. Fig. 1 was taken from a drawing by Signor Mascari, October 12, 1892, or about sixteen years after mine.

Now every eight years the earth and Venus come to nearly their same position again in their respective orbits, for 365·24d. × 8 = 2921·9d., and 224·7d. × 13 = 2921·1d.; and consequently if the rotation-period of Venus be 224·7d., any well-marked permanent feature will become visible every eight years.

The question is whether this curvature of the terminator will prove to be a permanent feature or not under the circumstances detailed above; and for the answer we shall have to wait until the western elongation of Venus in September or October 1900, when observations made at or a little after the time of dichotomisation will show whether the agreement of the drawings in October 1876 and 1892 was a mere coincidence or not.

Jamaica, March 14. MAXWELL HALL.

A Remarkable Meteor.

MR. BACKHOUSE'S observation of the beginning of flight of the slow-moving meteor of March 1 appears to have been from a point 2° south-east of α Canis Minoris instead of between α and β of that constellation, as I at first assumed from the description. This misunderstanding shows the extreme importance of noting meteor tracks according to the best method, viz. that of giving the R.A. and Decl. of the beginning and end points. This is at once simple and effective; it avoids the frequent errors which occur when projecting meteor tracks from descriptions (sometimes ambiguous) of their courses by the stars, and saves endless trouble.

A reinvestigation of the path of the meteor shows it to have commenced its visible career when nearly over York at a height of 55 miles, and it was last seen by the observer at Sunderland when 53 miles high. Mr. Clark at York, however, watched it much further, and after it had passed over Heligoland when its height had again increased to 55 miles. The radiant was nearly on the western horizon, and the meteor, which in the early part of its flight was descending towards the earth, showed a slight ascent towards the end. The average velocity from the two estimates of duration seems to have been about 20 miles per second.

An observation from Kiel or Hamburg would be very useful for comparison, as the meteor at its terminal stages was comparatively near those places, and must have been far more brilliant than it appeared from York and Sunderland.

Bristol, April 3. W. F. DENNING.

Simple Huyghens' Apparatus for the Optical Lantern.

IN his excellent handbook on experimental optics, "Light," Mr. Lewis Wright describes and figures the well-known double-image phenomena to be observed when an ink-dot is viewed through two superposed rhombs of calc-spar. He does not suggest, and I have not seen elsewhere the suggestion, that the experiment is readily adapted to lantern projection. This, however, is the case, and when so projected this experiment is more useful to the demonstrator than that of the double-image prisms, commonly known as Huyghens' experiment, since the apparatus is more simple. There is no colour correction to explain—nothing to occupy the mind of the student but the action of the spar.

My method is to take two small rhombs of a thickness of 1½ inches or more, and mount them near together in such a way that one or both can be rotated. I use by preference a small parallel beam from the parallelising lens, and between this lens and the rhombs, close to the latter, is placed a thin metal plate having an aperture of a size depending on the thickness of the rhombs. The thicker the rhombs the larger, of course, can be the aperture. The rays, after passing through the pieces of spar, are focused by the ordinary objective so as to give sharp images of the aperture in the plate. Rhombs can often be found whose cleavage faces are quite perfect enough to allow sharp images.

It is evident that a single rhomb in the position here indicated may be made to serve nearly or quite all of the purposes of the double-image prism—may sometimes, indeed, to the advantage of the demonstration, replace the analysing Nicol. This fact has its obvious usefulness in the present scarcity of Iceland spar.

THE MANAGEMENT AND PROTECTION OF FORESTS.[1]

II.

THE working plan of coppice woods is a simple matter. The area is divided into as many compartments as there are years in the rotation. If the coppice is cut, when it has attained the age of fifteen years, fifteen compartments are formed, and every year the old wood on one compartment is cut, after which the coppice shoots grow up to form the new crop. The rotation is determined by the species composing the coppice, and the class of material required, and the yield depends upon the areas cut over, which are equal, where the quality of the locality is uniform, unequal in inverse proportion to the quality, where the quality varies.

In the case of high forests, matters are more complicate, and a brief indication of the main subjects that must be attended to, may serve to explain what is done. A thorough examination of all portions of the forest, its previous treatment, soil, climate, and other conditions, which influence the growth of trees, an accurate and detailed survey of the growing stock, and, lastly, the market for timber and other produce, and the labour available for forest work, are the points which must be examined in the first instance. The next subject is the study of the lines of communication, roads, and water-courses to be used for the transport of timber; and, lastly, the subdivision of the forest into blocks and compartments. A forest to be manageable must consist of compartments of moderate and fairly uniform size. On level ground regular rectangular figures are most convenient; in a hilly country, compartment boundaries must follow the configuration of the ground. Obviously it is in every respect convenient that, wherever practicable, compartment boundaries should coincide with export roads; the sooner, therefore, a system of roads is projected and traced on the ground the better, the traces serving as compartment lines, though the roads need not be built until cuttings are made in the compartments adjoining them.

Simultaneously with the division of the forest into blocks and compartments, the method of treatment must be considered, the choice of species, and the sylvicultural system, particularly with regard to the regeneration of the forest, and the arrangement of cuttings. Large forest areas will generally have to be divided into several working sections, each with its own system of treatment—say one working section for coppice woods,

[1] "A Manual of Forestry," by William Schlich, C.I.E., Ph.D. Vol. iii. (pp. xix + 397). "Forest Management," by William Schlich. Vol. iv. (pp. xix + 593). "Forest Protection," by W. R. Fisher, B.A. (London: Bradbury, Agnew, and Co., 1895.) (Continued from p. 515.)

another for coppice under standards, a third for high forest of spruce or Scotch pine, worked on short rotations, with clear cutting and planting; others, again, for high forest worked on a long rotation, under the selection and shelter-wood compartment systems.

Two prominent points to be settled in a working plan are to determine the rotation and the annual yield. As regards the rotation—that is, the age at which the timber should be cut—the requirements of the market must be consulted in the first instance. It has already been mentioned, that where pit-props find a ready market, coniferous woods may profitably be grown on a short rotation of 50 to 70 years. Where building wood of moderate dimensions pays best, a rotation of from 80 to 100 years will be more profitable. Oak timber, on the other hand, takes a long time to attain a marketable size, and afterwards, with advancing age and increasing diameter, continues long to increase in value. Where it is intended to regenerate forests by self-sown seedlings, trees must of course be allowed to attain that age at which they bear good seed in sufficient quantity; nor must they be allowed to remain after the production of good seed has diminished.

These considerations follow as a matter of course. A more difficult question is, within these limits, to decide upon the most suitable rotation. It might be thought that the simplest plan would be to divide the total income expected during the rotation, less the expenses incurred, by the number of years in the rotation, and to select that which gives the largest mean annual net income. Adopting the data given on page 513, which represent the growth of a Scotch pine forest on land of middling quality, the mean annual net income under a rotation of 80 and 100 years would be as follows:—

$$\frac{2225 + 4 + 36 + 67 + 86 + 91 - (60 + 3 \times 80)}{80} = 27{\cdot}61 \text{ shillings.}$$

$$\frac{3376 + 4 + 36 + 67 + 86 + 91 + 95 + 94 - (60 + 3 \times 100)}{100} = 34{\cdot}89 \text{ ,,}$$

Under this mode of calculation, which takes no account of interest, the mean annual net income increases with the length of rotation, and this increase continues until volume- and value-increment become so much reduced that they will no longer cover the increased outlay. This result, however, does not agree with what has previously been explained. If, as ought to be done, interest is taken into account, a rotation of 80 years is that which, in the case here assumed, yields the highest net rental, and is hence financially the most profitable.

The rotation to be adopted is, it may readily be imagined, a fertile subject of controversy, which often gives rise to animated discussions among foresters in Germany. The author is in favour of what is commonly called the financial rotation, under which the forest capital (soil and growing stock) yields the highest interest, and under which, as explained above, the soil expectation value and net soil rental culminate. But Dr. Schlich justly observes that purely financial interests must in many cases be modified by considerations of a different character.

How the annual yield, that is the timber which may be cut annually or within certain periods, is determined in the case of coppice woods, has already been indicated. In the case of high forest, three different systems are generally followed. The first of these the author designates as the allotment of woods to the different periods of a rotation. A rotation of 80 years is divided into four periods of 20 years each. It will serve to make matters clear, if we assume the existence of a normal forest with an even distribution of age classes. To the first period would be assigned in such a forest all woods between 61 and 80 years, to the second those between 41 and 60 years, and so on, so that the fourth class would comprise the youngest woods under 20 years. Such a regular forest, however, does not exist, and what in reality is done, is to assign the oldest woods to the first period, and to distribute the others according to their age, as well as can be done. A number of compartments, stocked with old timber, are thus assigned to the first period, and care is taken to allot to each period approximately equal areas, which, if there are great differences in the quality of the locality, are reduced to a common standard. The woods placed in the first period are then measured, their volume calculated, and the increment for half the number of years in the period is added. The total volume divided by 20 gives the mean annual yield during the first period. The cuttings in the woods assigned to each period are arranged so as to suit sylvicultural requirements and economic considerations. The allotment of compartments to periods can obviously be made by volume instead of by area. In that case old woods are measured, and the proper increment added. For younger woods the volume, which will stand on the ground at the time of cutting, is calculated from yield tables. Equal volumes are assigned to each period, the oldest woods being allotted to the first, and the youngest to the last period. The compartments allotted to one period, whether by volume or by area, will not necessarily be contiguous; they will often be scattered over the whole forest. Whether the allotment to periods is regulated by area or by volume, a framework must be constructed, showing during which period each wood is to be cut. Hence this system is commonly known as the framework system. However irregular the forest may have been; at the end of the rotation its condition will approximate to the normal state. Thus the system introduces order, and is yet elastic, leaving sufficient latitude in the location of cuttings during each period.

The second system regulates the yield according to increment and growing stock. The legitimate yield of a forest during a given period in the first instance depends upon the quantity of timber produced during that period. During one year more should not, as a rule, be cut than the quantity represented by the sum total of the annual increment laid on in all portions of the forest. In a normal forest, with a regular succession of age classes, the legitimate annual yield is equal to the annual increment. In a forest, however, which, though well stocked, only contains the younger age classes, the produce of which is not marketable, no yield is possible, though the annual increment may be considerable. Again, in a forest where the older age classes preponderate, it is not only permissible, but it is in most cases necessary, to cut considerably more than the total annual increment. This principle has long been recognised, and as early as 1788 the management of the Austrian State forests was based upon it. When the older age classes preponderate, it is proper to fix a period, during which the surplus old growing stock shall be removed. If this period is called a, and I the actual annual increment, then the legitimate annual yield of the forest is

$$= \text{I} + \frac{\text{actual growing stock} - \text{normal growing stock}}{a}$$

This, which is known as the Austrian assessment formula, is still used in many public and private forests of Austria and Germany. Space forbids further discussion of this and similar methods. Suffice it to say that under this system no framework is needed, and that on this principle it is best to determine the yield for a short period only. Hence in those forests, where this system has been adopted, the yield is generally determined for ten years, and at the expiration of this time a new working plan is made.

The third system, which is in force in the State forests of Saxony, was originated by Cotta in 1811, and has been

brought to its present state of perfection by Judeich, for many years until his death in 1894, Director of the Tharand Forest School, one of the ablest foresters of Germany. Its leading idea is to treat each wood, or each compartment, or each group of compartments, on its merits, the management of the whole forest representing a summing-up of the treatment laid down for each wood. It has already been stated that a large portion of the State forests in the kingdom of Saxony are nearly pure spruce forests, managed on a very simple system by clear cutting and planting, and that most of them are worked on a rotation of 80 years. At first sight elaborate working plans might seem to be superfluous under these circumstances; it might be thought sufficient if a suitable area of the oldest woods were cleared and planted annually. However, had the forests been worked in this manner, without safeguards against storms and insects, their condition would not be what it actually is, nor would the financial results be so satisfactory. Pure spruce woods are apt to be blown down. Spruce plantations are apt to be destroyed by the pine weevil, and it was to a great extent the necessity for guarding against damages from these causes which led to the development of the present system in Saxony. On the spurs and in the valleys of the Erzgebirge and the other mountainous regions of Saxony, where most of the State forests are, the direction of the prevailing winds, though generally westerly, is greatly modified by the configuration of the ground. Accordingly the cutting series, in which all clearances proceed against the wind, must be most skilfully arranged, so as to guard against damage. Again, in order to guard against the ravages of insects, the principle of breaks in the successive clearances has been consistently carried out. When in one spot a cutting has been made, the adjoining area is not cleared until the young wood on the first area has become completely established. The result consists in numerous cutting series, separated by severance cuttings, and numerous clearances of limited extent. An essential feature in this, as in the second system, is that the yield is determined only for a period of 10 years. The woods proposed for cutting during that period are carefully examined. According to Judeich's plan, the question whether a wood should be cleared is determined by purely financial considerations. Dr Schlich, however, very properly urges that other considerations also should have due weight. Obviously a regulator is necessary, to prevent too large an area being assigned to one period. This regulator is obtained in a very simple manner. The total area is divided by the rotation. For a forest of 2400 acres, worked under a rotation of 80 years, 300 acres would be the area cleared during a period of 10 years.

The system here sketched is simple and effective, but, like all systems, the results depend upon the manner in which it is worked. The young woods must be complete and vigorous, and though the outlay in forming them, is multiplied seven-fold in 80 years under the operation of compound interest, even at the low rate of $2\frac{1}{2}$ per cent., undue economy in this first operation, and in the subsequent tending of the woods, would result in waste and diminished net revenue from these magnificent estates.

Thus far the management of forests has been discussed, as if timber were the only legitimate forest produce. This, however, by no means is the case. Large plantations have been made in Assam by the Forest Department, ever since 1870, of *Ficus elastica* for the production of india-rubber. Myrobalans, the fruit chiefly of *Terminalia chebula*, is an important article of forest produce in Western and Central India. The Scotch pine forests which surround the old town of Nürnberg, are important, less on account of the timber which they produce, than because the annual fall of needles furnishes litter to the peasants in the vicinity, who chiefly depend upon the growth of vegetables, and who use the dry needles as a substitute for the straw which they do not produce. In the drier regions of India, a commencement was made in 1874 to protect woodlands for the specific purpose of furnishing cattle fodder in times of drought. Had these attempts been carried on with sufficient vigour and perseverance, they might have contributed largely to mitigate the sufferings of the agricultural population during seasons of deficient rainfall, which in most parts of the Indian Empire occur from time to time.

Other articles of produce obviously demand other systems of management. With these, however, forest proprietors in the United Kingdom at present have no concern. Their interest is to produce timber of the best description, and to sell sufficient quantities to attract purchasers at regular intervals. A beginning can only be made by actual experience. Should any proprietor have the courage and foresight to ask the author of the manual here reviewed, or any other really competent and experienced forester, to take in hand his forest estates, and to organise their management on a well-considered plan, the result would certainly induce others to follow suit. In a matter of this kind, example is better than teaching, and the sooner a commencement is made, the better for the landed interest of Great Britain. Patience, however, and plodding perseverance, are indispensable conditions of success in forestry. Timber takes many years to attain marketable size, its growth in volume and value is slow, and the money returns are moderate. These are the chief reasons why systematic forestry is not yet respected in Great Britain. In this, as in other matters, the pressing needs of the moment stand in the way of undertakings which would, slowly but surely, advance the future welfare of the country.

THE PROTECTION OF FORESTS.

We now pass to the consideration of that branch of forestry which deals with injurious external influences, and with the measures that may be adopted to guard against them. These matters form the subject of Mr. Fisher's volume. In the introduction a brief account is given of the earliest attempts at forest protection, sacred groves, and game preserves. Sacred groves are found in many parts of India. In the moister regions, where forests are abundant, we find them, as Mr. Fisher correctly observes, in the hills south of the Brahmaputra river, but also in other districts; for instance, upon the Javadies and other hill ranges of South India. In the regions with a dry climate, as in Rajputana, the sacred groves of *Anogeissus pendula* are an ornament of the country, and have often proved a boon to the people by providing cattle fodder in seasons of drought. Old game preserves have in many instances been transformed into useful forests. The forests of Babul, *Acacia arabica*, on both sides of the Indus River, were originally formed and maintained as the game preserves of the Ameers of Sind, and are now of considerable importance in that dry and otherwise forestless country.

Part i. is devoted to the protection of forests against man. The destruction of forests through other agencies is insignificant, compared to that accomplished by the improvident cupidity and careless ignorance of man. These tendencies of mankind the entire manual is intended to counteract, in so far as it teaches how forests should be maintained and managed. The present volume only deals with special matters in this respect, the protection of forests against encroachment, damage, misappropriation, irregular and excessive exercise of rights of user.

Part ii. deals with protection against animals. Here the chapters relating to insects are the most important. The damage done to forests by caterpillars and beetles must be seen in order to be believed. The Nun Moth (*Liparis monacha*) has for several centuries been known as one of the most formidable enemies of spruce forests in Germany, Austria, and Russia. It is also very

injurious to the Scotch pine, and likewise feeds upon the leaves of the beech and other broad-leaved trees. From 1888 to 1891 this caterpillar appeared in such enormous numbers in the spruce woods of South Germany, particularly of Bavaria, that over large areas the trees became entirely denuded of their leaves, and were killed. In the Ebersberg Park, a densely stocked forest, spruce with a small proportion of beech and Scotch pine, forming a compact area of 16,510 acres, 4700 acres were completely bare, while on 7400 acres the trees were severely damaged. The timber that had to be cut on this area, in consequence, amounted to 53,000,000 cubic feet, more than half the normal annual yield of the State forests in the kingdom of Bavaria. Timber-cutters were brought from all parts of the country, and lodged in temporary barracks built in the forest. A railway seven miles long was constructed into the heart of the devastated area; tramways were laid upon the rides separating the compartments, and portable lines were used to bring out the logs. At the same time the Nun had devastated other extensive areas in Bavaria and the adjoining districts of Württemberg, necessitating the cutting of large quantities of timber. The news of these events created great uneasiness among timber traders, and a disastrous fall in timber prices was anticipated. This, however, was to a great extent guarded against by the prompt and carefully-planned measures taken by the Bavarian Government. The annual cuttings in the Bavarian State forests were at once considerably reduced, and the action thus taken was aided by the circumstance, that the timber of the Ebersberg Park has a very good name, and justly so, for the stems are well-shaped, clean, without knots, and the wood is even-grained. Most of the large timber was sent across the Alps by the Brenner line, and found a ready market in Italy. The smaller pieces were sold to paper factories to be converted into wood pulp, and what was only fit for fuel was collected at the great depôt that supplies the town of Munich with firewood. The cleared areas have since been planted up, and except that the working plan of the forest was completely upset, no permanent damage was done by the calamity.

If the timber of Conifers killed by caterpillars is not cut at once, it is apt to be much injured by bark beetles. In the present instance this was avoided; but formerly, with the means of communications less developed, and the plan of action less prompt and less comprehensive, the ravages of *Tomicus typographus* and other bark beetles have greatly intensified the mischief. In North Germany and in Russia the principal devastations by the Nun, and by the bark beetles in its wake, have been recorded in 1688 (Altmark), 1794 to 1797 (Southern Thuringia), 1837 to 1840 (the greater part of Germany, from the North German Plain to the lake of Constance), 1845 to 1867 (Western Russia and Eastern Prussia, extending over forest areas aggregating 32,000 English square miles).

The moth lays about 150 eggs, and, as is the case with other species (for instance, *Orgyia antiqua*), the male and female insects of one brood attain the perfect stage on different dates, necessitating the inter-breeding of different broods, and thus insuring a vigorous development of the pest. A succession of warm dry springs, with weather otherwise favourable to the life of the insect, brings about the rapid multiplication of the Nun, and, unfortunately, the protective measures are difficult, and their success uncertain.

Fortunately, the Nun has formidable enemies. A number of birds eat the eggs—up to 200,000 eggs have been found on one tree; but only the starling eats the hairy caterpillars on a large scale. Of insects, parasitic *Diptera* (*Tachinidæ*) are exceedingly useful in destroying the caterpillar wholesale. The most powerful ally of the forester, however, has in most cases been an epidemic disease, which breaks out among the caterpillars when the multiplication has attained its climax. They congregate in large masses at the tops of trees and branches, where they die without making any attempt at feeding. In the diseased caterpillars several species of bacteria have been found in large numbers; attempts have also been made to inoculate healthy caterpillars with these bacteria; the success, however, has not been sufficient for practical purposes.

Equally mischievous, not, however, in spruce woods, but in those of the Scotch pine, is the Pine Moth (*Gastropacha Pini*), a species, Mr. Fisher states, not found in Great Britain. Formerly the Pine Moth was dreaded as the greatest enemy of the extensive pine forests of Northern and Middle Germany. Fortunately, however, when its life-history became better known, a simple and most effective remedy was devised. The eggs are laid early in August; the caterpillars, which come out about the end of that month, proceed at once to feed on the needles; but, being small, the damage done at this season is not considerable. When night frosts commence, they descend from the trees, and spend the winter months ensconced in moss or dry needles near the foot of the stem. In spring, aroused by the warmth, they ascend the trees and eat them bare in no time. The average consumption by one caterpillar is estimated at 1000 needles. What is done by way of protection against this pest, is to prevent their ascending the trees in spring, and this is effected by putting broad bands of tar, grease and glue, mixed, round the stems, the outer rough bark having first been scraped off to present a smooth surface. These sticky bands the caterpillar cannot get over, and in this manner nearly the whole of the pine forests in the plains and broader valleys of Germany are now protected against the ravages of this insect. The pine woods on the hills, having generally a mixture of other trees, are safe from the attacks of the Pine Moth.

The Scotch pine has many enemies besides the Pine Moth. During the summer of 1895 the Pine Noctua (*Noctua piniperda*) and the Pine Looper Moth (*Geometra piniaria*) have appeared in immense numbers, the former between Darmstadt and the Main River, and the latter in the forests near Nuremberg, as well as in the Rhine Valley.

Among insects which attack young plants, the Pine Weevil (*Hylobius abietis*) is one of the most mischievous. The larva does not do much damage, but the beetle is found in large numbers in plantations of spruce and Scotch pine up to six years of age, killing the plants by gnawing the bark all round the stem, down to the root. It lays its eggs on stumps and roots, and the best protection is to give him as little opportunity as possible for breeding in the vicinity of young plantations. Small felling areas and intermittent fellings ought to be the rule; when a clearance has been made, the adjoining area should not be cut until after the lapse of three to five years.

Of the Cockchafer (*Melolontha vulgaris*) the beetle does some damage by eating the foliage of broad-leaved trees, particularly of the oak; but the chief mischief is done by the larva, which eats the roots of plants. A fungus (*Botrytis tenella*) some years ago in France was found to infest the larvæ, and at one time it was hoped that it might be possible, by inoculating larvæ with the spores, to spread the infection, and thus to destroy a large portion of the brood. Experiments have been made with great care in France, in Switzerland, and at Berlin, but hitherto without practical success.

Part iii. discusses protection against plants, forest weeds, climbers, parasitic and epiphytic phanerogams and fungi. In tropical and sub-tropical forests huge woody climbers play an important part, and are often very mischievous. They bend and twist the trees on which they have found their support, and finally, by their

dense luxuriant foliage, smother them. Several species of epiphytic ficus enclose the stem of teak or other useful trees by a network of aërial roots. The extirpation of climbers and epiphytes forms an important part of a forester's duty in India. Our North Europe climbers, the honeysuckle and *Clematis Vitalba*, are innocent representatives of those gigantic enemies of the forester in warmer countries.

Green parasites, such as *Viscum* and *Loranthus*, probably in a manner contribute their share towards the nourishment of the tree upon which they have established themselves, and some botanists have even gone so far in their appreciation of this symbiotic arrangement, as to claim for the mistletoe the gratitude of the apple-tree, upon which it lives. Be that as it may, in the Southern Schwarzwald, chiefly at lower elevations, *Viscum album* to such an extent infests the Silver Fir that many trees are killed, and that much of the timber is rendered useless by the haustoria of the parasite. And on the Nilgiris of South India several species of *Loranthus* have attacked the plantations made on those hills of the Australian *Acacia melanoxylon*, killing a large number of trees.

The damage done to trees by fungi has of late years justly attracted much attention. *Phytophthora omnivora*, de Bary, closely allied to the potato pest ((*P. infestans*) attacks the seedlings of the beech and other broad-leaved trees, and destroys them wholesale in May and June, especially if protracted wet weather sets in.

Æcidium elatinum, Link, is the fungus which infests the Silver Fir, manifesting itself in two different ways—by an abnormal hypertrophy of the branches, known as witches' brooms, and by canker or diseased swellings of the stem. The trees attacked with canker are worthless for timber, and the damage is very considerable. Nothing, however, can be done in the matter, save to destroy the branches bearing witches' brooms, and to cut out all trees attacked by canker. Fortunately, the system of management which suits the Silver Fir best, selection fellings, or gradual cuttings under shelter woods, permits the removal of canker trees.

The dreaded Larch disease is chiefly caused by a fungus (*Peziza Willkommii*, R. Hartig). Wounds made by the Larch Miner Moth, *Tinea* (*Coleophora*) *Laricella*, facilitate the entry of the spores into the tissue.

Broadly speaking, the most effective protection against the ravages of insects and fungi is a correct system of management. One important result, arrived at by long experience, in this respect, is that all other circumstances being the same, mixed woods are less exposed to such ravages than pure woods, consisting of one species only. Short-lived plants, such as our field crops, are exposed likewise to damage by insects or fungi; but, in the case of trees and shrubs, the damage is intensified, because they furnish food and other circumstances favourable for the multiplication of the pest, not during one season only, but continuously. This has been our experience hitherto, in the case of forests, as well as in the case of plantations of coffee, tea, cinchona, or other woody plants. The vineyards of Europe are a case in point. *Oidium Tuckeri*, Berk., commenced its ravages in South Europe in 1851, nearly destroyed the vineyards of Madeira, and probably was the fungus which, in 1856, put an end to the cultivation of the grape in the valley of Kunawar in the North West Himalaya. During the last ten years, two pests, a fungus and an insect, both introduced from North America, have done enormous damage—*Peronospora viticola*, de Bary, and the dreaded *Phylloxera vastatrix*, Planch. The coffee plantations of Ceylon have been annihilated between 1869 and 1880 by that terrible fungus *Hemileia vastatrix*, Berk. In Java, where this fungus has also made its appearance, without, however, doing much damage, other trees are invariably planted with the coffee, and this to a certain extent is also done in the coffee plantations of Coorg and the Wynād. In the extensive and magnificent tea plantations, which now cover the Assam valley, it formerly was the custom to preserve belts of the original forest on broken ground and along ravines, and the experience of foresters in Europe points to this plan as an important safeguard against the spread of fungus and insect pests. Among foresters in Germany and in other countries on the continent of Europe, the conviction has now generally gained ground, that every effort must be made to maintain mixed woods, consisting of several species, where they exist, and in pure forests to introduce a mixture of other species, wherever such is practicable. The object is to make the conditions for the multiplication and spread of insects and fungi less favourable than they are in pure forests, consisting of one species only.

The forester, unfortunately, has to contend with other enemies besides man, animals, climbing plants and fungi. The heat of the sun, drought, frost, snow and ice, storms and fires, smoke and acid fumes of factories and furnaces are destructive to an extraordinary degree, and often entirely upset his plans of operations. And in addition to all this, some species are subject to endemic widely-spread disease, such as the needle-shedding of young Scotch Pine plants, the cause of which has not yet been ascertained. All these matters are dealt with in the concluding parts of Mr. Fisher's book.

The recollection of the storms which blew down enormous masses of timber in Scotland in 1893 and 1894, ought to invest this portion of the book with special interest. Here again a correct system of management affords the best protection. Cutting series of moderate extent, adapted to the configuration of the ground and to the locally prevailing wind direction, severance cuttings timely made—these are the principal measures by which the extensive pure spruce forests of Saxony and Thuringia have, it is true, not been absolutely protected against storms, but protected so far, as such is possible in pure forests consisting of a shallow-rooted species that is easily blown down.

Protection against fire is not a matter of great practical importance in the moist climate of Great Britain. Mr. Fisher has, nevertheless, very properly treated it somewhat fully, and has also alluded to the work of fire protection in India. The peculiar feature of the climate in most provinces of India is the long dry season, at the end of which grass, leaves, herbs, are as dry as tinder. The natural results are the annual jungle fires of the hot season, an institution as old as the civilisation of the country. To the annual fires it is due that fully stocked and healthy forests were the exception, when the first attempts at regular management were made, and that the main portion of the so-called forests were groups of trees, separated by vast areas of scrub and grass land. Moreover, the majority of the older trees were unsound, hollow and crippled, the soil was hard and impoverished, and it was clear that protection against fire was the most important task to be accomplished, if real improvement of the forests was to be effected. The attempt, however, to put an end to this time-hallowed institution met with powerful opposition on all sides. Colonel Pearson, the Conservator of Forests in the Central Provinces, was the first to succeed in keeping out fires from the Bori forest in the Satpura hills. This was in 1865, and a few years later the effect of continued protection in that district was marvellous. This and other forests which have thus been really protected, are now dense compact masses of healthy trees and bamboos, which can with advantage be subjected to regular management. The total area of fire-protected forests in the British Indian Empire in 1893 amounted to 27,438 square miles, which is nearly three times the area of State forests in the kingdom of Prussia.

Proprietors of forest lands in Great Britain and in the

United States of North America will do well to bear in mind the success of fire conservancy in India. Systematic forest management is a difficult undertaking, which has many enemies. Nevertheless success is possible, and if these forestry manuals facilitate the attainment of success in this business, their authors will have reason to be well satisfied with their work.

DIETRICH BRANDIS.

THE DEVELOPMENT OF BUTTERFLIES UNDER ARTIFICIAL CONDITIONS.

The effects which cold and heat, applied to the pupa, produce in the colours and patterns of the imaginal wings, have been studied for many years and by many naturalists. Weismann in 1875 published an account of his own experiments, and those conducted by others, in an essay which was published in this country in 1882 among the "Studies in the Theory of Descent," translated and edited by Meldola.

The experiments described by Weismann have been repeated and greatly extended by Merrifield (*Trans.* Ent. Soc. Lond., 1888, 1889, 1891, 1892, 1893, 1894), while Dixey has published interesting observations on the phylogenetic significance of some of the results obtained (*Ibid.*, 1893, 1894).

While these careful and successful experiments were being conducted in this country, Standfuss of Zurich has been independently engaged on the same research, employing in many cases the very species which had been used by Merrifield. Standfuss's paper, appearing in 1894, has been translated by Dixey, and, after revision by the author, has been published, with an introductory note by Merrifield, in the pages of *The Entomologist* for March, April, and May 1895. The editors of this journal are to be congratulated on the effort they have made to lay before their readers some of the interesting results of entomological research conducted by continental naturalists. We may hope that the attempt which has been so successfully made, will be frequently repeated.

(1) *The Egg.*—The eggs of four species of moth (*Arctia fasciata*, *Dasychira abietis*, *Lasiocampa pruni*, and *L. pini*) were exposed to a high temperature, 34° C. (93° F.), as they were being laid, and subsequently up to the time of hatching. The larvæ hatched in two-thirds or less of the normal time, and although the temperature remained normal, 25° C. (77° F.), throughout the subsequent stages, 71 per cent. of *fasciata*, 90 of *abietis*, 100 of *pruni*, and 81 of *pini* emerged as imagos in that year, the remainder hybernating as larvæ; as against 23, 12, 64, and 28 per cent. respectively, when eggs from the same parents had been laid and kept at a temperature of 22° C. (72° F.) and at 25° C. during the subsequent stages. This persistence throughout the later stages of the hurrying-up of development, when the conditions which originally started it had ceased at the beginning of larval life, is very remarkable, and it is unfortunate that the author should have contented himself with giving his results in percentages instead of the actual numbers obtained. This criticism applies to nearly all the results recorded in the paper.

There was no evidence that the imagos were otherwise influenced by the condition of the ova.

(2) *The Larva.*—Experiments with an increased temperature generally shortened the period of larval development and reduced the size of the imago. From these experiments the author infers that the great difference in size between certain closely allied species (*e.g.* *Boarmia consortaria* as compared with the much larger *B. roboraria*) has been produced by the larvæ reacting in a different manner under changes of temperature, so that some acquired long and the others short larval periods. It would appear that the evidence in favour of this conclusion has not been sufficiently sifted, and that certain obvious difficulties raised by this interpretation have been overlooked.

Certain changes in form, colour, and marking are also described as following the temperature conditions of the larvæ. In these cases, however, the author does not appear to be giving the results of his own experiments, but reasoning from the differences observed in the several broods of many species appearing at different seasons, and especially contrasting the forms produced from hybernated larvæ with those produced without hybernation. In these cases it is the duty of the naturalist to determine by means of artificial experiments whether the observed changes are entirely due to conditions of temperature, and whether the larval stage alone is of importance.

Many experiments were made with foods, polyphagous larvæ being fed on poisonous or acrid plants, on such abnormal diet as raw meat, or on plants which had absorbed solutions of various substances. The perfect insects "often enough showed a failure in size or general colouring, but in no case any noteworthy variation in tint or pattern."

The effects of light transmitted through glass of different colours were negative, although the larvæ were exposed to these conditions "from the time when they were quite small."

(3) *The Pupa.*—By far the most complete results were obtained by subjecting the pupa to various degrees of temperature.

The effects obtained with *Papilio machaon* and *Vanessa antiopa* are of especial interest, inasmuch as Merrifield's material had been inadequate and his results, as regards these species, negative.

Seventeen pupæ of *P. machaon*, kept at a temperature of 37° C. (98°–99° F.) from the time when the cuticle hardened at the beginning of pupation, produced in seven to ten days fifteen insects, which were much lighter in colour than usual, owing to the development of a yellow powdering which obscured many of the dark markings on the upper and under sides of the wings, and the body. Changes in form are also described, including a marked lengthening of the "tail" of the hind wing. "Some of these specimens . . . bear a perfect resemblance to those that fly in August in the neighbourhood of Antioch and Jerusalem." The pupæ subjected to cold (for twenty-eight days) produced only two imagos, and these resembled the Swiss and German forms emerging from hybernated pupæ.

The pupæ of *Vanessa antiopa*, after being exposed to heat (37° C. or 98°–99° F.) for forty-eight hours, produced, ten days later, butterflies in which the marginal blue appeared to be reduced, and the yellow border broadened, but in neither case to a greater extent than in nature. Among these individuals, however, 2 per cent. presented a very remarkable variation, which Standfuss has named var. *daubi*. This well-marked form is constantly produced when the pupæ were exposed to heat (as above) for sixty hours, and then kept at a temperature of 24° C. (75° F.). Such pupæ produced the var. *daubi* in twelve days. The upper surface of both wings is greatly darkened, becoming almost black, the blue spots are much reduced and have a violet tinge, but the most remarkable change occurs in the yellow border, which is extremely darkened, so as to leave, in extreme cases, only a small remnant of yellow scales. The under side is as much darkened as the upper; and certain changes in the form of the wings are also described.

Cold produced very different effects according to the time of exposure. The most interesting results, and those which most strongly suggest the appearance of allied species (*V. urticæ*, *V. polychloros*), followed the shortest exposure of twenty-nine to thirty-four days in the refrigerator. In these cases the brown ground colour became lighter, and the blue spots (much enlarged on the

fore wing) acquired dark borders. At the same time traces of dark spots, like those of the allied species, appeared in certain individuals, while the under side, especially of the hind wing, underwent changes which are also described in *V. io*, gaining a pattern in brown scales which recalled that of *V. polychloros*, &c. A longer period (thirty-nine days) produced far less interesting results, the blue being increased, the yellow border diminished, and the ground colour darkened. Forty-four days in the refrigerator produced more marked effects in the same direction, the blue spots of the hind wing being so increased that they project into the yellow border. The ground colour of both upper and under sides is much darkened. This beautiful variety is called by the author var. *roederi*.

As regards other species of butterflies, Standfuss's results afford valuable confirmation of those obtained by Merrifield. Thus heat (37° C.) produced light-coloured imagines of *Grapta C-album* with less sharply-defined markings and less deeply indented wing margins; while cold produced opposite effects, the dark colours of the under sides of the wings being often "mingled with moss-green tints."

In *Vanessa polychloros*, heat (37° C.) reduced the marginal blue spots and the dark wing-border, and brightened the colour of the upper sides of the wings, cold producing the opposite results.

In *V. urticae*, more extreme effects in the same direction were witnessed, heat causing an approach towards the var. *ichnusa*, and to a certain extent towards *V. io*; while cold produced butterflies which recalled the North American *V. milberti*. It was noteworthy that pupae kept on ice for forty-two days (emerging thirteen to fourteen days afterwards), produced less deviation from the normal than those which had been exposed for only thirty-two days, and emerged nine to ten days afterwards. In neither case is there any record of the numbers of individuals made use of.

In *V. io*, heat produced little result, while cold (thirty-five days in refrigerator) caused most interesting changes in the direction of *V. urticae* and *V. polychloros*. A longer period of cold (forty-two days) still further intensified these changes, which affected the under as well as the upper sides of the wings, the well-known uniform darkness of *V. io* giving place in the most extreme examples to a sharply-defined pattern in brown scales, far more suggestive of the above-mentioned species of *Vanessa*.

In *Vanessa atalanta*, heat greatly reduced the blue in margin of the fore wing, widened the red band, and reduced the apical white spots; thus approximating towards *V. callirrhöe*. Cold (thirty-one days) conversely increased the large white spot, reduced the red band by the encroachment of dark shades, and increased the blue. A longer period of cold (forty-two days) produced ten almost normal insects and a single extreme form. It would therefore appear that less effects were, on the whole, produced by the longer period, although the materials for a valid comparison are absent, inasmuch as the author only informs us that there was "much individual variation" in the results of the shorter period.

In *Vanessa cardui* a higher temperature (40° C. = 104° F.) was made use of for two periods of six hours, alternating with one of twelve hours at the normal temperature (about 22° C. = 72° F.). Only two pupae out of forty-two failed to emerge, although twelve produced crippled butterflies. Four specimens were of the var. *elymi*, the remainder normal. In another experiment with 36° to 37° C. for sixty hours, a remarkably pale form was produced; while in other cases the red colour, often acquiring a brownish tinge, was increased in extent on both upper and under surface of the wings. Cold (twenty-three days), on the other hand, darkened both sides of the wings. A longer period of cold (twenty-eight days) produced, on the whole, rather more extreme effects.

In *Argynnis aglaia*, heat (four days at 36° C.) produced very little effect, the ground colour of the upper sides of the wings being lighter, the greyish-green shades of the under sides darker and more conspicuous than usual. After twenty-eight days of cold, only three uninjured insects emerged from twenty-one pupae; in these the ground colour was unaltered, the black spots at the base of the fore wing enlarged, while the greyish-green shades, described above, gained a brown tinge. After a longer period of cold (forty-two days), two insects emerged from twelve pupae, and these showed far more extreme effects in the darkening of both upper and under sides of the wings.

The pupae of *Dasychira abietis* were killed by heat 37° C., while cold (forty-two days) tended to darken the insects.

Some experiments were also made upon the effects of comparative dryness and moisture upon the pupae. Large numbers of pupae of *Saturnia pavonia* were kept very dry from June to the end of September, and were then exposed to moisture; a treatment which the author believes, from repeated experiments, causes about 1 per cent. of the moths to emerge in about ten to twenty days, instead of hybernating. In these moths the pattern was "not sharply outlined, but more or less washed out and confused."

Towards the end of the paper the author gives a brief and general account of the results obtained by subjecting the pupae to heat and cold. He summarises the various classes of effects as follows:

(1) "Seasonal forms" similar to those which are known to occur in nature (*V. C-album* and *P. machaon* to some extent).

(2) Local forms and races similar to those which occur constantly in certain localities (*V. urticae*, *cardui*, and to some extent *P. machaon* and *V. antiopa*).

(3) Entirely exceptional forms or "aberrations," also occurring from time to time in nature (*V. io*, *V. cardui*, *argynnis aglaia*).

(4) Phylogenetic forms, not now occurring on the earth, "but which may either have existed in past epochs, or may perhaps be destined to arise in the future" (*V. io*, *V. antiopa*, *V. atalanta*).

This portion of the paper, although of interest, is not equal to the experimental portion, and cannot be in any way compared with Dixey's careful consideration of the results of Merrifield's experiments.

It is to be hoped that Dr. Standfuss will continue his experiments on this most interesting subject. E. B. P.

A NEW SYNOPSIS ANIMALIUM—DAS TIERREICH.

FROM rough calculations lately made by the contributors to the *Zoological Record*, it would appear that some 360,000 species of animals have been described by naturalists up to the present date. To arrange all these species on a uniform system, and to add descriptions and other necessary particulars to each of them, would appear to be almost an herculean task. Yet it has been undertaken, we are told, by the German Zoological Society, which has entered into an agreement with Messrs. Friedländer and Son for the publication of such a work. Prof. F. E. Schultze, of Berlin, has been selected as general editor of "Das Tierreich," and will be assisted by numerous sub-editors in the different departments of zoology. Each of these sub-editors again will invite the assistance of specialists in the groups assigned to his charge, so that a very large number of naturalists will assist in this gigantic undertaking. It is proposed to issue the first parts of the work in 1897, and it is expected that at least twenty-five

years will elapse before the undertaking can be brought to a conclusion.

On looking down the list of contributors whose services have been already secured for "Das Tierreich," we see, as might have been expected, that they are mostly Germans. But a certain number of English and French naturalists, and some from America and Italy, have already given their adhesion to the plan, and have undertaken to furnish certain portions.

The language employed will be, as a rule, German, but contributions in English, French, and Latin will also be received.

In order to show the general style of the proposed work, Messrs. Friedländer and Son send out along with the prospectus a synopsis of the small group of *Heliozoa*, prepared by Dr. Fritz Schaudinn, of Berlin. So far as we can judge from this portion of the work, the information which it is proposed to give will be exactly what is required for such a manual, and the whole work, if carried out upon this plan, will be of the greatest value to zoologists.

One little criticism we may venture to make on the proposal. The title, we think, is not a very well-chosen one. Bronn's well-known and important work ("Die Klassen und Ordnungen des Thierreichs") has already monopolised the selected name, although in Bronn's days the new mode of writing it had not been introduced. A good Latin title, such as "Synopsis" or "Index Animalium" would have been better, and would have given to the work a more cosmopolitan character. Indeed, we believe that it would have been much better to have used Latin throughout the work, as the common language of science. There are many working naturalists in France, Italy, America, and England who do not understand German. But every one who has been to school acquired sufficient knowledge of Latin to understand a Latin diagnosis. And the proposed work will consist mainly of diagnoses.

NOTES.

THE first of the two annual conversaziones of the Royal Society will take place on Wednesday, May 6. This is the conversazione to which gentlemen only are invited.

MR. W. C. McDONALD has just given the McGill University, Montreal, further reason to be grateful for his unbounded generosity. We understand that he has offered to build and equip a building for chemistry and mining on the same scale as the engineering and physics buildings, which the University owe to his munificence, involving a cost of about £52,000. In addition to this, he has decided to found a chair of Mining Engineering and a chair of Architecture, and has added the sum of £31,000 to the endowment of the University. The completeness and liberality with which the physics and engineering departments of the McDonald buildings are equipped may be judged from an article which appeared in these columns in 1894 (vol. l. p. 558). We cherish the hope that Mr. McDonald's generous benefactions will create a spirit of emulation among those who are able to advance scientific education and research in this country by providing the necessary means.

THE well-known American naturalist, Mr. D. G. Elliot, and party left London for Somaliland on the 27th ultimo. The object of Mr. Elliot's expedition is to obtain a series of antelopes and other larger African mammals for the Field Columbian Museum of Chicago. Mr. Elliot had originally intended to go to Mashonaland for this purpose, but the recent troubles in South Africa induced him to change his plans. He will land at Berbera, and proceed southwards over the high plateau to the Shebeyli River, where he expects to find giraffes and Grévy's zebras. Mr. Elliot will endeavour to return to the coast by the valley of the Juba River, in order to procure examples of the recently-described Hunter's antelope (*Damaliscus hunteri*). Mr. Elliot takes with him a taxidermist from Chicago, and has secured in London the services of Mr. Dodson, who accompanied Dr. Donaldson Smith during his recent adventurous expedition in Lake Rudolph.

THE Liverpool Marine Biological Station at Port Erin is now quite full. The naturalists who have gone there to work, for the Easter vacation, are Prof. G. Gilson (Louvain), Mr. Arnold Watson (Sheffield), Mr. E. T. Browne (University College, London), Prof. Weiss, Mr. Gamble, Mr. Burtt, and Mr. Mellor (from Owens College, Manchester), Mr. Kermode (Ramsey), Mr. Clubb (Liverpool Museum), Mr. C. E. Jones and Prof. Herdman (University College, Liverpool). Several students from University College, Liverpool, are expected later. The tides have been exceptionally low, the weather is good, and the Committee have arranged several dredging expeditions, one of which will be to the deep water between the Isle of Man and Ireland.

THE death is announced of Mr. George Holt, who endowed the chair of Physiology in University College, Liverpool, and contributed altogether about £25,000 to the resources of the College.

ONE of the New York medical colleges has already incorporated instruction in the use of X-rays in surgery as a part of its regular curriculum.

AMONGST the experiments on Röntgen X-rays made during the past month by Italian physicists, several contributions may be cited which either tend to confirm the results established by other workers, or to establish new results. Signor A. Roiti describes (*Atti R. Acad. Lincei*) a series of experiments now in progress bearing on the question as to where these rays emanate. The principal conclusions arrived at are: (1) That fluorescence does not necessarily accompany the emission of X-rays; (2) that the rays are only emitted when kathodic rays impinge on certain substances, notably glass, aluminium, mica, platinum, and porcelain. Signor Roiti establishes some interesting results relating to the leakage of electricity which takes place when X-rays fall on a charged body. When the body in question is placed in a vessel from which air is exhausted, this leakage effect is found to diminish rapidly after the pressure falls below a certain limit, showing that the leakage effect depends on the presence of molecules, by which electricity is conducted from the charged body to the containing vessel.

OUR American correspondent writes, under date March 27:—"Reports are received of the favourable action of the Senate Committee with reference to the proposed National University, preliminary appropriations being recommended for 1897 and 1898. This measure is one which has often heretofore been broached at Washington, and has been so often deferred as to seem to many a hopeless scheme. Present indications, however, point to some real progress, and encourage the hope that something will at last be accomplished.—Progress in science seems to pervade all departments of the Government. Another notable move is the introduction into the Post-office at Washington, of cancelling stamps which indicate every day the weather forecast, and of course the stamps are changed from day to day. This scheme will be put in operation within a few weeks.

"THE site selected for the new free public library of New York, which has recently been so amply endowed, including the Astor and Lenox libraries and the Tilden bequests, is that of the old reservoir on the corner of Fifth Avenue and West Forty-second Street. At a public hearing before the

Mayor of New York, on March 25, the choice was approved by him; and application will be made to the Legislature for permission to use this site, which will no doubt be granted, as the old reservoir is now disused.

"THE annual exhibitions of the New York Academy of Sciences are now the scientific event of the year. The third annual exhibition was held on March 26, at the American Museum of Natural History. As a matter of course, the display of radiographs and radiographic apparatus attracted the most attention, and the lecture of the evening was by Prof. Pupin on the X-rays. A large and interesting array of exhibits was made in other departments. As space forbids any systematic report, a few salient features include the following: The new elements, argon and helium, were shown by electrical illumination, and their spectra exhibited. The astronomical exhibit included fine photographs of star clusters, and spectra of stars, planets, &c. A photograph was shown of a meteor trail at Arequipa, Peru, September 6, 1895. Improved apparatus for investigations in astronomy, physics, and experimental psychology included many novelties. A series of pictures giving restoration of extinct mammals was pronounced by palæontologists the most complete and accurate ever made. The exhibits in geology, mineralogy, and botany were numerous and interesting. President John I. Stevenson made a brief address, appealing to citizens of New York to move in the matter of securing a permanent home for the Academy.

"MR. BRYAN LAWRENCE, who died at New York, March 10, left a large number of bequests to various Roman Catholic charities, including several educational institutions. The larger educational bequests are 5000 dols. each to the American College at Rome, Italy, the R.C. Seminary, Westchester County, N.Y., and the American University (R.C.) at Washington, D.C.—Brigadier-General Thomas L. Casey, retired, for many years chief of engineers of the United States Army, dropped dead in the new congressional library building at Washington, March 25. He was engaged in superintending the construction of the building. The Washington monument, 555 feet high, being the highest structure in America, was completed by him some years ago, after a long delay in the work previous to his connection with it. General Casey was a Fellow of the American Association for the Advancement of Science.

"A NOVEL series of experiments is in progress at Wesleyan University, Middletown, Connecticut, to determine the nutritive and caloric value of food, and many other questions relative to nutrition and other vital processes. For this purpose a calorimeter is employed, consisting of a copper-lined box, measuring inside $7 \times 4 \times 6\frac{1}{2}$ feet, thus giving 182 cubic feet of air, within which space a man is confined for several days at a time. It is fitted with glass windows of three thicknesses. Fifty litres of air per minute are pumped in. Food is passed in three times a day through an air-tight tube, and is carefully weighed, as are all the exudations and excretions, and the quantity of heat is measured. A telephone enables the subject to converse with the outer world. The experiments are conducted by Prof. Wm. O. Atwater, and the expense is shared by the Department of Agriculture of the United States, Wesleyan University, and the Storrs Experiment Station at New Bethel. A careful record is kept of every action of the subject—of his hours of sleep, minutes of exercise, respiration, appetite, &c. To this end there are two watchers and two assistants, a watcher, who is a professor in the university, and an assistant being constantly present."

AT the Royal Institution, on Tuesday next, April 14, Prof. James Sully will begin a course of three lectures on "Child-Study and Education"; on Thursday, April 16, Prof. Dewar will begin a course of three lectures on "Recent Chemical Progress"; and on Saturday, April 18, Prof. W. B. Richmond, R.A., will begin a course of three lectures on "The Vault of the Sixtine Chapel." The Friday evening meetings will be resumed on April 17, when Prof. G. Lippmann will deliver a discourse on "Colour Photography."

THE next course of Cantor Lectures at the Society of Arts will be delivered by Prof. Henry A. Miers, on Monday evenings, April 13 and 20, the subject being "Precious Stones." The points to be dealt with are: (1) The properties which make precious stones esteemed among minerals; (2) the properties by which precious stones are recognised; (3) the distinction of stones which may be confused, as garnet and ruby, jacynth and cinnamon-stone, zircon and lux sapphire, garnet and olivine, tourmaline and diopside, &c. The lecture will close with some remarks on artificial stones. Mr. James Swinburne will deliver a course of Cantor Lectures on "Applied Electro-Chemistry," on Monday evenings, April 27, May 4, 11, and 18. Among the papers arranged for the meetings of the Society after Easter are: April 22, "The Perfected Photochromoscope and its Colour Photographs," by Mr. F. E. Ives; April 29, "Fruit Drying or Evaporation," by Mr. E. W. Badger. Papers at subsequent meetings will be read by Captain Abney, on "Orthochromatic Photography"; by Mr. Hudson Maxim, on "High Explosives and Smokeless Powders"; and by Mr. E. W. Moir, on "Tunnelling by Compressed Air."

THE French Association for the Advancement of Science held its annual meeting at Tunis last week, about four hundred members being present. The office-bearers of the Association were received by the Bey on Wednesday, April 1; and the French resident, M. Millet, welcomed the Congress on the following day. The principal streets of Tunis were elaborately decorated in honour of the occasion, and, as hotel accommodation was limited, the Lycée Carnot was placed at the disposal of visitors. The Association met at Algiers fifteen years ago, so the recent meeting was the second one held on African soil. Next year's meeting will take place at St. Etienne.

ON Thursday, March 26, Prof. Guido Cora, of Turin, delivered a lecture on the "Gypsies" (*Gli zingari*), in the Aula Magna of the Collegio Romano in Rome, having been invited by the Società Palombella (founded for the higher education of women). The lecture was attended by the Queen of Italy, the Minister and the Under Secretary of State for Public Instruction. Prof. Guido Cora gave a short but complete history of the question, dealing also with many facts about the origin, manner and habits of the gypsies in every part of the world. He referred in high terms to many British scholars of the subject, and to the importance of the "Gypsy Lore Society" of Edinburgh.

THE twenty-seventh annual meeting of the Norfolk and Norwich Naturalists' Society was held in the Castle Museum on Monday, March 30, the President (Mr. H. D. Geldart) in the chair. Sir F. G. M. Boileau, Bart., was elected President for the coming session. In his annual address, Mr. Geldart discussed the subject of Arctic distribution of flowering plants, especially with reference to the influence of the glacial epoch upon the flora of the British Isles. He concluded his remarks by suggesting, as a simple and likely solution of the difficulties arising from the present distribution of Arctic and Alpine floras, that before the commencement of the glacial epoch, what is now commonly known as the "Scandinavian" flora, but which would be better called the "Arctic" flora, was distributed from land then existing in the neighbourhood of the Pole; that a part of this flora, being well established,

had held its own without migration even to the present time, and that the hypothesis of destruction and migration of plants from north to south and back again was unnecessary to account for the actual facts of distribution.

In connection with M. Ragonneau's reported explanation of the "mango trick" of Indian native conjurers, it may be interesting to compare his results with Moggridge's observations on the harvesting ants of the Riviera. According to M. Ragonneau, the Indians sow the seed under experiment in earth which has been taken from an ants' nest, and the formic acid present causes it to germinate with extraordinary rapidity, and "grow up into a tree" before the astounded spectator. The French observer states that he has reproduced this experiment in every detail by sowing seeds in earth previously watered with a dilute solution of formic acid. On the other hand, Moggridge found that in seeds stored in the granaries of the Mediterranean ants the process of germination was indefinitely delayed. That their vitality was not destroyed was proved by removing and planting them in fresh earth, when they grew immediately. That ants should be capable of exerting such opposite influences on the growth of seeds is remarkable.

An interesting investigation on the specific heat of solutions has been given by Herr G. Tammann (*Zeitschrift für Physikalische Chemie*). It is well known that weak solutions of certain electrolytes have a smaller capacity for heat than the water present in them possessed previously to the introduction of the salt, and the object of the investigation is to establish a connection between this phenomenon and the contraction of volume which accompanies the process of solution. This contraction has often been accounted for by the hypothesis of a certain internal molecular pressure. Herr Tammann calculates the specific heat of the water present in a number of solutions of this class on the supposition that their pressure is the *increased* pressure postulated by the above theory, and he also calculates the specific heat of the dissolved substance, that of the mixture being deduced by adding the thermal capacities of the two components. The theoretical values thus obtained are found to agree closely with the values experimentally found by observing the solutions themselves, and it is inferred that contraction is the sole cause of the diminution of specific heat arising from the presence of the dissolved matter.

As an addition to the information about Northern Norway, contained in Dr. Reusch's article in Nature of March 5, we give the following data as to cloudiness, communicated to Mr. Lawrence Rotch by Prof. H. Mohn, Director of the Norwegian Meteorological Institute, and sent by him to *Science*. Prof. Mohn writes: "For Sydvaranger, the nearest place to Vadsö at which meteorological observations have been made, the amount of cloud on a scale of 0 to 10, and the chance in percentages of its occurrence are as follows:—

August 8, 8 p.m. Amount of cloud.	Chance.	August 9, 8 a.m. Amount of cloud.	Chance.
10	45·5	10	45·5
8	13·7	9	9·1
7	4·6	8	4·6
5	4·5	7	9·1
3	9·1	6	4·5
2	4·5	4	4·6
0	18·2	3	4·5
		2	9·1
		0	9·1
	100·1		100·1

Sydvaranger lies on the south side of the Varangerfjord, and Elvenes is the name of the posting station. Vardö, lying on the north side, is not to be recommended, having too often fog or clouded sky. In the interior of Finmarken the sun is lower than at Varangerfjord." Although the astronomical conditions of low altitude of sun and short totality are not good, yet Mr. Rotch thinks the meteorological conditions just noted compare favourably with those of stations in Japan, where the eclipse occurs later in the day and totality lasts longer.

From materials collected by the Meteorological Office from merchant ships' logs since the year 1854, from data contained in the logs and Remark Books of the Royal Navy since 1830, and from other sources, the Meteorological Council have prepared monthly current charts for all oceans, which will certainly prove of much value to navigators. The Hydrographic Office of the Admiralty has undertaken to generalise the large amount of material which has been collected, and already the charts for the Indian Ocean have been published. These generalised sheets show the average direction and rate of the currents, and other details; much valuable information has hitherto been masked by the grouping of the data for longer periods. They show, for instance, that near the African coast there is no month between January and July in which the rate of the Agulhas current does not occasionally reach 100 miles in 24 hours, and also that it follows very different routes after reaching the latitude of the Cape. The currents of the Bay of Bengal are shown to be subject to very abrupt changes with the change of the monsoon, but do not follow the precise direction that might be expected. In January there is a well-marked southerly drift near the coast, while in February the current assumes an entire change of direction, and sets to the northward. Similarly, important changes are shown to exist in the current round the southern part of Ceylon.

An ingenious and novel method, which it is hoped may prove of service in distinguishing genuine cholera-vibrios from their numerous rivals, has been recently introduced by Prof. Pfeiffer and Dr. Vagedes. Taking advantage of the now recognised fact, that the serum derived from cholera-immunised animals contains anti-cholera substances, Dr. Pfeiffer has traced the effect produced outside the body from cholera-vibrios when brought into intimate contact with such serum in artificial cultures. For this purpose broth, to which highly active cholera-serum was added, was inoculated with cholera-vibrios, and the effect watched under the microscope in hanging-drop cultures. The vibrios, usually so active, were almost immediately deprived of their powers of movement, and after twenty minutes' exposure to a higher temperature in the incubator, all traces of motility had vanished, although no morphological difference could be discovered in their appearance. When, however, such drop cultures were allowed to remain for twenty-four hours in the incubator, the vibrios were found to have almost completely regained their old activity, indicating that the original inimical effect produced by the serum had to a great extent been overcome. Dr. Pfeiffer states that this remarkable influence of the cholera-serum was only apparent with true cholera-vibrios, all the other numerous descriptions of allied vibrios which were examined being totally unaffected. Further extensive trials must be made before passing a final opinion upon this new method of cholera diagnosis, and Dr. Pfeiffer has expressed his willingness to assist all such investigations by supplying cholera-serum of the requisite degree of strength, to those who desire to carry out similar experiments.

A short paper by Mr. H. W. Seton-Karr, on his discovery of evidences of the palæolithic stone age in Somaliland, appears in the latest number of the *Journal* of the Anthropological Institute (vol. xxv. No. 3, 1896). His observations show that stone implements in Somaliland are found scattered all over the country, but probably mostly below the present surface, within a district included roughly between the Red Sea and lat. 9° 30′ N., and between E. long. 44° and 45°. Dr. Gregory made a collection of obsidian implements in Masai-land, but these were all neolithic; and he points out that, as no palæolithic implements

have been recorded from Tropical Africa previous to those described by Mr. Seton-Karr, if the identification of some of the specimens as palæolithic is verified, the discovery is a very important one.

IN nearly every county of Central and Northern Indiana there occurs a kind of black soil, often spoken of as "bogus land." It is also sometimes called "alkali," but not correctly, for the land has none of the essential characteristics of alkali soil. The improvement of these hitherto unproductive black soils is the subject of a *Bulletin*, by Mr. H. A. Huston, published by the Agricultural Experiment Station of Purdue University, Lafayette, Indiana. It is asserted that thousands of acres of such soil are susceptible of amelioration to such an extent as to be made the most productive maize lands in the State. The use of straw or kainit has proved very profitable as a means of temporary improvement, but for permanent improvement a resort to efficient drainage—and that of a special kind—is essential. It is strongly recommended that, before incurring any other outlay, a preliminary survey of each area should be made, and the system of improvement determined according to the results of such survey.

PROF. H. G. SEELEY, F.R.S., will begin the summer course of lecture-excursions with the London Geological Field Class at the end of April. The subject of the series will be the Physical Geography and Geology of the Thames and its Tributaries. This is the eleventh annual course. Mr. R. Herbert Bentley, 31 Adolphus Road, South Hornsey, N., is the hon. secretary to this society, which gives a systematic course of teaching in the open country.

THE *Proceedings* for 1895 of the Agricultural Research Association, the organ of the Research Station, Glasterberry, Milltimber, Aberdeen, contain reports by the Director, Mr. Thomas Jamieson, on the securing of crops, on the permanence of manure, on the "furrow-system" of sowing grain, on the mechanical conditions of soils as affecting the growth of plants, on the mechanical analysis of soils, and on new manures.

THE Danish Meteorological Institute has recently published a valuable series of observations made in the Isle of Denmark, Scoresby Sound, lat. 70° 27′ N., long. 26° 12′ W. From September 18, 1891, to July 31, 1892, meteorological observations were made every hour, under the direction of Mr. C. Ryder, the chief of the expedition. The mean temperature of the six months from November to April ranged between 1°·4 and – 13°·9 F. From the beginning of May the cold began to diminish, and in July there was only a frost on one day. The absolute minimum occurred on March 7, when the thermometer fell to – 52°, and the absolute maximum amounted to 58° on July 13. The wind was usually very light, while calms were very prevalent, amounting to about 80 per cent. Snow, and occasionally rain, fell on 131 days out of 318; neither hail nor thunderstorms occurred during the period of observation, but fog and mist were very frequent, especially between December and June. Aurora borealis occurred on 142 nights out of 183 between October and March; this phenomenon is made the subject of a special discussion.

THE additions to the Zoological Society's Gardens during the past week include a Moustache Monkey (*Cercopithecus cephus*, ♂) from West Africa, presented by Mrs. Polini; two Rhesus Monkeys (*Macacus rhesus*, ♀ ♀) from India, presented respectively by Mr. C. Harmer and Mr. C. T. Trevalyan; a —— Boa (*Boa* ——) from Dominica, presented by Mr. W. Weldon Symington; a Barnard's Parrakeet (*Platycercus barnardi*) from Australia, deposited; a Raccoon-like Dog (*Canis procynides*) from Japan, two Elliot's Pheasants (*Phasianus ellioti*, ♂ ♀), two Bar-tailed Pheasants (*Phasianus reevesi*, ♂ ♀) from China, two Rosy-billed Ducks (*Metopiana peposaca*, ♂ ♂) from South America, purchased.

OUR ASTRONOMICAL COLUMN.

THE ROYAL OBSERVATORY AT EDINBURGH.—The new Royal Observatory, which has been in course of erection on Blackford Hill, to the south of Edinburgh, during the last four years, was formally opened by the Secretary for Scotland, Lord Balfour, on Tuesday. A short article in the *Times* reminds us that the observatory owes its origin to the presentation to the Scottish nation by the Earl of Crawford of the splendid collection of instruments in his private observatory at Dun Echt, in Aberdeenshire, which was followed by the appointment of Dr. Ralph Copeland, the superintendent at Dun Echt, as Astronomer Royal for Scotland and Professor of Astronomy in the University of Edinburgh in 1889. As there was not sufficient accommodation for the new instruments in the old buildings on the Calton Hill, it was resolved to erect a new observatory worthy of the nation and of Lord Crawford's munificent gift. A Government grant of £33,000, afterwards increased to £36,000, was obtained, and the Town Council of Edinburgh granted on easy terms a site deemed in all respects suitable, on the eastern crest of Blackford Hill, which possesses exceptional stability, a convenient elevation, and unusual purity of atmosphere, the smoke nuisance intruding itself only in one day out of eighteen.

The buildings consist of the observatory proper, the official residence of the Astronomer Royal, the residence of the assistant astronomers, and subsidiary buildings. The observatory is a T-shaped building, the head of the T facing the north with a frontage of 180 feet, and having at each end a telescope tower, of which the eastern is 75 feet high and 40 feet in diameter, and the western is 44 feet by 27 feet. The former contains the most important instrument in the observatory—a new refracting telescope of 15-inch aperture. The latter contains the reflecting telescope, removed from the Calton Observatory, which has an aperture of 2 feet, and which is to be used in astro-physical researches.

Among the other instruments in the observatory are a meridian circle, 8½ inches in diameter; a self-recording anemometer; an ingenious chronograph; the telescope with which the late Prof. Piazzi Smyth made most of his observations on the Calton Hill; several good spectroscopes; a reversing transit instrument; and the clock, connected by wire with Greenwich, which fires the daily time-gun at Edinburgh Castle and drops the time-ball on the Nelson Monument. Connected with the observatory, there is a well-equipped photographic laboratory, and a library with accommodation for some 30,000 volumes, which is already well furnished with the treasures of the Dun Echt collection.

COMET PERRINE-LAMP.—The Perrine-Lamp comet was observed at the Astro-Physical Observatory, South Kensington, on the 1st inst., and spectroscopic observations were made by Mr. Shackleton. On account of the faintness of the comet the spectrum was weak, but a fair amount of continuous spectrum was seen, with three maxima in the green blue, which in all probability correspond to the carbon bands, as they had the same relative positions; this, however, could not be verified by direct comparison.

BOGGIANI'S RECENT EXPLORATIONS AMONGST NATIVE TRIBES OF THE UPPER PARAGUAY RIVER.

THE country along the upper course of the Paraguay has recently been attracting the attention of men of science. A short time ago naturalists were aroused by the wonderful discovery made by Dr. Bohls of *Lepidosiren paradoxa*, that rarest and strangest of fish, living in abundance in lagoons in the Lengua territory of the Gran Chaco, not very far from the right bank of the Paraguay.

I now intend to give a short account of the ethnological results of the explorations of an Italian artist, Cavaliere Guido Boggiani, who, little more than three years ago, lived amongst two of the less-known native tribes, further north, on both sides of the Paraguay River. They are the *Chamacocos* and the *Caduveos*. Boggiani brought home extensive ethnographical collections from both, which he has described in lectures delivered at Rome and Florence, recently published in elegant

and richly illustrated monographs, in which much new information is given on those two previously ill-known tribes.[1]

The *Chamacocos*, of whose singular long-handled stone axes and stone chisel I published an account some years ago in the *Archives internationales d'Ethnographie* of Leyden, inhabit the neighbourhood of Puerto Pacheco, on the right bank of the Paraguay River, now ceded back to Bolivia, their territory lying between 20° and 21° S. lat. They are, however, true nomads, and wander north and south along the main river, but generally from that inland. Their affinities appear to be with the lost *Zamucos*, who formed part of the Chiquitos confederate missions, which flourished about 150 years ago; but up to a quite recent date (*circa* 1885), the *Chamacocos* were quite unknown. The origin of this name is obscure; it is not that by which the tribe calls itself, if such a collective name exists.. Boggiani found that the names *Múria*, *Ibitéssa*, and *Ennima* were given to sections of the tribe.

The first Hispano-American settlers at Puerto Pacheco, who dubbed the natives as *Chamacocos*, became aware of the existence inland of a wilder people, whom they called *Chamacocos bravos*. These were not infrequently raided upon by the *Chamacocos manzos* (*i.e.* civilised), who carried off their children to sell as slaves, and pillaged their camps. Boggiani has found out that this is a kindred but distinct tribe from the *Chamacocos*, speaking a different language; their true name is *Tumanà*, and it appears that the singular long-handled stone axes, which have come into European hands through the *Chamacocos*, are mostly, if not all, taken from them. Further inland, beyond the *Tumanà*, Boggiani was informed that an agricultural settled tribe, the *Tinnàru*, lived, in whom he suspects the real descendants of the *Zamucos* may be found.

The Bolivian settlement at Puerto Pacheco was formed in 1885; it had hardly begun to prosper when the Paraguayans took possession, and re-named the place Bahia Negra. A few years later, Boggiani and an Argentine friend got a concession from the Paraguayan Government, and formed two wood-felling stations in the neighbourhood. It is thus that my friend came in contact with the *Chamacocos*, most of his workmen belonging to that tribe. Boggiani's descriptions of the country and the natives are vivid, the fruit of a refined artist's genuine admiration of a virgin country and wild men. These he depicts as splendid specimens of humanity; tall, perfect in shape, with skin of a bronzed reddish tinge; long black hair, worn tied in a knot behind, in a thick queue, ornamented with feathers, or flowing loose. The women, who, as usual amongst savages, are the beasts of burden, are less handsome, and wear their hair short. No clothing is worn by either sex, except rough sandals of Peccary skin when on the tramp, and a profusion of feather ornaments and necklets of seeds, &c., on festive occasions. As most of the natives of tropical America, the *Chamacocos* excel in the "Arte Plumaria," and it would be difficult to describe in words the beauty of their combinations of bright-coloured feathers of the parrots, toucans, and trogons, with the grey of the rhea, the glossy black of the musk duck, the lovely pink of the spoonbill, and the white plumes of the egrett. Amongst other curious ornaments, one of the strangest is the rattle of the *Crotalus*, for which these people have quite a predilection; for I have seen it dangling amongst feathers in diadems, armlets and leglets, united in bunches as ear-pendants (Fig. 1), and even tied on axes or clubs. I have never heard of other American tribes putting the caudal appendage of the dread rattlesnake to such use. During their dances the *Chamacocos*, besides small gourds containing stones, use belts made with loosely-strung carapaces of small tortoises, or the hoofs of stags. They make rude pottery with the hand, the potter's-wheel being quite unknown to them.

Formerly the *Chamacocos* lived in constant dread of the *Mbaya* or *Caduveos*, then a powerful predatory tribe, located on the opposite side of the Paraguay River, but who frequently raided the Chamacoco territory, carrying off young men and women as slaves. Now the white man, with his diseases and evil propensities, is their worst foe. Boggiani, however, appears to have been a general favourite with them. From his descriptions, the *Chamacocos* appear to be, on the whole, an inoffensive and happy people, and show off their exuberant spirits in frequent dancing and singing bouts. They have various games, one of which may be described as a kind of lawn tennis.

[1] Guido Boggiani. "I Ciamacoco, Conferenza" (Roma, 1894): "Viaggi di un artista nel l'America meridionale, I Caduvei" (Roma, 1895); "I Caduvei, studio" (Roma, 1895).

Besides the singular stone axes with long, flat hard-wood handles, which appear to belong properly to the *Tumanà*, are called *Nò scico*, and may be considered more like war-clubs than cutting implements, the weapons of the *Chamacocos* are plain clubs, wooden spears, large bows for shooting arrows pointed with hard wood, and small bows with a double string, used for shooting clay bullets; these for catching birds.

The women make neat bags and reticules of different kinds of netting, also hammocks, used generally for wrapping and carrying larger parcels. The *Chamacocos*, like most savages, make fine cord of various kinds, using mostly the fibres of the *Ybira*: the weaving loom is unknown to them. Their food is heterogeneous, but they have curious superstitions regarding some kinds; thus deer-flesh is only eaten by men, whilst women can feed on birds and small game; children cannot partake of the eggs of the ostrich (*Rhea*). Boggiani has also collected a small vocabulary of the hitherto unknown language of these people.

Boggiani spent two months and a half with the *Caduveos* of the Nabilecche River, mostly at their principal village Nalicche, living as one of them, and enjoying most favourable opportunities for studying the manners, customs, and character of this once powerful and partially civilised tribe, now sorely reduced in numbers and on the wane. It is strange how little has hitherto been known of them and of their country, so much so that even on recent maps the Nabilecche, which runs into the main stream of the Paraguay River some 10 or 12 kilometres north of Fort Olimpo, in Brazilian territory, is not only misplaced but considered a mere branch of the Paraguay. Nalicche is not on the

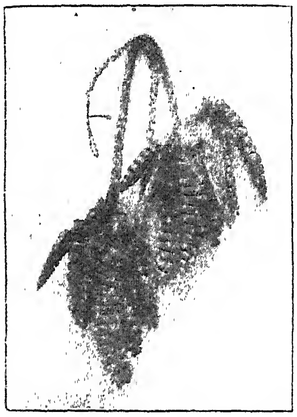

FIG. 1.—Chamacoco ear-pendants of rattlesnake tails.

banks of the Nabilecche, but some distance inland, half way to the Miranda mountains. It consists of a single row of huts slightly bent, united under a common roof of *Yatai* palm-leaves; at the back, separated by boards, are the true huts; the front forms a kind of covered corridor, continuous right through. In front is a square, kept quite clean, at the lower end of which is a spring, which gives the water supply to the village. The country around is a fine wooded and grassy undulated plain, on which the cattle and horses of the *Caduveos* graze. In cleared portions of the adjoining forest are the fields, in which each family cultivates the necessary crops of mandioca, maize, rice, gourds, and sugar-cane, besides papaws and bananas. Poultry and numerous mangy cur-like dogs complete the list of domesticated animals.

The *Caduveos* are known also under the names of *Mbayas* and *Guaycurù*: this last is erroneous, it is the Guarany for "savage." Boggiani believes that they came across the Chaco, and were once in contact with the civilised tribes of Peru; I can hardly follow him as far as that. It is evident, however, that amongst the surrounding wild nomadic tribes the *Caduveos* emerged as a warlike but agricultural people, with fixed residences and certain industrial arts, such as weaving and pottery; in this they excel even to this day. The beauty and variety of their ornamental designs is truly wonderful; Boggiani, as an artist, was particularly struck with this remarkable development in a savage people, and he gives quite a series of fine drawings in illustration of the artistic taste and invention of the *Caduveos*, to be seen on their earthenware and in their very elaborate body and face

painting. As Boggiani justly observes, the decorative art of the *Caduveos* is not the casual result of a complication of rude and primitive designs, but that of a logical study of the harmony and æsthetic combination of lines and figures.

Boggiani, after a long and careful comparative study of the ornamental designs of the *Caduveos*, comes to the conclusion that they show distinct affinities with ancient Peruvian art. In a paper read in September last, at the Italian Geographical Congress,[1] he gives a very interesting account of ornamental designs found on the skin of Peruvian mummies, and comes to the opinion that they were painted, not tattooed, the designs and the process being similar to that practised by the modern *Caduveos*, who stain their skin with the juice of the *Genipa* in ornamental designs of a blue-black colour, which penetrates partially the epidermis, and is sufficiently durable, lasting six or seven days; as the staining process of Genipa-juice, darkening by the action of light, is rather slow, powdered charcoal is added to heighten the effect. The instruments used are small sticks, to the end of which a tuft of cotton-wool is in certain cases tied; the artists are women. A red dye is obtained from the well-known *Urucú* or *Bixa orellana*, but it is far less durable. The *Caduveos* paint thus the feet and lower part of the legs, besides the face; the designs vary *ad infinitum*.

Boggiani describes the *Caduveos* as tall and well-made, of a light bronze colour; the hair is worn short and well combed and greased; the upper incisors are filed to a point; depilation is scrupulously practised. They are cleanly, often bathing and washing their bodies. The men wear a piece of cotton cloth from the waist downwards, held by a belt, richly decorated; the women have, besides, an upper garment covering the breast. Often both men and women have also a kind of *poncho*, which hangs from the shoulders, leaving the arms free. Necklaces, bracelets, and ear-pendants of beads or silver tubes are universally worn; they make their silver ornaments with skill and taste. The men smoke tobacco in cigarettes or in wooden pipes, tastefully carved in wood; the women only chew tobacco. The *Caduveos* were not many years ago skilful weavers of cotton cloth; at present the advent of cheap cotton textiles from Europe has virtually destroyed the native art. Boggiani was, however, able to secure some specimens, and the weaving and spinning apparatus.

As I have noted already, it is in the potter's art that the *Caduveos* excel; it is also the work of women; the ornamentation is rich, varied, and quite peculiar. The designs are traced on the unbaked clay with a cord; red is obtained with oxide of iron, black with the resin of *Palo santo*, white with a kind of chalk. The earthenware of the *Caduveos* presents a large variety in shapes and sizes. The only neighbouring tribe who do anything of the kind are the *Guanà*, but their ware is inferior in all respects.

The *Caduveos* now possess European weapons; bows and arrows are, however, yet in use for the chase and for fishing. Boggiani was able to secure a few rough stone axes, but they were designated as "sky stones," and used for crushing nuts. The *Caduveos* have canoes or dug-outs of different sizes, which they manage with skill. The chiefs, and their descendants also in the female line, form a sort of nobility, now more numerous than the commoners; the lower caste is formed by slaves, often the descendants of captured *Chamacocos*. The head chief is called *Mbaya*, a name which is also applied to the whole tribe; his authority is not great, and much freedom exists amongst the heads of families; even the slaves are well treated, and often ultimately are considered free. One wife is married, and the bridegroom goes to live in the house of the bride, taking with him the family poles, which are driven in the ground in front of the sleeping-place of the newly-married couple; these poles are carved with totemistic designs.

Fig. 2.—Caduveo decorated pottery.

The *Caduveos* are at present much reduced in numbers, and Boggiani foresees their speedy extinction. Many are the causes which have led to this, derived from the contact with the whites; but it must not be forgotten that abortion and infanticide are, unfortunately, but too frequent amongst the *Caduveo* women, who only care to rear one child. They are, besides, cursed with the red man's love for strong drinks. Otherwise they are gay and sociable, delight in dances to the sound of drum and flute, and in a game very much like golf; pugilistic bouts, *coram populo*, are also in great favour, in which men, women and children join.

The *Caduveos* have medicine-men or sorcerers, who monopolise the spiritual and mystic rites, and effect cures. One, whom Boggiani saw practising with a piece of a glass mirror and a bunch of feathers on a dark night, was a *Chamacoco*.

Boggiani writes well, he is a careful observer, and has proved himself an excellent collector; he is to be sincerely congratulated on the good work he has hitherto done for ethnology, and we cannot but cordially join in the hope he expresses of being able to continue and complete his investigations of the native tribes of the Northern Chaco and adjoining regions.

Henry H. Giglioli.

A NEW HUMAN SKULL OF A LOW TYPE FROM BRAZIL.[1]

A LOW type of human skull has recently been described by Prof. A. Nehring, which was found near Santos, in Brazil. It occurred in a breccia ("sambaqui"), the exact age of which is uncertain, associated with fish vertebræ, a portion of the lower jaw of a toothed-whale, and a few fragments of other human remains and implements.

The principal measurements given are the maximum length (183 mm.), maximum breadth (135 mm.), minimum frontal (88 mm.), maximum frontal (92 mm.), frontal sagittal arc (118 mm.), and the parietal arc (134 mm.) The cephalic index is thus 77·6. Virchow has also described two skulls from a sambaqui near Santos, with indices of 82 and 79·8; while de Lacerda measured three male skulls from sambaquis in Parana and Santa-Catherina, with the indices of 67, 68·8, 77·2, and two female skulls with 79·7 and 81·4. There is thus great variation among these people, which Nehring regards as individual or partly sexual, and not due to ethnical mixture.

The forehead is low and retreating, the glabella and orbital ridges well developed, and the frontal is greatly constricted behind the orbital region, as in Pithecanthropus. This constriction is also very characteristic of ancient and recent South American skulls (Peixoto and de Lacerda), some of which are absolutely and relatively not broader than Pithecanthropus.

Dr. Nehring, from his studies on the skulls of both sexes and various ages of anthropoid apes and of dogs of different breeds, is of the opinion that the occurrence of a constriction between the orbital and cerebral portions of the skull has direct relation to the strength of the head musculature, and more especially of the jaw muscles. If the skull of a muscular Eskimo dog be compared with that of a pug or a Bolognese lap-dog, it will be found that this constriction is very marked in the Eskimo dog, the zygomatic arches of which are widely outstanding, and all the muscular attachments strongly developed; but the constriction is scarcely noticeable in the pug, and is entirely wanting in the Bolognese lap dog; the two latter exhibit feminine rounded forms of the corresponding parts of the skull, with a feebly developed musculature.

The author compares human skulls with those of middle-aged female chimpanzees and gibbons, and finds a great similarity in the constriction of their respective frontal bones. He justifies this comparison by pointing out that the human skull always remains in a juvenile stage, while that of the ape, especially the male, is strongly modified by the jaw and neck muscles. The human condition is accounted for by the erect position, with the consequent balancing of the skull on the vertebral column, and the reduction in the dentition owing to the artificial preparation of food. According to Nehring, the constriction of the orbital portion from the cerebral portion of the skull of Pithecanthropus does not prove a simian origin.

The face of the sambaqui cranium is strongly prognathous; perhaps this is increased by an abnormality in the arrangement of the teeth, there being seven upper incisors, of which two are placed behind the others, and the third is in the middle of the normal series and has a curious curve on its anterior aspect. Only one of the normal teeth is slightly displaced. Nehring does not regard these as persistent milk-teeth, but as supernumerary teeth.

The whole dentition is strong, in fact it is one of the most powerful of known human dentitions, and the two molar series are parallel to each other, and are not in the form of a horse-shoe. All the teeth are perfectly sound.

The dimensions of the pre-molars and molars come very close to those of Spy No. 1 skull, any difference there may be being in the direction of the dentition of Spy No. 2; thus we find that the exceptional size of the wisdom-teeth in the Spy skulls is also characteristic of the sambaqui cranium.

While the length-breadth dimensions of the new skull agree fairly closely with those of Pithecanthropus, the cranial height is considerably higher, and consequently the capacity, if it could be measured, would be much greater. Looked at from above, the skull is better filled than that of Pithecanthropus, both posteriorly and in the anterior temporal region; there is also a marked difference between the orbital portion of the frontal bone, which somewhat resembles that of the Neanderthal calvaria, and the flat projecting character of that region in Pithecanthropus erectus.

A. C. Haddon.

[1] Prof. A. Nehring: "Menschenreste aus einem Sambaqui von Santos in Brasilien, unter Vergleichung der Fossilreste des Pithecanthropus erectus Dubois." *Verhandl. Berliner anth. Gesellsch.*, 1895-6, p. 710.

THE SURFACE-DIMENSIONS OF AN EARTHQUAKE-PULSATION.

IT is now well known that the effects of a great earthquake are not confined to the more less limited area over which it is perceptible to human beings, or capable of disturbing seismographs. With suitable instruments, the oscillations may be traced for thousands of miles, and there is no reason whatever for doubting that in the future they may be traced (possibly several times) completely round the globe. As to the exact nature of the pulsations, we are still in partial ignorance; but part of the movement certainly consists of a real tilting of the surface of the ground. Prof. Milne regards earth-pulsations as long, low waves, somewhat resembling an ocean-swell; and the object of this short note is to show that, in one case at any rate, his view is correct.

On April 27, 1894, a severe earthquake occurred in North-east Greece, and the pulsations were observed in Birmingham with one of Mr. Darwin's bifilar pendulums (Nature, vol. l. pp. 7, 246–9). The average period of the pulsations was fourteen seconds, and the maximum change of inclination of the ground in the east and west direction was not less than one-quarter of a second. A comparison of the times at Athens, Birmingham, and other places, shows that the velocity of the first large pulsations was nearly constant, and equal to 3·21 km. per second.

Assuming the form of a right section of the pulsation to be a simple harmonic, the length of a complete pulsation is vt km. where v is the velocity in km. per second, and t seconds the duration of its period. The amplitude of the pulsation, *i.e.* the height of its crest above the position of equilibrium, is easily shown to be $\alpha vt/6^4$ metres, where α seconds is the maximum tilt of the ground with reference to a horizontal plane. In the case of the Greek earthquake, we have $t = 14$, $v = 3{\cdot}21$ and α not less than $\frac{1}{8}$. These figures show that at Birmingham the length of a pulsation must have been 45 km., and the height not less than 4·4 mm.

The estimate of the height is not great enough for two reasons: (1) owing to its suspension in oil, the mirror of the pendulum was unable to perform its full swing during the brief period of the pulsation; and (2) the pendulum showed only the component of the tilt in the east-west plane. When the frame of the pendulum is suddenly tilted through an angle of 2″, the deflection of the mirror at the end of a quarter of a minute is only half the correct amount. If, therefore, we multiply the above result for the height by 3, we shall probably be not far from the true value.

Thus, translated into ordinary units, the largest pulsations of the Greek earthquake at Birmingham must have been about 28 miles long and half an inch in height.

Charles Davison.

SCIENCE IN THE MAGAZINES.

WITH an article on "The Evolution of the Professions," Mr. Herbert Spencer concludes the series of papers on professional institutions which he has been contributing to the *Contemporary* for some months. The fact which the whole of the papers have aimed at showing, and which is illustrated by the present article, is that society is a growth, and not a manufacture, and has its laws of evolution. "From Prime Ministers down to ploughboys," we read, "there is either ignorance or disregard of the truth that nations acquire their vital structures by natural processes and not by artificial devices. If the belief is not that social arrangements have been divinely ordered thus or thus, then it is that they have been made thus or thus by kings, or if not by kings then by parliaments. That they have come about by small accumulated changes not contemplated by rulers is an open secret which only of late has been recognised by a few and is still unperceived by the many—educated as well as uneducated." In support of this law of the evolution of society, Mr. Spencer cites numerous instances drawn from agriculture, manufactures, commerce, and various professional institutions where advancement has been achieved by spontaneous co-operation of citizens, and not by legislative direction. We have "knowledge developing into science, which has become so vast in mass that no man can grasp a tithe of it, and which now guides productive activities at large, has resulted from the workings of individuals prompted not by the ruling agency but by their own inclinations." So, and in like manner, it is held that the unprompted workings of humanity, and not time-serving legislation, are responsible for real social progress.

Prof. James Sully contributes an amusing article to the *National Review*, on "The Humorous Aspect of Childhood." Some of the stories he tells in illustration of the simplicity and openness of child-nature deserve repetition here. The little boy who, in describing a fat lady, said she was just like a seal, used a singularly appropriate simile; for the human figure bereft by its obesity of the neck and waist divisions does grow seal-like. Then the purely arbitrary character of many of our language-forms affords opportunities for such remarks as that of the small boy who spoke of Charles the First's body having been cut off from his head. Another example of this childish tendency to rearrange things is supplied by the remark of a boy of five, who being asked whether the baby was christened, answered with alacrity, "No, she isn't christened, but she's vaccinated." Children are entirely anthropomorphic, believing that things about them have some mysterious relation to them. This is exemplified by the story of a child who quaintly remarked to an older child that seemed frightened on hearing about earthquakes, "They don't have earthquakes in little towns like this." Prof. Sully remarks on this: "The words suggest that the little comforter conceived of the earthquake as something which was specially designed for human spectators, to throw them into cold shudders, or possibly to electrify them with the delicious excitement of danger, according to their temperaments, and which would not therefore be brought on the scene where there was not a full house, so to speak. The saying seems to me full of the characteristic quaintness of child-thought. It is so deliciously comical to us who know, or fancy we know, what these alarming oscillations of the earth's surface really are, to have them thus turned by the naive conceit of the child-mind into a kind of show. Yet may we not here too detect an exaggeration of something in older people's thought about the universe, and in smiling at the crudity of the child's whimsical fancy be half-quizzing our own occasional lapses from the perfectly detached and unimpassioned point of view of science?" All who are interested in child-thought and child-observation should read Prof. Sully's collection of stories. The pity of it is that our educational system should so effectually crush the faculties of quick and acute observation and logical reasoning possessed by children.

Prof. John Trowbridge describes experiments with Röntgen rays in *Scribner's Magazine*, under the title "The New Photography by Cathode Rays." He refers to the new actinic rays as "cathode rays" throughout his article. An interesting illustration accompanying his article is a double picture of the Röntgen shadow of a turkey's wing, taken by rays from two cathodes slightly separated from one another. By measuring the distance between the double images, the depth of the shot can be estimated by triangulation.

Among the articles of minor scientific interest, we notice one on the boundary dispute between Great Britain and Venezuela in the *National*, by the editor, Mr. L. J. Maxse. This is accompanied by two maps from the recent Venezuela Blue-book. In *Longman's*, Mr. Fred Whishaw has a sympathetic paper on life in a pine-forest in winter. *Chambers's Journal* has its usual complement of information articles, the most noteworthy being on "Toad-Lore," "Modern Gunpowder and its Development," "Pets and Pests in Barbadoes," and "Bird-Catching in Heligoland." The *Humanitarian* has two papers on "University Degrees for Women," in one of which Dr. A. W. Verrall states the case for degrees, while Mrs. B. J. Johnson writes for the opposition. In the *Strand Magazine* is an instructive account of "Diamond Mining in South Africa," by Mr. J. Bucknall Smith. Finally, scientific phonographers will find much to interest them in the clearly-printed pages of the *Phonographic Quarterly Review*.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

The Education Bill of Sir John Gorst, to which reference has already been made in these columns, makes, it is true, several provisions for secondary education, but it can hardly be supposed that the comparatively few recommendations under this heading are to be the only outcome of the prodigious labours of the recent Commission. The county education authority, the constitution of which was explained in a note last week, may, amongst other matters, aid any school in the provision of secondary education, or, with the consent of the Education Department, may take a transfer of any secondary school. It may also establish such schools; found and maintain scholarships or exhibitions; supply, or aid in supplying, teachers; make inquiries with respect to the sanitary condition of the school-buildings (including boarding-houses) of any school within their county; and make inquiries with respect to the education given by any school within their county. Schools which in the opinion of the Education Department are of a non-local character are, however, excepted. The education authority may then take such measures as they think fit for giving information to the public with respect to the result of such inquiries. The county education authority is to be given power to *aid* any establishment or organisation for the training of teachers, but there seems to be no provision for the formation of new training schools or colleges. Provision is made for the transfer of higher grade board schools to the county authority, either at their own request or that of the School Board concerned. If the education authority desire, they may make it one of the conditions of any grant to a secondary school that representatives of the authority be added to the trustees or governing body of the school. The consent of the trustees being given, such representatives will become for all purposes members of the governing body of the school. It is further arranged that the amount which can be raised under the Technical Instruction Act, 1889, shall not be exceeded. One satisfactory point is that, in the event of this Bill becoming law, it will be impossible to have any further diversion of the money available under the Local Taxation Act, 1890, to purposes other than those of education. These funds are, moreover, to be in the future available for all degrees and kinds of secondary education, and not only for technical instruction.

At the meeting of the Manchester City Council, held on Wednesday, April 1, Mr. Alderman Hoy reported that the Co-ordination Sub-committee of the Technical Instruction Committee had been dissolved. This Sub-committee was composed of representatives of the principal educational institutions in that city, and has been successful in arranging for the better co-ordination of the spheres of work of these institutions, and has so prevented over-lapping. It has been successful in bringing the School Board into line with the work of the Committee specially concerned with technical education, and has done very valuable work in other ways. We hope to see other large towns following the example thus successfully set by Manchester, for it is certain that by friendly conferences of this sort the best results for education will be obtained. It has been decided to appoint an Advisory Committee in the place of that dissolved, which will comprise the Chairman of the Technical Instruction Committee (Mr. Alderman Hoy), the Chairman of the School Board, the Principal of Owens College, and the High Master of the Grammar School. This Sub-committee will have power to call together the General Committee whenever they deem it necessary in view of any educational emergency.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, vol. ii. No. 6, March 1896.—"The three great problems of antiquity considered in the light of modern mathematical research" is a review, by Miss C. A. Scott, of Prof. Klein's Festschrift for the third meeting of the Association for the Advancement of Mathematical and Scientific Teaching in the Gymnasia, entitled "Vorträge über ausgewählte Fragen der Elementargeometrie." Of course the problems intended are the duplication of the cube, the trisection of an angle, and the quadrature of the circle. The pamphlet is divided into two parts: the first deals with algebraic numbers, the second with transcendental numbers. The analysis is very full, so that the reader gets a thoroughly good idea of Prof. Klein's work. "But while reading this brilliant exposition it is difficult to avoid cherishing a lurking regret, which is possibly very ungracious, that Klein could not himself spare time to arrange his work for publication; for though we have here in full measure the incisive thought and cultured penetration which together make even strict logic seem intuitive, yet at times we miss the minute finish and careful proportion of parts that we feel justified in expecting from him. And yet revision and consolidation might have seriously interfered with the graphic simplicity of these chapters, and left them less adapted to their special purpose." From Miss Scott's account we are thoroughly disposed to endorse her wish that the

pamphlet should be translated for the use of corresponding English associations. Why should not she undertake the task, if she has the leisure?—Prof. A. S. Chessin gives an abstract of Painlevé's Leçons sur l'intégration des équations differentielles de la Mécanique et Applications, and of his Leçons sur le Frottement.—The other articles are a geometric proof of a fundamental theorem concerning unicursal curves, by Prof. Osgood; Notes on the expression for a velocity-potential in terms of functions of Laplace and Bessel, by Prof. J. McMahon, and an additional note on divergent series by Prof. A. S. Chessin.—In the Notes we are told that the German Mathematical Society, at its meeting held at Lübeck, in September last, decided to combine in one volume the official reports of the Vienna and Lübeck meetings.—A list of papers, in addition to that given in vol. i. of the *Bulletin*, completes the tale of papers read at the Vienna meeting (1894), and the titles and names of authors for the Lübeck meeting are also given here.

American Meteorological Journal, March.—The diurnal oscillation of atmospheric pressure at the Peruvian stations of Harvard College Observatory, by Prof. S. I. Bailey. (A note upon this paper will be found in our issue of March 26, p. 493).—Cyclones and anticyclones, by Prof. H. A. Hazen. The author gives an epitome of the theories and researches of the principal investigators, and makes a special appeal for further atmospheric exploration. He considers that the most promising line of research is in connection with the observation of atmospheric electricity, and some useful hints are given with reference to the most promising means of increasing our knowledge by observations on high mountains and balloons, either manned or carrying recording instruments only.

Himmel und Erde, March.—This number contains many attractive contributions.—Herr Paul Spies writes on the Röntgen X-rays, this article being the sum and substance of a lecture delivered by him in the Urania at Berlin. Johann Christian Doppler and the "principle" connected with his name is the subject treated of by Dr. Julius Scheiner. That which is generally known about Doppler's life has been drawn from the biographical notice contained in the almanack of the Kaiserl. Akademie der Wissenschaft in Wien, which was written by the, then, general Secretary of the Academy, Prof. Strotter. With the help of Prof. Safarik, Dr. Scheiner is here able to increase our information on many points of interest, by publishing for the first time some characteristic notes gathered from Prof. Koristka, of the German Polytechnic in Prague.—The *Mitteilungen* contain several astronomical notes. A reference, with an illustration, is made to the Fabricius monument which was erected at Osteel last November. This monument consists of the goddess of astronomy in a sitting position, and looking towards the sky, holding in her right hand a small telescope, and supporting with her left a tablet on which in relief is seen the solar disc with some spots on his surface. The time of rotation of Jupiter and the cosmical origin of meteors form subjects for the next two notes, the latter referring more especially to Niessl's investigation, which appeared in the *Denkschriften der Wiener Akademie*. Two other notes refer to the "Internationale Erdmessung" and to the possible inconstancy of the length of a day, this latter having been raised by Prof. Deichmüller, who considers that very small secular variations may be present, although they have not as yet been detected.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 19.—"On the Spinal-root Connections and Ganglion-cell Connections of the Nerve-fibres which produce Contraction of the Spleen." By Prof. E. A. Schäfer, F.R.S., and B. Moore.

We have investigated, in four dogs, the effects upon the spleen volume of excitation of the thoracic and lumbar nerve-roots.

The following are the results which we have obtained from excitation of the nerve-roots from the second postcervical to the fifteenth postcervical inclusive. In none of the four experiments did excitation of the *second* postcervical (second dorsal) pair produce any contraction of the spleen. In none of the four experiments did excitation of the *fifteenth* postcervical pair produce any contraction of the spleen. In three out of the four experiments a distinct contraction of the spleen was got on stimulation of all the roots on both sides from the third postcervical to the fourteenth postcervical inclusive. This effect was relatively smaller on stimulation of the third and fourth postcervical nerves and of the eleventh to the fourteenth postcervical than on stimulation of the intermediate pairs, the most marked effects being obtained from the sixth, seventh, and eighth pairs. In all cases the effect was got, as already stated, from the nerve-roots of *both sides*, but with each nerve pair it comes out as an almost constant occurrence that a decidedly less marked effect is obtained with the same strength of stimulus upon the right side than upon the left.

We have found that after intravenous injection of small doses of nicotine, the effect upon the spleen of stimulating the nerve-roots may entirely disappear, while stimulation of the splanchnics is still quite effective. We infer, therefore, that the nerve-fibres which produce contraction of the spleen have a cell station in the prevertebral chain of ganglia.

"Problems in Electric Convection." By G. F. C. Searle.

The paper contains an investigation into the distribution of electric and magnetic forces which are called into play when some electro-magnetic systems are made to move with uniform velocity through the ether. Maxwell's theory is employed in obtaining the fundamental equations, and it is found that though the electric and magnetic forces, E and H, have generally no potential, still they can be derived from two functions Ψ and Ω; the differential equations satisfied by these functions are obtained, and are employed to obtain the solutions for various cases and conditions.

Zoological Society, March 17.—Prof. G. B. Howes in the chair.—Mr. Sclater called the attention of the meeting to the prospectus of the great work of the German Zoological Society, to be called "Das Tierreich," spoken of at the last meeting, and gave some particulars as to the mode in which the plan was intended to be carried out. Mr. Sclater also called attention to the appointment of a Committee on Zoological Nomenclature at the International Zoological Congress held at Leyden last year.—A communication was read from Lieut.-Colonel C. T. Bingham, containing a contribution to the knowledge of the hymenopterous fauna of Ceylon.—A communication was read from Mr. Edward T. Browne, on British Hydroids and Medusæ. Mr. A. Smith Woodward read a paper on some extinct fishes of the Teleostean family Gonorhynchidæ.

Entomological Society, March 18.—Prof. Raphael Meldola, F.R.S., President, in the chair.—Mr. C. G. Barrett exhibited a series of drawings of varieties of British Lepidoptera in the collection of Mr. S. J. Capper, of Huyton Park, Liverpool. The drawings, which were beautifully executed, were by Mr. S. L. Mosley, of Huddersfield, and comprised 389 figures, representing 139 species, of which 33 were butterflies and 50 moths.—Mr. J. J. Walker, R.N., exhibited a specimen of *Procas armillatus*, taken on Durland Hill, near Chatham, during the present month.—Herr Jacoby exhibited a specimen of *Loxoprosopus ceramboides*, Guér., from Brazil.—Mr. E. E. Green exhibited the eggs of some species of Locustidæ extracted from the stem of a young cinchona tree at Punduloya, Ceylon. He said the species of the parent insect was undetermined; it was possibly either a *Cymatomera* or a *Cyrtophyllus*, both of which possess large sabre-shaped ovipositors. A slit half inch deep and more than two inches long had been cut into the hard wood, in which the eggs had been symmetrically deposited, edge to edge, with the coloured part inwards. The greater part of each egg was of fine texture, and coloured green; but at the extremity from which the young insect would make its exit the egg-shell was soft, pliant, and beautifully reticulated. Mr. McLachlan and Dr. Sharp, F.R.S., made some remarks on the subject.—Mr. Green read a short paper entitled "Notes on *Dyscritina longisetosa*, Westw." He remarked that drawings of the species had been exhibited by him at a recent meeting of the Society. Dr. Sharp said Mr. Green seemed to think that the insect was an earwig, but he could not accept it as belonging to the Forficulidæ. He thought that further specimens for examination were required before attempting to determine its position, which was quite doubtful at present.—Mr. W. F. H. Blandford communicated a paper entitled "Descriptions of New Oriental *Scolytidæ*."

Linnean Society, March 19.—Mr. C. B. Clarke, F.R.S., President, in the chair.—Mr. Clement Reid exhibited fruits of *Naias marina* from a peaty deposit below mean-tide level in the new docks at Barry, South Wales. In Britain it had only been found living at a single locality in Norfolk, but in a fossil con-

dition it had been obtained in the pre-glacial forest-bed at Cromer.—Mr. Clement Reid also exhibited some wood forwarded by Mr. H. N. Ridley from the jungle near Singapore. It appeared to have been eaten into a honeycombed mass of peculiar character, and was found only in wet places, but always above ground, the entire tree rotting. Neither Mr. Ridley nor Mr. Reid had seen anything like it in England; and the latter, while suggesting that the small lenticular unconnected cavities in the wood were probably caused by insects or their larvæ, thought they were unlike the work of either beetles or white ants.—A paper was read by Dr. Otto Stapf on the structure of the female flowers and fruit of *Sararanga*, Hemsley. The materials utilised consisted of female flowers and fruits of *Sararanga sinuosa*, Hemsley (*Journ.* Linn. Soc., vol. xxx. p. 216, t. 11), which had been collected by the officers of H.M.S. *Penang* in New Georgia, Solomon Islands, and were in excellent preservation. There were also photographs and a description, taken upon the spot, of the tree, about 60 feet high, shortly branched at the top, with terminal, nodding, white-flowered, very compound, and gigantic panicles. The leaves are like those of an ordinary screw-pine. The flowers consist of a rudimentary, sinuously bent, saucer-shaped perianth, and a sub-globose, sinuously lobed gynæcium, with very numerous (70–80), dark, discoid, or reniform stigmas which are arranged in double rows over the dorsal ridges of the main body and the lobes, having between them minute pores which end behind some way below the surface. There are as many ovary-cells as stigmas, each containing one anatropus ovule from the base of the inner angle. The vascular bundles of the gynæcium end below the stigma in a cluster of tracheids, and supply it probably with a viscid or sugary liquid. The base of the pore is surrounded by a compact, thin-walled parenchyma, very rich in plasma. It is suggested that the pollen-tubes grow from the stigma down into the pore, and descend from here through the conductive tissue to the ovule. The ripe fruit is a succulent drupe with numerous pyrenes, in shape like the flower, but much larger. The endocarp is bony, the albumen copious and oily; the embryo is as in *Pandanus*. The complex structure of the flower is explained as a modification of the type represented, *e.g.* in *Pandanus utilis*, and in accordance with Count Solms-Laubach's theory of the flower of the Pandanaceæ. On this paper some critical remarks were offered by Mr. Rendle.—On behalf of Mr. G. S. West, a paper was read by Prof. Howes on two little-known Opisthoglyphous Snakes. The author had examined and compared, in respect of the structure of the buccal glands and teeth, specimens of the grooved and non-grooved varieties of *Erythrolamprus æsculapii*, as recorded by Dr. Günther ("Biologia Centr.-Amer.," part cxxi. p. 166), and he proved that the latter were rightly referred to the species.

Geological Society, March 25.—Dr. Henry Hicks, F.R.S., President, in the chair.—On submerged land-surfaces at Barry, Glamorganshire, by A. Strahan, with notes on the fauna and flora by Clement Reid, and an appendix on the Microzoa by Prof. T. Rupert Jones, F.R.S., and F. Chapman. Excavations for a new dock at Barry have disclosed a series of freshwater or slightly estuarine silts with intercalated peats, below sea-level on the north-eastern side of the island. The site of the excavation was overflowed by the tide until the year 1884, when the docks were commenced. The newest deposits seen are, therefore, blown sand, *Scrobicularia*-clay, and sand or shingle with recent marine shells. These rest on an eroded surface of blue silt, with sedges in position of growth. Four peat-beds occur in this silt, at 4, 11, 20, and 35 feet below Ordnance datum respectively. The uppermost peat contains a seam of shell-marl, partly composed of the shells of ostracoda, and partly of *Bythinia*, *Limnæa*, &c. The second is a mass of matted sedges. The third is a land-surface, and in places consists almost wholly of timber with the stools and roots *in situ*. The fourth is also an old land-surface, as is proved not only by the presence of roots in place beneath it, but by numerous land-shells. A fragment of a polished flint-celt was found by Mr. Storrie embedded in the lower part of the uppermost peat. By a comparison with the existing maritime marshes of the neighbourhood, it was shown that the fourth peat indicates a subsidence of not less than 55 feet. The sea encroached upon the area in consequence of this subsidence. It entered by the lowest of three low cols in the southern water-parting of the Cadoxton River, thus isolating the portion of land now known as Barry Island. A slight further movement would have converted the water-parting into a chain of islands.—On a phosphatic chalk with *Holaster planus* at Lewes, by A. Strahan, with an appendix on the ostracoda and foraminifera by F. Chapman. This rock, which occurs at the base of the upper chalk, at the horizon of the chalk rock, does not exceed 1½ feet in thickness, and persists for a few yards only. In composition and microscopic character it presents a close analogy to the Taplow phosphatic deposit, which, however, occurs at the top of the upper chalk. Like it, it consists of brown phosphatic grains embedded in a white chalky matrix. The grains include a large number of pellets, attributable to small fish, phosphatised foraminifera, chips of bone, &c. Fish-teeth also occur in abundance. To complete the resemblance, the Lewes deposit rests on a floor of hard nodular chalk, beneath which is a white chalk traversed by irregular branching pipes filled with the brown variety. Such "floors" were attributed to concretionary action ensuing upon a pause in the sedimentation. The piped chalk was compared with the structure known as *Spongia paradoxica*. It was concluded that phosphatised deposits may occur at any horizon in the chalk; that the phosphatisation is due to small fishes, attracted by an unusual abundance of food; that they are shallow-water deposits, and associated with a pause or change in the sedimentation. Mr. Chapman furnished a list of 42 species and varieties of foraminifera, and 6 species of ostracoda. The former indicate a deeper water origin than do those of the Taplow chalk. He noted the occurrence for the first time in this country of *Gypsina Cretæ*, Marrson.—On the classification of the strata between the Kimeridgian and the Aptian, by Dr. A. P. Pavlow, Professor of Geology in the University of Moscow. In this paper the author discussed the new evidence respecting the palæontology of the Lower Cretaceous and Upper Jurassic deposits of Russia, which had come to light since the publication, by Mr. Lamplugh and himself, of "Les Argiles de Speeton et leurs Equivalents" (Moscow, 1892).

DUBLIN.

Royal Dublin Society, March 18.—Prof. G. F. Fitzgerald, F.R.S., in the chair.—A paper was read on the Röntgen X-rays, by Mr. Richard J. Moss (see NATURE, April 2, p. 523).—Prof. Arthur A. Rambaut read a note on the rotation period of dark spots on Jupiter.—A memoir on the carboniferous Ostracoda of Ireland, by Prof. Rupert Jones, F.R.S., and Mr. J. W. Kirkby, was communicated by Prof. W. J. Sollas, F.R.S.

PARIS.

Academy of Sciences, March 30.—M. A. Cornu in the chair.—On the properties of the invisible radiations emitted by uranium salts, and by the antikathodic wall of a Crookes' tube, by M. Henri Becquerel. The rays given off by uranium salts are doubly refracted by tourmaline, a parallel experiment with a Crookes' tube giving a negative result.—On the variations in the brightness of the star Mira-Ceti, by M. Duménil.—On the inversion of systems of total differentials, by M. P. Painlevé.—Extension of the theorem of Cauchy to more general systems of partial differential equations, by M. E. Delassus.—On the penetration of gases into the glass walls of Crookes' tubes, by M. Gouy. Glass which has been exposed to intense kathodic rays gives off numerous bubbles of gas on heating.—On the use of non-uniform magnetic fields in photography with the X-rays, by M. G. Meslin.—The time of exposure in photography by the X-rays, by M. J. Chappuis. The effect produced by a Crookes' tube upon a gold-leaf electroscope was studied under varying conditions. An increased action was obtained by concentrating the rays by a strong magnetic field, and especially by replacing the ordinary metallic contact-breaker by a Foucault's interrupter.—Action of the X-rays upon electrified bodies, by MM. Benoist and Hurmuzescu. In reply to criticisms by MM. Righi, Dufour, and Borgmann and Gerchun, the authors have repeated their original experiments with additional precautions, and find that the discharge of an electrified body by the rays is complete, and is independent of the sign of the original charge. Different metals appear to be discharged at different rates, a result difficult to explain by the theory advanced by Prof. J. J. Thomson, that dielectrics become conductors under the action of the X-rays.—On the refraction of the Röntgen rays, by M. F. Beaulard. With a prism of ebonite no clear evidence of deviation could be obtained.—On the diffraction and polarisation of the Röntgen rays, by M. G. Sagnac.—Stereoscopic photographs obtained with the X-rays, by MM. A. Imbert and H. Bertin-Sans.—Determination of the exact position of a foreign body in

the tissues by means of the X-rays, by MM. A. Buguet and A. Gascard.—Experiments relating to the action of the X-rays on *Phycomyces nitens*, by M. L. Errera. This *Phycomyces* was not sensitive to these radiations.—On the Röntgen rays, by M. C. Henry. General considerations as to the nature of the rays, and a *résumé* of their properties.—Reply to some observations of M. Henri Becquerel relating to a note "On the principle of an accumulator of light," by M. C. Henry.—Remarks on the preceding, by M. Henri Becquerel.—Safrol and isosafrol. Synthesis of isosafrol, by M. C. Moureu.—On citronnellal and its isomerism with rhodinal, by MM. P. Barbier and L. Bouveault.—On the macroblasts of the oyster; their origin and localisation, by M. J. Chatin.—On the relations between *Lepismina myrmecophila* and ants, by M. C. Janet.—On the tertiary basin of the lower valley of the Tafna, by M. L. Gentil.

Amsterdam.

Royal Academy of Sciences, January 25.—Prof. Van de Sande Bakhuyzen in the chair.—Prof. Lorentz showed a number of photographs prepared by means of X-rays by Prof. Röntgen, of Würzburg.—Prof. MacGillavry presented the dissertation of Dr. D. MacGillavry on the actiology and the pathogenesis of congenital defects of the heart.—Mr. Jan de Vries gave applications of the introduction of a third radius vector into the bipolar system, so that the three poles lie in a straight line.—Prof. Schoute treated Steiner's quartic surface $y^2z^2 + z^2x^2 + x^2y^2 = 2kxyz$.—Prof. Engelmann communicated the result of an investigation made by Dr. H. J. Hamburger into the importance of respiration and peristaltics to the resorption in the intestine. The resorption of liquids in the alimentary canal increases with the intra-intestinal pressure, and disappears altogether when this pressure is artificially lowered to 0 or a negative value.—Prof. Kamerlingh Onnes made, on behalf of Mr. D. van Gulik, a communication concerning an investigation made, under the direction of Prof. Haga, at Groningen, into the cause of the variation of resistance in microphonic contacts brought about by electric vibrations. In investigating the cause of the diminution of resistance through electric vibrations generated in bad microphonic contacts, it has been ascertained that the ends of a current-chain, when brought very close together, attract each other if the wires are exposed to Hertz's waves. The arrangements being made with proper care, the movable ends were seen under a microscope to touch each other as soon as electric vibrations were generated near them. The original air-gap must not be larger than four microns, and a contact arisen in this way offered a resistance of $\frac{1}{4}$ Ω to the current. The removal of the element from the chain had no influence upon the phenomenon. When the air-gap was a few microns too large, then small sparks resulted on the wires being acted upon by the above-mentioned waves. Prof. Kamerlingh Onnes, starting from his theorem that Van der Waals's corresponding states are dynamically similar, inferred that the cooling of the gas in Thomson and Joule's porous plug will, according to their experiments with hydrogen (1862), become zero and turn into heating, with all gases, at sufficiently high temperatures. The author extended the theorem to thermo-dynamical similarity, and thus supplied the means to find the dimensions of an apparatus to liquefy hydrogen, if there is given one liquefying oxygen in a satisfactory manner. Linde's and Dewar's methods were considered from this point of view. The author also commented on his endeavours to get a small self-cooling motor, liquefying oxygen, to be used as a model for apparatus to liquefy hydrogen by doing work adiabatically after the manner of Solvay, and intended to form part of a series of theoretically perfect cooling apparatus. Finally the author pointed out the superiority of Dewar's vacuum-jackets, and their great importance for low temperature work.

February 29.—Prof. van de Sande Bakhuyzen in the chair.—Prof. Suringar described, in connection with previous communications, some *Melocacti*, lately received from the island of St. Martin, and belonging to the tribe of *Melocacti communes*. They most nearly approach to the one described by Link and Otto as *M. communis*, var. *macrocephalus*. They represent two types, which speaker has called *M.* (*communis*) *Linkii* and *M.* (*communis*) *croceus*, the name *communis* between parentheses indicating the affinity. From a comparison of the specimens discussed with those the author formerly brought away from St. Eustace, and with the description and drawing by Hooker of specimens from the island of St. Kitts, it appears that in these islands, situated very near each other, distinctly different, constant varieties of the common type have developed themselves. This had induced the author to collect and to critically examine all the older accounts, and especially the drawings by Lobelius (1576) down to Miquel's monograph (1840). In anticipation of the Iconography, which he is preparing, he presented a treatise on the subject, as a fourth contribution to the *Transactions* of the Academy. It treats partly of crook-thorned Melocacti, to which those of Lobelius and Besler belong, and of which the author has found a variety of species in Aruba; partly and especially of *Melocacti* of the *Melocacti communes* tribe, peculiar to the Northern Antilles, and which treatise will be illustrated by two plates.—Mr. Jan de Vries made a communication concerning Cartesian confocal ovals in connection with a hyperboloid of one surface.—Prof. Rauwenhoff communicated the results of investigations, made by Dr. H. F. Jonkman at Utrecht, into the embryogeny of Angiopteris and Marattia.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—The Island of Dr. Moreau: H. G. Wells (Heinemann).—A Manual of Forestry: Prof. W. Schlich, Vol. 1, 2nd edition (Bradbury).—Die Vegetation der Erde. I. Grundzüge der Pflanzenverbreitung auf der Iberischen Halbinsel: M. Willkomm (Leipzig, Engelmann).—Monographie der Gattung Euphrasia: Dr. R. v. Wettstein (Leipzig, Engelmann).—A Handbook to the Birds of Great Britain: Dr. R. B. Sharpe, Vol. 3 (Allen).—Röntgen Photographs: Profs. Reid and Kuenen (Dundee, Valentine).—Leçons de Géographie Physique: Prof. A. de Lapparent (Paris, Masson).

Pamphlets.—Summary Report of the Geological Survey Department for the Year 1895 (Ottawa).—A Laboratory Note-Book of Elementary Practical Physics: L. R. Wilberforce and T. C. Fitzpatrick. I. Mechanics and Hydrostatics (Cambridge University Press).—Kepler's Lehre von der Gravitation; Dr. E. Goldbeck (Halle a/s., Niemeyer).—Flora of West Virginia: C. F. Millsuaugh and L. W. Nuttall (Chicago).—The Classification of the Chemical Elements: Prof. O. Masson (Melville).—The Jack Rabbits of the U.S.: Dr. T. S. Palmer (Washington).

Serials.—Fortnightly Review, April (Chapman).—Scribner's Magazine, April (Low).—Geological Magazine, April (Dulau).—Imperial University College of Agriculture, Bulletin Vol. ii. No. 5 (Tōkyō).—Reliquary and Illustrated Archæologist, April (Bemrose).—Journal of the Royal Agricultural Society of England, third series, Vol. vii. Part 1 (Murray).—Geographical Journal, April (Stanford).—Phonographic Quarterly Review, April (Pitman).—Zeitschrift für Physikalische Chemie, xix. Band, 3 Heft (Leipzig, Engelmann).—Annals of Scottish Natural History, April (Edinburgh, Douglas).

CONTENTS.

THURSDAY, APRIL 16, 1896.

OLD AND NEW THEORIES OF EVOLUTION

The Primary Factors of Organic Evolution. By E. D. Cope, Ph.D., Professor of Zoology and Comparative Anatomy in the University of Pennsylvania. Pp. xvi + 532. (Chicago: The Open Court Publishing Company, 1896.)

The Present Evolution of Man. By G. Archdall Reid. Pp. 370. (London: Chapman and Hall, Limited, 1896.)

PROF. COPE tells us in his preface that his work may be regarded as containing a plea on behalf of the Lamarckian view of the factors of evolution; and he believes that evidence has now been accumulated to demonstrate the doctrine, which, he says, he has defended as a working hypothesis for twenty-five years. At p. 9 of the introduction, he states, referring to one of his own papers: "By the discovery of the palæontologic succession of modifications of the articulations of the vertebrate, and especially mammalian skeleton, I first furnished an actual demonstration of the reality of the Lamarckian factor of use, or motion, as friction, impact, and strain, as an efficient cause of evolution." Such statements as these lead the reader to expect that at last we shall have something of the nature of proof of the inheritance of acquired characters, and that the difficulties and objections of those who hold Weismann's views will be fairly met and satisfactorily answered.

The work is divided into three parts, headed respectively: "The Nature of Variation," "The Causes of Variation," and "The Inheritance of Variation." The first part deals with variation, phylogeny, parallelism, and catagenesis. Very full accounts are given of the varieties that occur in some of the animals inhabiting the United States, with special reference to climatal conditions. Aridity is said to produce a blanching of colours, while moisture produces intensity. Some groups increase in size as they spread southward, others towards the north, and this is connected with the centre of the area of distribution being in the south or the north. We have also a careful description of the progressive development of several important groups as indicated by their fossil remains, with a general outline of the phylogeny of the mammalia; while the chapter on parallelism deals with the general correspondence between the course of development of the individual and of the class or order to which it belongs.

At the end of this part of the volume, which has been purely descriptive and has entirely avoided any reference to natural selection or to the broader features of variation, we find this extraordinary statement.

> "It has been proved, as it appears to me, that the variation which has resulted in evolution has not been multifarious or promiscuous, but in definite directions. It has been shown that phylogeny exhibits a progressive advance along certain main lines, instead of having been indefinite and multifarious in direction."

Of these two statements the latter is true, and has been fairly proved by the facts which have been set forth; while the former is absolutely untrue, and if the facts which this volume sets before the student do not show it to be untrue, it is only because they have been selected and set forth in such a way as to illustrate the theory that variations are in definite directions only. For example, although Dr. J. A. Allen is quoted largely to show the variations of birds in definite directions in accordance with changes of climate, nothing is said of his more important work on "The Mammals and Winter Birds of Florida," in which he has given detailed measurements showing that all the commoner species do exhibit "multifarious variations" which are also "multifarious and indefinite in direction." He shows that the total length, as well as the length of the wing, the tail, the beak, and the feet, all vary simultaneously but to a large extent independently. Further, he shows that each of the primary wing feathers, and each of the toes also vary simultaneously and to a large extent independently. Other writers have shown that in mammalia the skull and all its parts vary simultaneously; while what is known of the variation of the muscles, the nerves, the blood-vessels, the intestines, and other internal organs, show that these even exceed the external organs in the multifarious and indefinite character of their variations. All this is the common knowledge of every biologist; yet we have a great authority and experienced biological teacher, first omitting all reference to these facts, and then declaring that he has *proved* that they do not exist!

Coming now to the second division of the book, we find abundant evidence as to the changes effected in individuals by the action of various external causes, by far the larger portion being devoted to a statement of the supposed mechanical origin of the peculiar forms of the teeth and bones in the vertebrata, illustrated by the various lines of evolution made known by palæontology, and always assumed to be the result of use (or disuse) and motion. Then follows a short chapter on natural selection, which is described in the most cursory manner, almost immediately diverging to sexual selection, to which more space is given. We then have a single paragraph devoted to protective modifications of colour or form; and the author here takes the opportunity of dealing a blow at the Darwinians by first misstating their views, and then demolishing his own misstatement. He says:

> "Much is to be found of interest on this attractive subject in the writings of Wallace, Poulton, Beddard, and others. The two authors first named ascribe these colour and form characters to natural selection *as a cause.* This is, however, impossible; yet natural selection has undoubtedly been the cause of their survival."

The italics are Prof. Cope's. He then goes on:

> "The first objection to the belief that natural selection is the primary cause of organic evolution has already been stated as follows: 'A selection cannot be the cause of those alternatives from which it selects. The alternatives must be presented before the selection can commence.' But the supporters of the view that natural selection is the origin of variation, allege that it produces this result by the continual survival of minute differences which are useful, thus accumulating variation. That minute advantageous differences will secure survival no one can doubt, but it must be remembered that the variations which constitute evolution have been in a vast number of cases too minute

to be useful. But the general question is not affected by the supposition that advantageous variations may be sometimes minute. Minute or great, they have to be assumed in the argument for selection; and whether minute or great, they have a definite cause."

This very ingenious argument is well calculated to impress those readers of Prof. Cope's book who have no other sources of information that natural selection is quite a subsidiary agent in causing evolution, and that—as he says in his concluding paragraph—"the stimuli of chemical and physical forces and also molar motion, or use, or its absence, are abundantly sufficient to produce variations of all kinds in organic beings."

But they can produce this effect only on the assumption that all the modifications so produced in individuals are, partially at least, transmitted to their offspring; while those very numerous cases in which essential characters could not possibly have been produced by the causes he suggests, are entirely unnoticed. Such are all those curious structures which are only used once in a life-time; those whose only function is to alarm enemies; most of the protective forms, motions, and colours of insects, as illustrated in the stick and leaf insects, or in those which are deceptively like moss, or flowers, or the dung of birds; the poison-fangs of snakes and the stench-glands of skunks, and innumerable other examples which will occur to every naturalist. Note, too, how "*as a cause*" in the first quotation is changed immediately afterwards to "the primary cause," and the implication that we believe natural selection to be the "origin of variation" and "the cause of the alternatives from which it selects," a theory for which Prof. Cope never states his authority, and which, so far as I know, has never been even suggested, except by incompetent or careless reviewers. Strange to say we have the acknowledgment that "minute advantageous differences will secure survival," but it is followed by the proviso that "the variations which constitute evolution have been in a vast number of cases too minute to be useful." This, I suppose, means that the changes produced by external causes in the individual are too minute to be useful till transmitted and accumulated by inheritance. Whether that is so or not, no evidence whatever has been adduced; while abundant evidence exists in the works of Prof. Cope's own countrymen, and in the measurement of many hundreds of specimens of common species in this country, that normal variability is *not* minute but very large, and that this variability extends to every part and structure, and to every external and internal organ when search has been made for it. That such well-known facts as these should be entirely ignored, and the extraordinary and wholly unprovable statement made, that the variations which constitute evolution "have been in a vast number of cases too minute to be useful," seems to show that the advocates of Neo-Lamarckism feel that they have a very bad case.

In the third part, on the inheritance of variation, we expect to find some experimental facts bearing on the question at issue. But I can only find assumptions and opinions. Breeders of animals, it is said, all believe in the inheritance of the results of nutrition and exercise, and pages are given to prove such beliefs; and after describing the evolution of the American trotting-horse, Prof. Cope says:

"Viewed as phenomena, there is every appearance and indication that the changes acquired by individuals through the exercise of function have been to some degree transmitted, and have been cumulative, and that this has been one factor in the evolution of speed."

However unsatisfactory is the author's treatment of the evidence for the doctrine which forms the main subject-matter of the book, we did not expect that he would repeat the absurd argument which Lord Salisbury used at Oxford, and which has been so destructively criticised by Herbert Spencer. Yet in the chapter on "The Energy of Evolution" he gives, among the "weighty considerations" showing that natural selection cannot be the cause of the origin of new characters, the following statement:

(3) "In order that a variation of structure shall survive, it is necessary that it shall appear simultaneously in two individuals of opposite sex. But if the chance of its appearing in one individual is very small, the chance of its appearing in two individuals is very much smaller. But even this concurrence of chances would not be sufficient to secure its survival, since it would be immediately bred out by the immensely preponderant number of individuals which should not possess the variation."

Whence of course it follows, that without the Lamarckian factors to produce the right variations at the right time, natural selection is powerless, as it will have nothing to select from! It really seems incredible that after nearly forty years' discussion of evolution and natural selection such an argument as that here quoted can be set forth in a serious book by a life-long teacher and worker in the field of biology.

It is refreshing to turn to Mr. Archdall Reid's volume which, though unnecessarily diffuse, is full of original ideas and acute reasoning. The larger part of it is devoted to a discussion of the general subject of organic evolution. This is exceedingly well done, and it contains a very forcible argument against the possibility of the inheritance of acquired characters in the higher animals, derived from the facts of cell-division and specialisation in the development of the individual. This argument has not, within my knowledge, been so clearly and forcibly set forth by any other writer. There are also some very acute criticisms of the writings of Herbert Spencer and others on evolution, and great stress is laid on a rather neglected subject, the development of acquired characters during the growth of the individual, though on this point the author's views seem rather exaggerated and open to criticism. The latter portion of the book, which gives the title to the work, though original is somewhat disappointing, as it is entirely limited to evolution against disease. The author argues that this is effected solely by natural selection, and in the facts presented by the various amounts of resistance of different races to certain zymotic diseases he finds another powerful argument against the Lamarckian theory. He maintains that there is no such thing as hereditary disease, but only hereditary tendency to contract the disease. He traces most of the zymotic diseases to the unhealthy crowding that is universal in civilised communities, and he has some very strong remarks on the way in which our false civilisation is exterminating so many of the lower races. One of

these passages may be quoted as a fair example both of the author's style and of the interesting subjects he discusses.

"Are not all our efforts, whether prompted by philanthropic or religious zeal, by which we seek to protect and preserve the aboriginal races of the New World, wholly mistaken? Are they not in effect absolutely murderous? We gather them into close school-rooms and churches, where teachers and missionaries speak to them from infected lungs. We endeavour to persuade them to abandon their nomadic habits and form settled communities. We—and thereby we prove our own barbarism, the imperfection of our own civilisation—force them in climates where clothes are wholly unnecessary, and therefore a species of dirt, to wear clothes, than which a better vehicle for air and earth-borne disease cannot be well conceived. In fact we strive to bring them at one bound into that state of society which has become possible to us only at the cost of tens of millions of lives during thousands of years."

There are a few errors and perhaps some fallacies in this very interesting and well-written volume; but much may be forgiven in a book that is both original and suggestive; while in its thorough-going advocacy of the main doctrine of Weismann—the non-inheritance of acquired characters—it affords an excellent antidote to the elaborate but one-sided arguments of Prof. Cope.

Alfred R. Wallace.

THE ATOMIC THEORY AGAIN.

A New View of the Origin of Dalton's Atomic Theory: a Contribution to Chemical History, &c. By Henry E. Roscoe and Arthur Harden. Pp. 191. (London: Macmillan and Co., 1896.)

La Théorie Atomique et la Théorie Dualistique. Transformation des formules. Différences Essentielles entre les deux théories. Par E. Lenoble, Professeur de Chimie a l'Université libre de Lille. Pp. 94. (Paris: Gauthier-Villars.)

THE origin of the former of these two books is well explained in the following passage from the short introduction:

"It may seem remarkable that after the lapse of nearly a century since John Dalton first applied the atomic theory of matter to chemical phenomena, it should be possible to find anything new respecting the genesis of his ideas. And this is the more remarkable when we remember that the life and scientific labours of the great Manchester chemist have formed the subject of independent memoirs at the hands of two such able contemporaries as Charles Henry and Angus Smith. The explanation is to be found in the unlooked-for discovery, in the rooms of the Literary and Philosophical Society of Manchester, where the whole of Dalton's experimental work was carried out, of his laboratory and lecture note-books contained in a number of manuscript volumes. A careful study of these has led us to conclusions concerning the origin of the atomic theory of chemistry which differ widely from those which have been generally accepted. It has hitherto been supposed that it was the experimental discovery of the law of combination in multiple proportions which led Dalton, seeking for an explanation of this most remarkable fact, to the idea that chemical combination consists in the approximation of atoms of definite and characteristic weight, the atomic theory being thus adopted to explain the facts ascertained by chemical analysis. This prevailing view is found on examination to rest upon the authority of contemporary chemists, rather than on any explicit statement on the part of the author himself: for, strange as it may appear, no attempt to explain the genesis of his ideas is to be found in any of Dalton's published writings."

It now appears that Dalton was probably led to his theory by an attempt to apply the Newtonian doctrine of the atomic constitution of matter to the explanation of the physical properties of gases, and more especially to the case of the gases present in atmospheric air.

The evidence upon which this conclusion is based is derived partly from the newly-discovered manuscript notes of a course of lectures given by Dalton at the Royal Institution in London early in 1810. In the course of these he says that it was the consideration of the constitution of mixed elastic fluids which led him to contemplate the effect of differences of size in the particles, and thus "it became an object to determine the relative *sizes* and *weights*, together with the relative *numbers* of atoms in a given volume. This led the way to the combinations of gases, and to the *number* of atoms entering into such combinations. . . . Thus a train of investigation was laid for determining the *number* and *weight* of all chemical elementary principles which enter into any sort of combination one with another." This is a statement of Dalton's own recollection of the course of events after the lapse of seven or eight years from the time when he made his first attempts at estimating atomic weights. To this must be added the fact that the first part of his "New System of Chemical Philosophy," published in 1808, contains no account of any chemical analyses, and in the short chapter on chemical synthesis, at the end of this first part, the author speaks of the application of certain general rules which he lays down "to the chemical facts already well ascertained," the experiments conducted by himself being reserved for part ii., published two and a half years later.

On the other hand, Dr. Thomas Thomson, after a visit to Dalton in 1804, makes the very definite statement upon which chemists have generally relied. He says: "Mr. Dalton informed me that the atomic theory first occurred to him during his investigations of olefiant gas and carburetted hydrogen gas." If this was the impression carried away by an interested visitor at the time when Dalton was occupied by the earlier stages of his investigations, it is impossible to avoid the conclusion that there was some foundation for it. Dalton was occupied with the idea of atoms, their relative sizes, &c., from 1801. In the summer of 1804 he collected and analysed the gas from ponds ("System Chem. Phil.," p. 445). In 1805, he says (MS. Lecture 17, p. 16 in the book) the idea occurred to him that the sizes of the particles of elastic fluids *must* be different. We cannot, therefore, admit that the authors have fully made out their case, though it does appear probable that the idea of atomic structure was growing in Dalton's mind before he made any chemical analyses for himself; but whether it had taken the final definite shape in which it appears in the notes of the lectures at the Royal Institution, and in the "New System of Chemical Philosophy," appears to us to be still open to question.

The second book on our list is a production of wholly different type. This little volume explains how to trans-

late the language and the formula of the dualistic system into the language and formulæ current at the present day. The process is simple. It consists in writing down the dualistic formula in equivalents say HO, from this deducing *the formula of M. Berthelot*, H_2O_2, and then dividing by two the number of equivalents of all elements in the formula not comprised in a table given in the book; that is, the elements of uneven valency, and so in this case we arrive at the unitary atomic formula H_2O. This little book is not wanted in England. It might have been useful thirty years ago, but for very shame it should not have been published now, and addressed to university students by a university professor in the land of Laurent, of Gerhardt, and of Wurtz. French chemistry half a century ago was still in the front rank. For the last generation it has been practically nowhere. France owes a debt to M. Berthelot for his labours of the last forty years, first in the development of chemical synthesis, and latterly for his store of exact calorimetric determinations; but whatever gratitude the chemical part of the nation may feel for these substantial labours, the warmth of such feeling must be considerably reduced by the reflection, that chiefly to the obstinacy of M. le Ministre de l'Instruction publique, an office held for many years by the great chemist, is due the position to which French chemistry has sunk, and from which, spite of the brilliant work of a few men like le Bel, Lecocq de Boisbaudran, and Moissan, it will take the best part of another generation to rise.

OUR BOOK SHELF.

Die Mikroskopische Thierwelt des Süsswassers. Abth. I. Protozoa. Von Dr. Friedrich Blochmann. Zweite Aufl. 4to xv + 134 pp., 8 plates, 259 figs. (Hamburg: Lucas Gräfe and Sillem, 1895.)

IT is true that there are many books dealing with the microscopic fauna of fresh waters, but it is also probably the case that there are many more students and amateurs working more or less seriously at this than at any other branch of microscopic zoology. This is the first section of the second part of Kirchner and Blochmann's "Microscopic Fauna and Flora of the Fresh-waters," and the present second edition has been completely reorganised and enlarged. It treats of the Protozoa alone, and discusses them from the systematic point of view. The classification adopted is, in the main, that of Bütschli, but our author agrees with Klebs in the grouping of the Flagellata. We have general accounts of the classes and other divisions, dichotomising tables, and definitions of the genera and species, beginning with *Hyalodiscus* and *Amœba*, and working through to *Stylocometes* in the Suctorial Infusoria. *Volvox* and other forms sometimes claimed by the botanists are here included in the Flagellata, and of course the Dinoflagellata (*Peridinium* and *Ceratium* and their allies) are placed along with the Flagellata in the Mastigophora. The figures on the plates (Werner and Winter) are abundant, and are excellently drawn; a large number of them are tinted so as to show natural colours. Many of them are now very familiar, being taken from the classic works of Bütschli, Leidy, Cienkowsky, Hertwig, Greef, Stein, Klebs and Kent. The last plate gives in outline over forty selected types (the best-known forms) from the various groups of Protozoa, all magnified 100 times so as to show the relative sizes, and enable the student to realise the contrast between *Urotricha* and *Spirostomum*, between *Oikomonas* and *Pelomyxa*, and between *Actinophrys* and *Actinosphærium*. W. A. H.

Manual of Lithology: treating of the Principles of the Science, with special reference to Megascopic Analysis. By Edward H. Williams, jun. 418 pp. Six plates. (New York: Wiley and Sons. London: Chapman and Hall, 1895.)

IN general plan this book differs little from many other text-books on the same subject. The main portion is devoted to the systematic description of the different types of rocks belonging to the three groups, primary or igneous, secondary and metamorphic. By way of introduction to this part, about a hundred pages are occupied with an account of the principal rock-forming minerals and with definitions of the structures exhibited by rocks; while at the end is added a short chapter, intended for the engineer, dealing with the economic value of rocks. Throughout the book the subject is treated as far as possible from the macroscopic point of view. In the classification of the igneous rocks, a two-fold division into intrusives and extrusives is adopted. In this system the line of distinction appears to be drawn in the wrong place. The result is that types presenting very similar characters are separated widely from each other; and owing, it would seem, to the influence of the German school, this separation appears to be effected, in many cases, not so much because the rocks differ in mode of origin as because they have been kept apart by German writers who still uphold the criterion of geological age, a method of distinction, however, which we are glad to see the author clearly repudiates in the introduction.

In the description of varieties of the main types many new names, and some old ones which we hoped had become obsolete, will be met with; so that, in this part of the book, the author's own pages hardly serve to impress upon the reader the truth of the statement made in the introduction that "the tendency of modern rock analysis is toward a simplification of the subject, and the discarding of useless and misleading divisions and names."

If the book had been kept within narrower limits, we are inclined to think that it would have been more useful to the class of student for whom it is intended, viz. "the beginner in the subject who wishes a thorough knowledge in the megascopic presentation of the subject, in a fuller and more compact arrangement, than can be obtained in geological text-books." G. T. P.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Sacred Tree of Kum-Bum.

THE identification of the Kum-Bum tree with *Ligustrina amurensis* (not *amurentis*) (see p. 534) has already been communicated by M. Grigoriev to the *Bulletin du Muséum d'Histoire Naturelle* (1896, p. 33). But the Paris botanists appear to consider it doubtful.

As, however, *Ligustrina* is now merged in *Syringa*, there is a general agreement that the Kum-Bum tree belongs to that genus. We are still of opinion that the authentic leaves brought back by Mr. Rockhill belong to *S. villosa*.

Kew, April 10. W. T. THISELTON-DYER.

The Röntgen Rays and Optically Active Substances.

IN an article in NATURE (February 27) by Prof. J. J. Thomson, it is suggested that the leakage of electricity through non-conductors under the influence of the Röntgen rays is "due to a kind of electrolysis, the molecule of the non-conductor being split up, or nearly split up, by the Röntgen rays, which act the part played by the solvent in ordinary electrolytic solutions." It has occurred to me that if such ionisation really

does take place, independent evidence of it should be obtainable in the case of optically active substances by a change in their rotatory power taking place when they are exposed to the X-rays, as it is well known that the ionised molecules of active compounds are possessed of very different activity from the undissociated molecules themselves. To put this point to the test, Mr. MacGregor and I have polarimetrically examined two optically active compounds, ethylic dibenzoylglycerate and methylic acetylglycerate, interposing a Crookes' focus tube between the polarising Nicol and the column of active liquid; but although the discharge was maintained in both cases for three-quarters of an hour, there was not the slightest change in the rotation observable. To facilitate the passage of the rays, we employed a thin microscope cover-glass to close the polarimeter tube at the end nearest to the Crookes' tube, and that the rays were actually traversing the column of active liquid was demonstrated by obtaining a photographic effect at the other extremity of the tube, whilst the efficiency of the Crookes' tube was further proved by the favourite test of the skeletal photograph of a hand, which yielded an impression of great sharpness and exhibiting a most remarkable amount of detail. It would appear, therefore, that the Röntgen rays either do not give rise to any ionisation at all, or that the concentration of the ions is so small as not to be detectable by means of a sensitive polarimeter. I have previously shown, in conjunction with Mr. Pickard (*Trans. Chem. Soc.*, 1896), that the active bodies in question exhibit what appears to be a process of ionisation when dissolved in certain organic solvents, which process is accompanied by a very conspicuous change in their rotatory power, so that they appeared to be specially adapted for testing this suggested influence of the X-rays.

Incidentally we have roughly tested the relative opacity of a number of organic compounds to these rays by spreading approximately equal thicknesses of each on a number of microscope cover-glasses, which were placed on a photographic plate enclosed in a black envelope, and then exposing them all simultaneously to a Crookes' tube placed a few inches above. Out of nearly forty organic compounds belonging to both the fatty and the aromatic series, the only ones exhibiting any marked opacity contained iodine, bromine, or chlorine, the iodine compounds being the most and the chlorine compounds the least opaque. Thus methyl iodide, ethyl bromide, ethylene iodide, ethylene bromide, monobromacetic acid, tribromacetic acid, bromobenzoic acid, and trimethylenebromide were very markedly opaque, and curiously monochloracetic acid was much more distinctly opaque than either dichlor- or trichlor-acetic acid.

Mason College, Birmingham. PERCY F. FRANKLAND.

Radiographs by Fluorescent Screens.

It may perhaps interest those who occupy themselves in photographing with Röntgen rays to know that a very effective and rapid method is obtained when proceeding as I will explain. I had a piece of scheelite or native tungstate of calcium, such as occurs in a collection of minerals, crushed to a somewhat coarse powder, and made it into an emulsion with gelatine; this was applied in a consistent and uniform layer on a piece of stiff black paper, and after this was dried the surface showed numerous crystalline, glittering particles. The right condition for fluorescing was attained, as was evident, when a Crookes' tube in action was placed behind and looked at in the dark, though the luminosity was not so strong as with a screen covered with crystals of platinocyanide of barium. The paper, thus prepared, was simply laid down on a very sensitive photographic glass plate, with its fluorescent side of course in contact with the film; on the upper surface metallic objects or the fingers were put. Applying now Newton's focus tube (which, I may add, gave me excellent results in former experiments) with an induction coil, regulated to give sparks of five to six inches, I obtained sharply-defined radiographs of keys, &c., in twenty-five seconds, and of the fingers, showing the bones and metallic objects hidden between them and the plate, in ninety seconds, distinct enough to perceive even the eye in a needle that was put in the epidermis. I also tried the fluoride of calcium mentioned by Prof. Winkelmann, of Jena; but I perceived no fluorescence, perhaps because the powder was amorphous throughout. As scheelite is a very cheap mineral, large screens with fluorescent surfaces may be constructed at a trifling expense. L. BLEEKRODE.

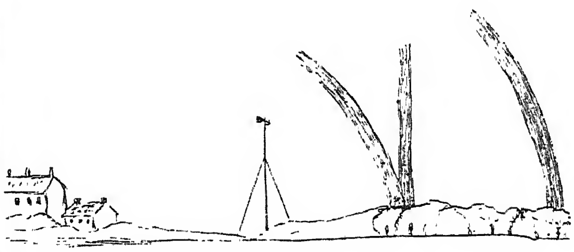
The Hague, April 6.

Perhaps some of your readers who are practising electrography are not aware that those of them who possess a potassium platino-cyanide screen can diminish their exposures to a quarter of the time now necessary. I tried the experiment yesterday, and have been more than pleased with the results. The *modus operandi* is as follows. The screen is first laid on the dark-room table, platino-cyanide uppermost. A celluloid rapid sensitive film is then placed upon it, gelatine side downwards, and in contact with platino-cyanide. Upon the top of all is placed the hand or other object to be electrographed, and in contact with the celluloid. The whole, including screen, celluloid film, and object, are then raised from the table, and a light tight cloth bag drawn over them and properly secured. This arrangement, exposed under the Crookes' tube in the usual way, gives about four times the speed attainable without the reinforcing action of the screen. The "grain" of the screen shows; but if the salt has been finely powdered before preparing it, this is no great objection. Glass-sensitive plates are of course inadmissible.

Oaklands, Chard, April 13. J. WILLIAM GIFFORD.

Abnormal Rainbows.

On March 22, about 6 p.m., a rainsquall was passing south-east of this station, and as the sun was shining clear and bright in the opposite quarter of the sky, a rainbow soon appeared. The colours were very brilliant, and a secondary bow was at once seen. From the base of the primary bow a perfectly straight vertical pillar arose of similar width, and the same colours, arranged in similar order from right to left; this was quite as distinct, and persisted quite as long as the usual rain-



Coast Guard Station.

bow, and the singular spectacle of the two rainbows with the vertical shaft attracted considerable attention, and was noticed by a large number of persons. It was described by several as the V-shaped rainbow. The sketch, made by my assistant, Mr. C. Grover, shows it as seen from the East Lodge, Rousdon, over the Coast Guard Station. C. E. PEEK.

Rousdon Observatory, Lyme Regis, Dorset.

Family Data.

A year ago circulars were printed and cards issued with a view to the formation of a collection of simple measurements on parents and children, which would be of service in testing theories of heredity. In particular, such problems as are dealt with by me in a memoir on regression, heredity, and panmixia (printed in the *Phil. Trans.* of the current year), which treats of biparental inheritance, require statistics far more numerous than have been hitherto available. The measurements are of a simple character, involving but little elaboration, and all that is required is a willing father, mother, and one or more sons or daughters.

Three thousand cards and circulars were distributed, but experience has shown that general distribution is of little practical value. The cards are readily taken, but rarely returned. The only satisfactory method is to find a willing helper who is sufficiently conscious of the importance of the problems of heredity to distribute and collect himself ten or twelve data cards.

Up to the present I have obtained measurements on about 700 families. I am most anxious to reach at least 1000. May I make an appeal through NATURE for such helpers? I am prepared to send full directions and any number of cards to any of your readers who are willing to help. All I would ask is that

they do not merely give the cards away, but themselves collect them and forward to me, as my experience has so fully demonstrated that not 5 per cent. of the recipients will take the trouble of returning them directly to me.

A collection of 1000 family measurements would be of immense value for testing various problems in heredity, and, if it be formed, I shall be only too glad that it should be ultimately deposited where it would be available for all future students of heredity.

It is, perhaps, needless to remark that the measurements required are of normal and not pathological characteristics, and no name except that of the recorder (in case of there being need of reference) is required.

All communications should be addressed to me at University College, London. KARL PEARSON.

University College, London, April 10.

The Retinal Circulation.

THE phenomenon of the retinal circulation, referred to in Mr. James W. Barrett's letter in NATURE of April 2, was, I believe, first described by Dr. Robert Waring Darwin in 1786. He writes:—"By being accustomed to observe such small sensations in the eye, it is easy to see the circulation of the blood in this organ." . . . "It is sometimes necessary to rub the eyes with a certain degree of force after they are closed, and to hold the breath rather longer than is agreeable, which by accumulating more blood in the eye, facilitates the experiment." He further states that it depends on the state of health, is most distinct when the eye is fatigued, and is best seen by looking at the sky, shading the eyes with the hand.

I have myself seen it often when a boy under much the same conditions as your correspondent, viz. lying on my back looking up at the blue sky after severe exercise.

But about fifteen years ago I discovered a method of observing it far more perfectly. While calibrating a somewhat powerful spectroscope by measuring the Fraunhofer lines with a very narrow slit and direct sunlight, I noticed that when the region between G and H occupied the field of view, the retinal circulation showed so plainly as to inconvenience me. On slightly altering the focus, so as to get rid of the lines, I could see not only the corpuscles, but the walls of the capillaries themselves with great distinctness, especially when the eye began to be fatigued. With a sufficiently narrow slit the corpuscles were visible against the other parts of the spectrum, even the red, but they appeared as mere specks, and the outlines of the vessels could no longer be discerned. Judging from this that violet light was more important than a narrow slit, I tried last year the effect of various coloured media. Of these the most successful was ammonio-sulphate of copper. A six-ounce flask, filled with a solution of this substance, held close to the eye about a yard from an arc-lamp, enabled me to see the retinal circulation and some of the vessels, but not nearly so distinctly as with the violet light of the pure spectrum. GEORGE J. BURCH.

Oxford.

JUPITER AND HIS PERIOD OF ROTATION.

A QUESTION which has recently been attracting considerable interest with regard to the greatest of our planets, Jupiter, relates to the determination of the time of rotation deduced from observations of markings on the visible surface of this planet's disc. The difficulty to be contended with here is that the appearance of the markings on the disc is always changing, and further great changes, even in short intervals of time, are noticeable. The chief characteristic features of the disc are the dark belts situated on each side of the equator, resembling to some extent the two belts of trade winds on the earth, which lie on either side of the belt of equatorial calms and rains. More minute scrutiny reveals to us other belts which are sometimes seen in considerable numbers, while their individual structure is by no means simple. These details are for the most part only temporary, and so quickly do changes take place, that the surface of the planet seldom, if ever, appears the same two nights together. Often spots are observed among these belts, which are generally of a more distinct nature than the usual markings; these are for the most part dark, but in some cases they are bright, round, and small, resembling the satellites as they travel across the primary's disc.

The extreme lack of constancy in the positions and forms of all the surface-markings has long ago taught us to cast aside the idea that we are looking at the surface of a rigid body. What we really see is the dense vapour and cloudlike formations between us and the real surface, encircling the whole planet from pole to pole, and always in a state of turmoil. This and other reasons have given us sufficient evidence to form some idea of the temperature of the planet itself, and it is now thought that the internal temperature is considerable, and probably sufficient to render the planet capable of shining to a small extent by its own light.

In consequence of the proper motion of several spots observed on Jupiter's surface and the primitive state of his atmosphere, the planet is said to resemble the sun to some extent. On account of these many points of similarity, Zöllner was led to believe that perhaps a similar law of rotation might here be in vogue which had been proved to hold good in the case of the sun by observations of spots on his surface. Lohse also, some time afterwards, after a minute discussion of all the available evidence, came to a similar conclusion, namely, that Jupiter in the region of his equator rotated quicker than in regions some distance from it.

Now this question is by no means so easy to settle as may seem at first sight. In the first place, in the cases of both the sun and this planet, the spots that are generally visible are confined to two belts north and south of the equator, while the equator and the poles are, for the most part, devoid of all such markings.

In the case of the sun, however, one need not necessarily be restricted to spot observation to determine the time of rotation near the poles, for we possess a very simple means of solving this problem by the application of Doppler's principle. The sun's limb on the east and west sides will be rotating towards and away from the observer, and an examination with the spectroscope of these regions will show us, by measuring the displacement of the lines in the spectrum from their normal positions, the velocities in the two directions. Curiously enough, both Crew and Dunér made investigations on this principle, and the results obtained were by no means the same, but, on the contrary, apparently antagonistic. The former, who observed the photosphere, found that for all latitudes the time of rotation was the same, while the latter, who examined the spots spectroscopically, obtained a decrease in the velocity as their distance from the equator increased. To explain these apparently contradictory results, Brester suggested that it seemed probable that Dunér observed the spectral lines of gases situated inside the photosphere, while Crew's observations were restricted in all probability to gases in those atmospheric layers which lie above the photosphere.

As yet no such observations near the poles of Jupiter have been attempted, although, as will be seen further on, this application of Doppler's principle has been employed for the region near the equator. Fortunately, however, in the year 1892 (October 10) a short dusky streak, oblong in shape, was observed by Stanley Williams near the north limb, extending nearly to north latitude 85°. Other similar streaks have been subsequently noticed, and frequent determinations of the times of mid-transit have been made. By good fortune the observers at the Lick Observatory had secured at the same time some good photographs of the planet, the surface-markings of which, on the negative, were sufficiently distinct for measurement.

A comparison of the times of rotation deduced from both the visual and photographic records seemed to give very satisfactory results, the mean periods differing only

by two seconds. The mean result for the surface material of Jupiter between latitudes 40° to 85° north gave 9h. 55m. 38·9s. ± 1·20s., this being the length of a sidereal rotation expressed in mean solar time. Observations of some dark, well-defined spots in 1891 gave as a value for the period of rotation 9h. 55m. 38·5s., while Denning found (1894–5) the value 9h. 55m. 39·0s., still closer to that given above.

It will be noticed that up to the present the observations of Stanley Williams do not corroborate a reduction in the rate of rotation in higher latitudes, as would be expected from Lohse's discussion. The observations of the two may, however, be harmonised to some extent if, as before, one supposes that they observed markings at different levels in the atmosphere of the planet. If this were so, then very probably Stanley Williams generally watched those markings in the higher regions, while the spots observed by Lohse were situated at a far deeper level, and in which perhaps were strong currents.

A spectroscopic investigation of great interest is that due to Dr. Belopolsky, who undertook the determination of the velocity of a point in the equatorial region of Jupiter. The method of procedure was as follows. He assumed that the equatorial region of this planet made one rotation every 9h. 50m.; knowing the angular diameter of the disc from measures made with the micrometer, he then calculated the velocity of a point on the equator, the resulting velocities being 12 and 13 kilometres per second, according to the special value of the diameter used. The second part of the work consisted in observing the east and west limbs of the planet spectroscopically, using the principle of Doppler to find out the displacement of the lines due to the velocities in the line of sight. The value he obtained was 11·4 kilometres per second, a number smaller than that which would apparently be expected. The great difference between the observed and computed velocity may be due to errors of observation, but its magnitude calls for another explanation. Belopolsky himself prefers to account for this difference by regarding it as a result of refraction, an assumption which is quite permissible, as Schmidt has shown in his theory of the sun.

Perhaps the best idea of the drift of the Jovian surface can be gathered from a summary of the determinations of the length of the period made from surface-markings at different Jovian latitudes. This table we owe to Mr. Stanley Williams, and it appeared in a previous number of Nature (vol. liii. p. 376). It will be noticed that the nine zones represent practically nine distinct currents in the planet's atmosphere, their boundaries being described as sharply defined. These currents completely encircle the planet, and have an east and west direction; very little indications of motion towards the poles having been noticed.

Zone.	Lat.	Period: In time. h. m. s.	Period: In terms of equatorial period.
I.	+85° to +28°	9 55 37·5	1·0089
II.	+28 ,, +24	9 54 30	1·0071
		9 56 30	1·0104
III.	+24 ,, +20	9 48 0	0·9973
		9 49 30	
IV.	+20 ,, +10	9 55 33·9	1·0089
V.	+10 ,, −12	9 50 20	1·0000
VI.	−12 ,, −18	9 55 40	1·0090
VII.	−14 ,, −28	9 55 40	1·0090
VIII.	−18 ,, −37	9 55 18·1	1·0084
IX.	−37 ,, −55	9 55 5	1·0081

Curiously enough, the zone numbered VII., which represents the red-spot zone, has not an equivalent in the northern hemisphere, that numbered III. having a much quicker drift.

Apropos of this red spot zone, we may mention that Mr. Stanley Williams expresses the opinion that the mysterious red spot acts in the same way as, and has some analogy to, an island in a river (*Knowledge*, April). The spot lies between the south equatorial belt and the south temperate belt, and as the white material between these two belts drifts past the red spot with a velocity of sixteen miles per hour, it is obliged to force a passage round the spot. Most of this white material passes to the north side of the spot, making a depression in the south equatorial belt; but some of it finds a way through a very narrow channel on the south side. There is less resistance to the passage of the material on the north side of the spot, probably for the reason that the surface is most plastic in the equatorial regions. As the channels on the north and south sides of the red spot are together narrower than the main channel, there is a heaping up of white material on the following side of the spot and in the channels, and this seems to possibly explain the bright annulus which is frequently seen encircling the red spot. The union of the two currents produces a commotion on the preceding side of the spot, giving rise to the hazy patch which is usually visible in that position. As a working hypothesis, the idea seems likely to be of use in suggesting observations, but it is admittedly difficult to conceive how such an effective obstacle as the red spot can drift about in the way it has done.

The latest observations regarding Jupiter's surface thus show us that the whole disc of vapour that we see is in a state of slow circulation in currents more or less parallel to the equator. The rifts that appear to traverse the disc in the north and south direction may be the effects of a slow circulation in this direction.

The east and west currents do not then necessarily increase their rate of rotation the nearer the equator is approached; but there may be zones of quicker rotation, followed by zones of slower rotation before the equator be reached. It will thus be seen that a very accurate value of the period of rotation of Jupiter is difficult to determine, since the several drifts are in relative motion one with another.

W. J. S. L.

THE LIFE OF JOSEPH WOLF.[1]

It seems now to be rather in fashion to write lives of persons still in existence. In some cases, such as the present, there is little to be said against this practice; in others, it may be open to very serious objections. But when the biography of a living person is given to us by an intimate personal acquaintance, we have, at any rate, one advantage: it may be assumed that the narrative has been more or less supervised by the person to whom it relates, and that the facts and incidents stated are generally correct. Such, we know, is not always the case with biographies of departed heroes.

Joseph Wolf, well known to all zoologists as the "Prince of Animal Painters," and one whom savants and artists alike agree to class as "absolutely unrivalled" in his special department, was the son of a German farmer, or what was formerly called in the south of England a "yeoman," farming his own land at the little village of Möerz, between Trèves and Coblentz. Born in 1820, Wolf was sent to the village school at Metternich, where his observant habits and "superior skill in drawing maps" told favourably with the master. But to his fellow-scholars a boy who "refrained from bird-nesting on principle," and would fight any of them in defence of a nest of young birds, was somewhat of a puzzle. Here, however, Wolf had many opportunities, both during his school-days and in the course of the initiation into farm-life which followed, of studying nature. A fine wild country was around him, where beasts and birds were abundant, and he soon taught himself to observe them,

[1] "The Life of Joseph Wolf, Animal Painter." By A. H. Palmer. Illustrated. Pp. xviii + 328. (London: Longmans, 1895.)

to collect them, to capture them as models, and to draw their pictures. Notwithstanding these facilities, which, however, could only be enjoyed at off-times, the monotonous drudgery of farming became at length unbearable to the nascent artist, and he at length secured his father's consent to desert the plough, and to become an apprentice to the brothers Becker, a firm of lithographers at Coblentz. At the age of sixteen, therefore, Wolf managed to struggle out of agriculture into a profession which had, at all events, an artistic character about it, and a good knowledge of which must have been of paramount value to him in after-life.

Fig. 1.—A Family Group of the Eastern Red-footed Hobby.

His apprenticeship being over, Wolf's second step in life was still more decidedly in advance. As he passed through Frankfort in search of work, his sketch-book at once attracted the notice of Rüppell, the distinguished traveller and naturalist, to whom he had been advised to show it. Rüppell sent him on to Kaup, the director of the museum at Darmstadt, where the young artist ultimately settled. At the same time, Rüppell engaged Wolf to prepare the plates for his "Systematische Uebersicht der Vogel Nord-Ost-Afrikas," upon which he was then engaged. The fifty figures of this volume, published in 1845, were the first lithographs of this sort that Wolf ever produced. They are a little rough in execution, but no one can doubt their truthfulness and artistic merit. The receipt of this book in England quickly attracted the attention of our zoologists, who at once understood that an artist had come into existence who could figure birds in a way hitherto almost undreamt of, and very different from Spix's "Aves Brasilienses," or even the best designs of Temminck's "Planches Colorées."

On visiting Leyden shortly afterwards, Kaup showed the young artist's portfolio of sketches to Schlegel, and Schlegel, who was then engaged on his "Traité de Fauconnerie," immediately secured Wolf's services for that work, to which he contributed eleven or twelve excellent plates. But after a few years at Darmstadt, Wolf came to the conclusion that there would be a better market for his artistic talent in England, where several naturalists of the day required his services. The late G. R. Gray, of the British Museum, was then engaged on "The Genera of Birds," which Mitchell had undertaken to illustrate but could not find time to complete. On Wolf's arrival in London, Gray at once set him to work on the plates of this folio work, in the Insect Room at the British Museum. The *Proceedings* and *Transactions* of the Zoological Society were, at this period, also much in want of a good artist for their better illustration. For the *Proceedings*, commencing in 1848, Wolf drew figures of a large number of mammals and birds, of which we have a list given to us in the appendix to the present work. Wolf continued to supply the illustrations of mammals and birds required for the *Proceedings*, and the greater number of those of birds wanted for *The Ibis* for about twenty years. After this our artist grew rather tired of the minute and technical details required for scientific bird-structure, and it became difficult to persuade him to undertake such subjects except on special occasions, when a new parrot was discovered, or a rare antelope brought home from Africa, of which the artist was assured that no one else could make a proper picture.

Among Wolf's drawings in *The Ibis* will be found some of the very best examples of his excellent handicraft. Hawks and falcons were always favourite subjects of his pencil, and the family group of the Eastern Red-footed Hobby (*Erythropus amurensis*), (Fig. 1.) which we are enabled to reproduce here through the favour of the publishers of the present work, is one of the prettiest of them. Not less attractive is the elegant figure of the Guatemalan Swift clinging to its rocky home (p. 8), while its pendent nests and flying companions are shown in the background. Mammals have also been always equally within the range of Wolf's able pencil, and not even Mr. Stacy Marks

himself can surpass Wolf in the introduction of feeling and humour into pictures of mammal-life.

Although after deserting scientific work Wolf was hardly the less active, and executed a large number of pictures, both in oil and in water-colours, these products of his brain and pencil are not, perhaps, so well known as his earlier work. Wolf was not elected a Royal Academician, as he certainly ought to have been, and very seldom exhibited pictures in the galleries of Burlington House. His splendid efforts are mostly hid away in the palaces and country mansions of certain great patrons, who were always ready to give him full employment. Such mansions as Lilford Hall, Colebrooke, and Guisachan, must be visited by those who wish to examine Wolf's paintings of this class. But, after all, we agree with the biographer that oil is not the material in which Wolf most excels, although it may be as an oil-painter that he prefers to be known. The best of his productions are in water-colour, and in charcoal and chalk. Such, at least, is the opinion of those who regard his work from a scientific point of view.

Before concluding this notice, we cannot avoid alluding to the way in which Wolf's scientific work has been plagiarised in Germany. On turning to the last page of the present volume, the "Royal Natural History" will be found given in the list of the most recent works which Wolf's genius has served to illustrate. Wolf's pictures, however, have arrived here in this instance by a curious route. Originally prepared for the *Proceedings* of the Zoological Society and other works, they were copied by the artist employed on Brehm's "Thierleben." Not only was this done, but in some cases Wolf's initials were removed and those of the copier ("G. M.") inserted in their place. The blocks thus altered for Brehm's "Thierleben" were subsequently purchased by Messrs. Warne and Co. for use in the "Royal Natural History," and have been so employed without the slightest acknowledgment that the designs were originally the products of Wolf's pencil. To prove this, we have only to compare the figure of the "Variegated Spider-monkey," in the "Royal Natural History" (vol. i. p. 64), with the original figure of Wolf in the *Proceedings* of the Zoological Society for 1867 (plate xlvii.). It will be seen that the former figure is initialled "G. M.," but the latter "J. W."

We will now only add an anecdote of Wolf, extracted from Mr. J. G. Millais's recently published "Breath from the Veldt." Mr. Millais, who appears to be as great an admirer of Wolf as his father is known to be, tells us that one day, some years ago, Wolf was busy on one of the superb panels which grace the walls of the late Lord Tweedmouth's Highland residence, Guisachan. Landseer, who was staying at the same house, and who, it should be remarked, was a firm believer in the pre-existence of man in other forms, came up behind Wolf, who was hard at work, and stood gazing at his picture for some time without making any remark. At last Wolf got a bit nervous, and fidgeted about. Then turning round to Landseer, on whom he was afraid the picture had created an unfavourable impression: "Well, Landseer," he said, "you might say something: I'm afraid you don't like it." "Well, not exactly that," was the dry reply; "for I was just thinking that before you were a man, Wolf, you must have been an osprey" (the bird at which the artist was working).

CHARLES CHAMBERS, F.R.S.

We have already briefly announced the death of Mr. Charles Chambers, who for thirty years has directed the Colàba Observatory of Bombay, and who, by his zeal and ability, has materially increased its reputation, and worthily upheld the cause of science in the East. Mr. Chambers received his practical and scientific training under the late Prof. Balfour Stewart, at Kew; and when, in 1866, he was appointed Superintendent of the Bombay Observatory, the fortunes of that institution appear to have been at a low ebb, and its continued maintenance by the Indian Government open to question. Mr. Chambers's appointment was at first of a temporary character, and his office the thankless one of discreetly covering the shortcomings of his predecessors, and of making the results of their observations available for scientific use. The difficulties which he had to overcome are hinted at in some of his numerous papers, which have appeared as appendices to the volumes issued from the Bombay Observatory, or in the publications of the Royal Society. For instance, in his discussion on the meteorology of the Bombay Presidency, it is mentioned that the whole of the original manuscript registers prior to the year 1847 (the observatory was founded in 1841) had disappeared, that it was doubtful, in some of the printed records, whether the time was referred to the Bombay or the Göttingen Meridian; while other evidences of looseness hindered the preparation, or necessitated the rejection of his predecessors' work.

The magnetic results appear to have been in a more satisfactory condition, and very soon after his appointment he was able to report the probability of their turning out trustworthy and valuable. With the mass of accumulated arrears Mr. Chambers grappled manfully, and in the *Philosophical Transactions* for 1869, the Bombay observations from 1859–1865 are employed to discuss the solar variation of magnetic declination at that station. The energy displayed by Mr. Chambers, and the favourable position of the observatory, intermediate in longitude between Kew and Nertchinsk, induced the Scientific Committee, consulted by the Indian authorities, at the head of whom was Sir Bartle Frere, to continue the grant to the observatory, and to supply it with new instruments of the Kew pattern. Some delay appears to have occurred in sending out these instruments from England, a delay which permitted Mr. Chambers to organise his staff and reduce his arrears.

Trained in the school of Sabine and Stewart, Mr. Chambers's earliest investigations had reference to the possibility of referring the disturbances of terrestrial magnetism to the sun, considered as a magnet with its axis perpendicular to the plane of the ecliptic. The conclusion at which he arrived was that no effect of the sun's action as a magnet is sensible at the earth. This decision, at the time, received the approval of the late President of the Royal Society, and subsequent and more elaborate investigations have tended to confirm the conclusion. This tendency to trace the magnetism of the earth to the sun, induced Mr. Chambers later to investigate, from long series of observations, the solar and lunar variations of the three magnetic elements observed at Bombay, and likewise the effect of sun-spot on terrestrial phenomena. It is not easy to do full justice to the long series of varied researches which have come from the Bombay Observatory under his able direction, or to the heavy loss which that institution sustains in his removal.

Not the least of his services to science is to enable his successor to continue the observatory under more efficient conditions than he himself found, and with a reputation considerably enhanced by his devotion.

NOTES.

A MEETING for discussion will be held at the Royal Society next Thursday; the subject, "Colour Photography," will be introduced by Prof. Lippmann.

A MEMORIAL has been projected in Germany to the late Prof. Hermann Hellriegel, of Bernburg, who died in September last. It is proposed to erect a monument in the churchyard at

Bernburg, where the remains of the distinguished investigator are interred. An appeal for contributions has been issued, and a small Committee, consisting of the President and Secretary of the Bernburg Agricultural Society and Dr. Wilfarth, Hellriegel's colleague in his researches, has been formed to carry out the details. Contributions from this country may be sent to Sir Henry Gilbert, F.R.S., Harpenden, St. Albans.

At a quarterly meeting of the Council of the Royal College of Surgeons of England on Thursday, April 9, the Jacksonian prize for the year 1895 (open only to Fellows or members) was awarded to Dr. A. A. Kanthack, of St. Bartholomew's Hospital, the subject of the essay being "Tetanus." The Walker prize, for the best work in advancing the knowledge of the pathology and therapeutics of cancer, done either partially or wholly within the five years preceding the year in which the prize is granted, has been awarded to Mr. Harold J. Stiles, of Edinburgh University. The prize consists of a gift of £100—except on this, the first occasion, when it is only £60—and a document declaratory of the award. It is open to foreigners as well as to British subjects, and the Committee are not restricted in any way as to the selection of persons qualified to receive the prize, with the exception that members of the Council are not eligible.

The following aids to scientific research are announced in the *British Medical Journal*:—M. Renier has bequeathed to the Belgian Treasury the sum of two million francs (£80,000), to be applied to the foundation of a medical institute to be called the "Institut Rommelaere."—A sum of 5,000 roubles (£500) has been granted to the St. Petersburg Medical Academy for the purposes of experiments with the X-rays. A Committee, consisting of Profs. Jegoroff (Rector of the Academy), Tavnezki, Bechtereff, and Ratimorn, has also been appointed to consider the question of the application of Röntgen's discovery to practical medicine.—A new prize has just been added to the long list of those awarded by the Paris Academy of Medicine. The prize is of the value of 24,000 francs (£960), the proceeds of a capital sum of 800,000 francs (£32,000) bequeathed by Mdme. Audiffred for the purpose. It is to be called the "François-Joseph Audiffred Prize," and is to be awarded to any person, of whatever nationality and of whatever profession, who shall within twenty-five years from January 28, 1896, discover a remedy, curative or preventive, recognised by the Academy as efficacious and specific for tuberculosis. In the meantime, the interest accruing from the bequest is to belong to the Academy, and can be applied in any way which that body may think proper.

We regret to notice the deaths of Prof. F. R. Fava, Professor of Civil Engineering at the Columbian University; Mr. John Gundlach, known for his works on the fauna of Cuba; Admiral Carlo Alberto Racchia, Vice-President of the Società Geografica Italiana; and Baron Negri, first President of the same Society.

The *Journal of Botany* for April contains a short biographical sketch of the late Mr. T. H. Buffham, who died on February 9, at the age of fifty-six. He was one of the new English botanists who have devoted themselves to the study of Algæ (especially seaweeds), and had made many interesting observations on their mode of reproduction, which have been published in the botanical journals.

The death is announced in the *Times* of Dr. William Sharp, F.R.S., at the advanced age of ninety-one. He began the study of medicine in 1821, and in 1827 he obtained the diploma of the Royal College of Surgeons. Going over to Paris he attended the University lectures at the Sorbonne, listening to Gay Lussac on physics and Thenard on chemistry. He also attended Orfila's lectures at the School of Medicine. In 1828 Dr. Sharp returned to England, and settled in Bradford; in the ensuing year he was elected surgeon to the infirmary, and in 1837 senior surgeon. In 1843 he resigned his practice in Bradford, and after four years spent in Hull, where he gave winter courses of lectures on chemistry, he went to Rugby in 1847. As early as 1839 Dr. Sharp spoke in favour of local museums. A Philosophical Society was established in Bradford, of which he was elected first President; and his paper on "Local Museums," read before the British Association, led to the establishment of such museums in most provincial towns. He was elected a Fellow of the Royal Society in 1840. It was in consequence of his urgent recommendation that the teaching of physical science was introduced by Dr. Tait into Rugby School, and Dr. Sharp himself became the first "Reader in Natural Philosophy" in 1849 and 1850. From the latter year onwards he gave all his thought and attention to the improvement of the medical treatment of the sick. He made searching investigations into all the systems and schools of medicine, and embodied the results of his studies in a series of "Essays on Medicine," which appeared at irregular intervals, and reached a total of upwards of sixty treatises before his death.

The Council of the Society of Arts offer the Fothergill Prize of £25 and a silver medal for a paper on "The Best Means of Effectually Preventing the Leakage of Current to Earth in Electrical Installations from Generating Heat and Setting Buildings on Fire." The paper should consist of about eight thousand words, and be written with a view to being read and discussed at an ordinary meeting of the Society. Papers submitted for the prize must be sent to the Secretary on or before October 1, 1896. Each paper must be type-written, and bear a motto, the name of the writer being enclosed in a sealed envelope with a similar motto.

Our American correspondent writes, under date April 3:—"Prof. Ogden N. Rood, of Columbia College, has reflected the X-rays from platinum, the amount of reflection being estimated at 1/1260th part of the incident rays.

"The schooner-yacht *Coronet*, which left Brooklyn on December 5, with an equipment for observing the total eclipse of August 9, at Japan, arrived at San Francisco after a successful voyage of 117 days around Cape Horn. Captain James, the owner, and Prof. Todd and his assistants of the Amherst College observation party, will immediately cross the continent by rail, and the yacht will proceed on her voyage in a few days.

"The Local Committee of the fourth Buffalo meeting of the American Association for the Advancement of Science has been organised, and all the Sub-committees appointed. Mayor Jewett is President, and E. P. Dorr is Local Secretary. The Association will meet on August 24. The city of Buffalo will also entertain this year the National Educational Association, the League of Press Clubs, and the American Public Health Association.

"The intense cold weather and numerous severe storms of the past few weeks call for special mention. As late as March 24, a man was frozen to death in central New York. On the 28th the most severe snow-storm of the season, and one of the worst ever known, was reported from Quebec. Even after the month of April began, one of the most severe blizzards on record swept over the north-west, with temperature near zero at some places, accompanied by a remarkable snow-fall, sufficient to blockade roads generally, and to cause snow-drifts from ten to twenty feet deep.

"Ground will be broken this month for the Polhemus Clinic, an adjunct to the Long Island College Hospital. It is the gift of Mrs. Caroline H. Polhemus, as a memorial of her

deceased husband, Henry D. Polhemus. The building will be eight stories high, 67 by 92 feet in dimension, with the top coping 116 feet above the street. The land and building cost over 300,000 dollars, and apparatus and equipment will bring the total cost up to about 500,000 dollars; being, with perhaps one exception, the largest individual contribution to one charity ever made in Brooklyn. The admirable Hoagland Bacteriological Laboratory is in immediate proximity."

WE learn from *Science* that a Bill has been passed by the Legislature of Maryland, and signed by the Governor, entitled "An Act to establish a State Geological and Economic Survey, and to make provision for the preparation and publication of reports and maps to illustrate the natural resources of the State, together with the necessary investigations preparatory thereto." 10,000 dols. annually is appropriated for carrying out the provisions of the Act, and a Commission has been established, composed of the Governor of the State, the Comptroller, the President of the Johns Hopkins University, and the President of the Maryland Agricultural College. At a meeting of the Commission, on March 25, Prof. William Bullock Clark was apppointed State Geologist. He will at once begin work in the field.

A MEETING of the Institution of Mechanical Engineers will be held on Wednesday, April 29, and Friday, May 1. The President, Mr. E. Windsor Richards, will deliver his inaugural address on Wednesday evening. The adjourned discussion will be resumed on the same evening upon the paper, "Notes on Steam Superheating," by Mr. William H. Patchell, read at the last meeting. The following papers will be read and discussed on Friday evening: "Steel Steam-Pipes and Fittings, and Benardos Arc Welding in connection therewith," by Mr. Samuel MacCarthy, of London; "Research Committee on the Value of the Steam-Jacket—Experiment on a Locomotive Engine," by Prof. T. Hudson Beare and Mr. Bryan Donkin. The anniversary dinner will take place on Thursday, April 30.

THE spring meeting of the Iron and Steel Institute of Great Britain will be held on Thursday and Friday, May 7 and 8 next, at the Institution of Civil Engineers, Westminster, under the presidency of Sir David Dale. Upon that occasion the Bessemer Gold Medal, which is awarded annually in recognition of meritorious services in advancing the science or practice of the metallurgy of iron and steel, will be presented to Dr. Hermann Wedding, of Berlin. The list of papers down for reading and discussion is a full and comprehensive one, there being no fewer than ten communications on a variety of metallurgical subjects. Prof. Roberts-Austen, C.B., will contribute a paper on the rate of diffusion of carbon in iron, whilst Mr. J. S. de Benneville, of Philadelphia, will read one on some alloys with iron carbides. The application of Mond gas to steel-making will be described by Mr. John H. Darby, and Mr. B. J. Hall will discuss the subject of hot-blast stones. The Baron von Jonstorff, of Neuberg, will read a paper on standard methods of analysis, whilst the hardening of steel will be dealt with by Mr. H. M. Howe, of Boston, and M. F. Osmond, of Paris. Mr. Perry F. Nursey will read a paper on a new process for the production of metallic bars of any section by extrusion at high temperature. The treatment of magnetic iron sand will be brought under notice by Mr. E. Metcalf Smith, of New Zealand, and the iron ores of Oxfordshire will be dealt with by Mr. E. A. Walford.

THE sixty-fourth annual meeting of the British Medical Association will be held at Carlisle on Tuesday, Wednesday, Thursday, and Friday, July 28–31. The officers are as follows:—President: Sir J. Russell Reynolds, Bart., F.R.S., President of the Royal College of Physicians. President-Elect: Dr. Henry Barnes. President of the Council: Dr. J. Ward Cousins. Treasurer: Dr. Henry T. Butlin. The scientific business of the meeting will be conducted in nine sections, of which the respective Presidents are as follows, namely:—(A) Medicine, Dr. George F. Duffey; (B) Surgery, Dr. Alexander Ogston; (C) Obstetrics and Gynæcology, Dr. J. Halliday Croom; (D) Public Medicine, Sir Joseph Ewart; (E) Psychology, Dr. J. A. Campbell; (F) Pathology and Bacteriology, Mr. Sheridan Delépine; (G) Ophthalmology, Dr. David Little; (H) Diseases of Children, Dr. James Finlayson; (I) Ethics, Dr. T. F. I'Anson. An address in Medicine will be delivered by Sir Dyce Duckworth, and one in Surgery by Dr. R. Maclaren.

AN instructive article on "The General Bearings of Magnetic Observation," contributed to the current number of *Science Progress* by Captain E. W. Creak, should be read by all who are interested in terrestrial magnetism. What the article chiefly aims at showing is the great importance of magnetic observations. As an example of the application of the same, it is remarked: "We have now heavily armed, protected steel cruisers steaming over all parts of the world with less change of deviation of the compass than the wood-built *Erebus* and *Terror* of Ross's Antarctic expedition, and this remarkable result could not have been achieved if the terrestrial magnetic observer had not done his work." Still, much more remains to be done before sufficient is known about the secular change of terrestrial magnetism to enable magnetic charts to be provided to navigators for years in advance, just as the tides can now be tabulated for his use.

THE Council of the Physical Society, in a circular issued to the members, call attention to the expense attending the publication of abstracts of physical papers, which has been so successfully undertaken by the Society for a little over a year. The proposals now submitted to the consideration of members with a view to meeting this expense are, firstly, that the annual subscription should be raised to two guineas; secondly, that existing life members should pay an annual subscription of one guinea, or an additional composition of fifteen guineas; and, lastly, that an annual guarantee fund should be raised for the next five years to cover the probable deficit. Towards this latter fund nearly £100 per annum has been already promised. It is universally admitted that these abstracts have proved an incalculable boon to physicists all over the world, and we therefore hope that the last proposal will commend itself to all, whether members or non-members, who appreciate this useful and important work.

A FINE series of photographs of flying bullets, both in free air and in different stages of penetrating through a pane of glass, have been taken in Italy by Dr. Q. Majorana Calatabiano and Dr. A. Fontana, of the Italian Artillery. The apparatus described is a modification of that employed by Prof. C. V. Boys, and these photographs might, perhaps, more correctly be described as skiagraphs, since they are shadow-pictures produced on the photographic plate by the light from an electric spark produced by the discharge of a condenser. The chief peculiarity of the present figures is that, in addition to the anterior wave produced by the advance of the aërial disturbance, they exhibit dark striæ just in front of the projectile—a result not previously observed, and which the authors account for by supposing that the sudden compression of the air causes condensation of moisture producing an opaque cloud. In support of this theory, it is stated that the experiments were performed in a moist atmosphere. This blurred appearance is very similar to that which would be produced by the sparks arising from an oscillatory discharge of the condenser, but the careful precautions adopted by the experimenters to prevent any secondary discharge negative this explanation.

In two papers which appear in English, in No. 22 of the *Communications* from the Laboratory of Physics at the University of Leyden, Dr. P. Zeeman gives the results of the measurements he has made on the absorption of electrical vibrations in electrolytes. The method employed consists in starting oscillations in a Lecher wire system by means of a Blondlot oscillator; the wires passing for a part of their length through a trough containing the electrolyte. In order to measure the energy of the vibrations at any point of the wire, the arrangement employed by Rubens, consisting of two very small Leyden jars, the outside coatings of which are connected through a bolometer, is used by the author. In a preliminary series of experiments, in which a solution of sodium chloride having a conductivity $3 \cdot 2 \times 10^{-7}$ times that of mercury was employed, it was found that, for oscillations having a wave-length in air of 6·4 metres, and for which the logarithmic decrement (the γ of Bjerknes) was 0·34, the intensity of the oscillations are reduced to $1/e$ of their initial intensity after passing through 5·7 c.m. of the solution. These results were somewhat vitiated by the fact that the deflections of the bolometer decreased as the jars were moved along the wires in the electolyte, but instead of becoming zero they gradually reach a constant value. The result given above was obtained by diminishing all the readings by this constant amount. In a subsequent series of experiments, in which the spark gap of the primary oscillator was altered, this constant deflection was practically eliminated. In this series experiments were also made, using a solution of copper sulphate having the same specific resistance as the solution of common salt, and it was found that in both cases the intensity of the vibrations was reduced to $1/e$ after passing through 5·1 c.m. of the electrolyte. Hence, the author concludes that, in dilute solutions of different electrolytes having equal conductivities, electrical vibrations of the same period are equally absorbed.

The velocity of an earthquake-wave within a short distance from the epicentre is so difficult to ascertain on account of the large error resulting from a small error in the recorded times, that all estimates with an approach to accuracy are of value. In the Brescian earthquake of November 27, 1894, good time-determinations were obtained at ten stations, all within 445 km. from the epicentre. Assuming the velocity to be uniform in all directions, Dr. M. Baratta calculates it to be 1·411 km. per second. Taking account of the nature and extent of the rock traversed by the earth-wave, he also finds the average velocity to be ·782 km. per second in alluvium, and 1·569 km. per second in the older and more coherent rocks.

A couple of teeth found at Taubach, near Weimar, are claimed by Dr. A. Nehring to be the oldest human teeth yet found in Europe (*Verhandl. Berlin Anthrop. Ges.*, 1896, p. 573). One of these is a milk molar, and the other a permanent first molar of the left lower jaw. The crown of the latter measures 11·7 by 9·9 mm., and has three outer and two inner cusps, besides minor cusps and folds; in this, and in the occurrence of grooves and holes in the outer side of crown, the tooth is remarkably like that of the chimpanzee, but not much like that of the gorilla or orang. Dr. Nehring calls attention to the fact that the first pre-molar and last molar are reduced in size in modern man as compared with early man, and he finds exactly the same in domesticated, as compared with wild, dogs. In domesticated dogs, as in civilised man, the jaw is relatively feebly developed, and there is a tendency to reduction of the last molar.

In the collection of mammals, made in connection with the recent re-survey of the boundary line between Mexico and the United States, are several which appear to be new to science. In view of the probable delay in issuing the complete report on these collections, advance sheets are being issued containing preliminary diagnoses of the new forms. In one of these sheets, just received, Dr. E. A. Mearns describes as new sub-species *Spermophilus mexicanus parvidens* (Rio Grande Spermophile) and *S. harrisi saxicolus* (Rock Spermophile). The common "Jackrabbit" of the Rio Grande, described by Audubon and Bachman, Baird, Allen, and other writers as *Lepus callotis* and *L. texianus*, is taken to represent a new species, which has been named *L. merriami*. Two new species of mouse, *Peromyscus canus* (Texas grey mouse) and *P. tornillo* (Tornillo mouse), are described, and two new sub-species, *P. texanus medius* (San Dilgo-plains mouse) and *P. t. clementis* (San Clemente mouse).

Technical bacteriology has received an interesting addition to its list of useful fermenting moulds, in the shape of a recent contribution from Dr. C. Wehmer. At the instigation of and with the assistance of Dr. Went, of Java, Dr. Wehmer has isolated and carefully studied the organism responsible for the production of the well-known Soja (Tao-Yu). So far, it appears to have every right to be regarded as a novelty, although in some respects closely allied to the *Aspergillus oryzæ* of Japanese fame. In designating this organism as *Aspergillus Wentii*, Dr. Wehmer gracefully acknowledges Dr. Went's important share in its discovery and identification. In artificial cultures it is readily distinguished from its Japanese *confrère*, as it produces a pigment approaching a light chocolate in colour, whilst the former elaborates a greenish-yellow growth. The method adopted for its collection is very simple, merely consisting in covering up boiled beans, subsequently superficially sun-dried, with the leaves of *Hibiscus tileacus*; the much-valued *Aspergillus* then invariably makes its appearance on the beans, and the usual process of manufacture is then proceeded with. Curiously no other article of food offers any attraction to the Aspergillus, beans alone serving for its capture. This method of collecting the mould exactly resembles that employed by the Chinese in their process of arrak manufacture. The original memoir is accompanied by some beautiful plates, and one of these shows very clearly the different appearance on rice-cultures of the *Aspergillus oryzæ* and the *Aspergillus Wentii* respectively.

We have received the first part of a *Handbuch der praktischen Zimmergärtnerei*, by Max Hesdörffer (Berlin: Oppenheim). It appears to be a very complete practical guide to the indoor cultivation of plants, published at a very low price (75 pf. when complete). The present part contains a chromolithograph, and a number of wood-block illustrations of utensils and of gardening processes.

The Rebman Publishing Company, Limited, have in the press for publication a serial work exemplifying the uses of the new photography in medical and surgical diagnosis, entitled "Archives of Clinical Skiagraphy," by Mr. Sydney Rowland. The first part will consist of six collotypes (10 by 12½ inches), illustrating cases in which the method has been successfully applied to elucidating obscure injuries to the knee, elbow, and other parts of the body. The first plate is a skiagram of the complete osseous system of a full-grown child—the largest subject as yet done.

A new local bi-monthly magazine—the *Halifax Naturalist*—has made its appearance, its object being to publish information concerning the natural history and archæology of the ancient parish of Halifax, and to record the doings of the Halifax Scientific Society. The first number contains a coloured geological map of Halifax, by Mr. C. E. Fox, and articles on some physiographical features of the district, by Mr. W. Simpson; the birds of the Luddenden Valley, by Mr. H. Waterford; and the flora of Halifax, by the editor, Mr. W. B. Crump. Such a magazine should awaken interest in the wild life of the parish to which it belongs, and lead to a keener and wider appreciation of the works of nature.

WE have received the meteorological *Jahrbuch* of the observatory of the Magdeburg *Journal* for the year 1894. The results are given in the same form as in the previous twelve volumes, and the work is a good sample of the way in which complete observations and means may be condensed into a compact and convenient form. The first part contains eye observations made thrice daily, and the second part contains hourly observations from self-recording instruments with facsimile traces of the sunshine recorder, and also curves of the barograph and thermograph for periods of disturbance, mostly during thunderstorms. The highest shade temperature recorded during the year was 94°·3 in July, and the lowest 0°·9, in January. The total annual rainfall amounted only to 19·4 inches, and the greatest fall in twenty-four hours was 1·6 inches.

AMONG the papers published in the March number of the *Journal* of the Royal Horticultural Society (vol. xix. part 3, 1896), are three to which attention may profitably be directed here. Mr. Francis Darwin has a paper on "Etiolation as a Phenomenon of Adaptation." Mr. A. W. Sutton contributes an account of the introduction and cultivation of the potato, illustrated by numerous figures. He has made some grafting experiments with the potato and tomato, and describes his results in his paper. As a result of introducing a tomato graft upon a potato stem, the potato roots, maintained in growth by tomato foliage, produced a crop of potatoes in the pot, while the tomato foliage above ground produced a crop of tomatoes, nourished by the potato roots in the pot. In a short paper, Dr. Maxwell Masters describes a number of substitutes for larch. He shows that there are many conifers which more or less fully realise the characteristics of an ideal substitute for larch trees.

WHEN Henri St. Claire Deville, in company with Debray, Morin, and Rousseau Bros., erected the first plant specially designed for the manufacture of aluminium, forty years ago, they did not foresee the greatness of the future of the industry they founded. A sign of the growth of the industry in the United Kingdom is the appearance of a monthly periodical, *Aluminium and Electrolysis*, which will be concerned with all matters pertaining to the manufacture and use of the metal. France and the United States have for some time led the way in aluminium manufacture, and have had their special journals, but no paper primarily devoted to the interests of aluminium has hitherto been published in the United Kingdom. The addition to the ranks of industrial journals is made at an opportune time, for, after a period of quiet, once more increased attention is being given to aluminium in Great Britain.

IT is not given to many scientific discoveries to command so much popular attention as Röntgen's discovery of the X-rays; and the demand for information on the subject has resulted in a copious supply of lectures and literature, while the desire to revel in the marvellous has been gratified by a plenitude of photographs of invisible objects, published in various forms. Messrs. Valentine and Sons have added to their series of collotype view-books a brochure containing reproductions of eight Röntgen photographs taken by Profs. E. Waymouth Reid and J. P. Kuenen at University College, Dundee. A brief description is given of the method of work, and of each photograph. Another publication on the same subject, by August Dittmar, has been published by Mr. F. Bauermeister, Glasgow. This pamphlet contains a general statement of the elementary principles which result in the production of kathode rays and Röntgen photography, illustrated with eleven text-figures and one photograph obtained by means of X-rays.

AMONGST the products of the reaction at 400°–500° of hydrobromic acid upon phosphoryl trichloride, M. Besson (*Comptes rendus*, April 11) has succeeded in isolating the missing phosphoryl chlorobromide $POClBr_2$. This is a solid substance at the ordinary temperature, melting at 30°, and distilling under normal atmospheric pressure at 165°. Its boiling-point is not fixed, however, as it slowly decomposes into the chlorobromide $POCl_2Br$ of Menschutkin and phosphoryl tribromide, a property which renders its isolation by fractional distillation difficult. Besides these two chlorobromides and the tribromide, M. Besson obtained considerable quantities of solid phosphorus pentabromide from the product of the original reaction. The formation of this substance is remarkable, as it involves the replacement of the oxygen of the phosphoryl group by bromine with elimination of water, whereas at ordinary temperatures the inverse change is known to take place with great vigour.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♂) from India, presented by Mr. Owen L. Hancock; a Red and Blue Macaw (*Ara macao*) from Central America, presented by Mr. Eugene E. G. Jones; a Dusky Duck (*Anas obscura*, ♀) from North America, presented by Mr. W. H. St. Quintin; an Indian Elephant (*Elephas indicus*, ♂) from India, two Red-beaked Weaver Birds (*Quelea sanguinirostris*) from West Africa, a Java Sparrow (*Padda oryzivora*) from Java, a Rose-breasted Grosbeak (*Hedymeles ludovicianus*) from North America, a Lesser Black-backed Gull (*Larus fuscus*), British, deposited; a Caffer Cat (*Felis caffra*) from South Africa, purchased.

OUR ASTRONOMICAL COLUMN.

MIRA CETI.—For some years past it has been found that the predicted maxima of this famous variable star, based upon a period of 331 days, have been several weeks in advance of the actual maxima, and it would seem that the time has arrived when a new discussion of its light-curve should be undertaken. According to the ephemeris, the last maximum was due on December 9, but the greatest brightness did not occur until towards the end of January, as shown by the following summary of the observations (*Bull. Soc. Ast. de France*, April):—

Date.		Mag.	Date.		Mag.
Nov.	1–11	9·0	Jan.	15	3·7
	15–30	8·2		18	3·5
Dec.	1–10	7·8–7·5		20	3·2
	15–31	7·5–6·5	Feb.	1	3·2
Jan.	1	6·0		15	3·4
	7	4·8		20	3·6
	9	4·2	March	1	3·8
	10	3·8		10	4·2

According to M. Dumenil (*Comptes rendus*, March 30), the magnitude at maximum during the last twelve periods has varied between 2·5 and 4·7. This fact, in conjunction with the apparent irregularity of the light-curve, indicates that there is more than one source of variability. On the meteoritic hypothesis the variations are produced by two or more swarms of meteorites revolving round a larger central swarm, and passing through its outlying parts near periastron. On this supposition it may be possible to analyse the light-curve of Mira so as to determine the part played by the individual sources of variation, each of which may be perfectly regular.

AN EXHIBITION OF ASTRONOMICAL PHOTOGRAPHS.—An international exhibition of astronomical photography will form part of the Berlin Industrial Exhibition to be held this year, from May 1 to October 15. Herr F. S. Archenhold, who is arranging the collection, has just sent out a circular asking for contributions of photographs of astronomical instruments of historic interest, of plans and buildings of observatories, as also the reproductions of astronomical drawings and kindred subjects (such as spectra, luminous night-clouds, &c.), lantern-slides 8½/10 cm. in size, or larger, also separate heliogravures already published in the annals of observatories, may be sent in to complete the photographic collection. In all cases, where it is not especially requested that they shall be returned, photographs will be retained and preserved as a complete collection, which, together

with the models of telescopes, made especially for this purpose in the mechanical department of the Grunewald-Sternwarte, will form the foundation for an astronomical museum. It is requested that every photograph shall be furnished with the name of the observatory sending it in, also the exact particulars as to date and time of exposure, method of developing, name of object, and any thing of interest connected therewith. It would also be desirable to state on the backs of the photographs, if, and in what publication, any further particulars may be found concerning the same subject. Though the exhibition opens on May 1, any pictures, which owing to the distance of the observatory sending them, should not arrive by that date, can be received at any subsequent period. As, however, a catalogue is to be completed by July 1, it will be to the interest of exhibitors to see that their contributions arrive in Berlin on July 15 at latest. Particulars as to the number and extent of intended contributions should be sent as early as possible to Herr F. S. Archenhold, Grunewald-Sternwarte, bei Berlin.

THE SUN'S ROTATION.—Two methods have hitherto been chiefly employed to determine the period of the sun's rotation, namely, observations of sun-spots and determinations of the displacements of lines in the spectrum of the sun's limb. A third method, depending upon the movements of faculæ, has recently been utilised by W. Stratonoff (*Ast. Nach.*, 3344). His results are based upon an investigation of 400 photographs of the sun, taken during 1891–1894, and the number of daily angular movements available for discussion amounts to 1024, after rejecting those in which identifications on successive photographs were at all uncertain. All the facts which are brought together clearly indicate that faculæ in different heliographic latitudes move with different velocities, and that the rate of movement diminishes in passing from the equator towards the poles. In the zone 10°–19° the retardation amounts to 0°·37 per day as compared with the equatorial angular velocity, while in the zones 20°–29° and 30°–40° it is 0°·47 and 1°·0 respectively. The law of variation of the velocity of the faculæ with the latitude is much more complex than in the case of spots; from 0° to 8° the angular velocity is almost constant, from 9° to 16° it decreases very rapidly, between 16° and 25° it remains nearly uniform, while from 25° to 34° it again diminishes quickly. Similar results are obtained for both solar hemispheres. The faculæ appear to move more rapidly than the spots in all solar latitudes from 0° to 40°, as shown by the following mean values:—

Heliographic latitude.		Diurnal angle of rotation. Faculæ.		Spots.
° °		°		°
0–9	...	14·61	...	14·30
10–19	...	14·24	...	14·15
20–29	...	14·14	...	13·83
30–40	...	13·61	...	13·40

The spectroscopic measurements made by Dunér indicate that the photosphere rotates even more slowly than the spots, and the following comparison shows the relation of the surface rotation with that of the faculæ:—

Heliographic latitude.		Diurnal angle. Stratonoff.		Dunér.
°		°		°
0	...	14·61	...	14·14
15	...	14·24	...	13·66
30	...	13·87	...	13·06

So far as the available data permit any conclusions to be drawn, it thus appears that there are three distinct laws of rotation for what in all probability correspond to three different solar levels.

THE TSETSE FLY-DISEASE.[1]

FOR forty-six years the Tsetse fly has been notorious as a terrible scourge to live-stock, and the most formidable of impediments to colonisation in Equatorial and South Africa. First brought into prominent notice by the explorers Gordon-Cumming Oswell and Captain Vardon, it was described by Westwood[2] in 1850, under the name *Glossina morsitans*, from specimens collected by the last-named traveller. The genus, an ally of our common blood-sucking *Stomoxys*, contains six described African species, for all of which Tsetse appears now to serve as a common name.

The peculiarities of the fly and "fly-disease" have been made familiar by most other African travellers, Livingstone, Andersson, Chapman, Selous, &c. The Tsetse (Fig. 1) is a dipterous insect, of no striking appearance, grey, with darker stripes on the thorax, and a pale or yellowish abdomen furnished with two dark spots on the anterior portion of each segment; it is rather larger than the house-fly, but is narrower when at rest, the wings overlapping. The mouth-parts form a powerful, piercing and suctorial beak. Local in distribution, the fly occurs in numerous detached regions of Africa south of the Equator, its headquarters appearing to be along the Zambesi and its tributary the Chobe. "Fly-country" is hot, moist and low alluvial ground, along river-banks, covered with forest or scrub vegetation, and uninhabited save by wild animals. Within its sharply-defined limits, which may extend along one bank only of a river, the Tsetse swarms; it is extremely active, and eagerly attacks man or animals for the purpose of sucking blood. On man no effect is produced beyond temporary irritation, of which the extent has been very variously described, probably in accordance with the idiosyncrasy of the victims. Wild animals do not suffer; but domestic animals, which have entered fly-districts, are seized in the course of a few days with fever and wasting, and almost invariably die. Horses and dogs rapidly succumb, while goats, donkeys and unweaned calves are said by some travellers to be resistant; this, however, is not generally true of the two former kinds. Slight non-fatal attacks confer no immunity, but some native breeds of dogs enjoy partial protection, although a certain number of pups in each litter perish. Books of African travel are full of records of horses, teams of oxen, or herds of native cattle having been destroyed by entering fly-districts, and on one occasion a Masai army, proceeding to the attack of a neighbouring tribe, was effectually routed by having incautiously crossed fly-country.

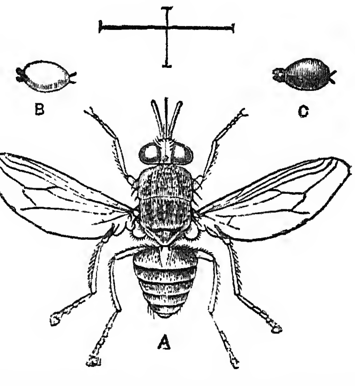


FIG. 1.—A, Tsetse fly (*Glossina* sp.), Transvaal; B, larva; and C, puparium of a Tsetse (after Bruce).

For some years the accounts of fly-disease were not seriously questioned, until in 1870 a Mr. St. Vincent Erskine[1] endeavoured to show that it was due solely to change of grass or climate, and severely criticised Livingstone's account, forgetting that the proper course lay in attempting to reconcile the apparent discordance between his own and other observations. Since then Hartmann, Marno, Falkenstein and other travellers who found either the fly present and disease absent (as on the Loango coast), or the reverse, have further discredited the earlier statements, and so eminent a dipterologist as Van der Wulp,[2] in summarising the evidence, has concluded that the Tsetse is not injurious, or that its ill-effects are exaggerated. Nevertheless travellers, especially in the Zambesi district, whilst adding nothing to our knowledge, have constantly reaffirmed the connection between the fly and the disease.

One or two naturalists have indeed hit the truth, and among them Schoch, who in an ably-reasoned little paper[3] concluded that the facts pointed, not to the action of a specific fly-virus, as was originally supposed, but to the transmission of a bacterial

[1] "Preliminary Report on the Tsetse Fly-Disease, or Nagana, in Zululand." By Surgeon-Major David Bruce, A.M.S. (Bennett and Davis, Field Street, Durban.)
[2] *Proc. Zool. Soc. Lond.*, 1850, pp. 258–270.

[1] Paper read before the Nat. Hist. Assoc. of Natal, reported in *The Entomologist*, v. p. 217.

[3] *Mitth. Schweiz. ent. Ges.*, 1884, pp. 685–686.

poison-matter. It will be seen that this conclusion is substantially correct.

Mysterious as has been the connection between the Tsetse and the animal-disease endemic in its haunts, there has been never any reason to doubt that a properly-conducted investigation would throw much light on the subject. At last, on behalf of the Natal Government, such a research is being made by Surgeon-Major Bruce, and the results of the first three months' work are just published. They are of great interest, and are full of promise that our knowledge of this disorder will be placed at least on a level with that of kindred diseases.

Dr. Bruce, in a somewhat brief recapitulation of the characteristics and habits of the fly, adds one important new fact, of which he appears scarcely to recognise the significance. The fly investigated, which is not necessarily Westwood's species, is viviparous, giving birth to an adult larva (Fig. 1, B), which creeps about actively in search of a hiding-place, where, in the course of a few hours, it changes by the usual skin-hardening to a jet-black puparium (Fig. 1, C). Hitherto the accounts of Bradshaw and Chapman have asserted, on native authority, that the maggot lives in buffalo-droppings, and a statement of Edwards, quoted by Castelnau,[1] that the Bushmen declared and demonstrated the Tsetse to be viviparous, has gone almost unnoticed.

This fresh observation must be accepted with some reserve, as the fly has not yet been bred from the puparium. Assuming it to be correct, it is of two-fold interest; the mode of reproduction is substantially that which exists in the Pupipara, though, to judge from Dr. Bruce's account and rough figures, the newly-extruded Tsetse-larva, though equally mature, is somewhat less abnormal than that, for instance, of *Melophagus*.[2] A transitional series from oviparous forms has been described in Muscidae by Portschinsky,[3] and viviparous Oestridae are well known to occur. Nevertheless, this peculiarity of *Glossina*, which could not have been prognosticated on systematic grounds, sufficiently demonstrates the unsoundness of separating the Pupipara from Muscidae on account of developmental differences.

Moreover it shows that the Tsetse, unlike most blood-sucking insects, such as the flea or mosquito, is absolutely dependent for its continued existence upon the food taken in the imaginal state, and, unless it is capable of feeding upon other matters than blood, which, though unlikely, should not be disregarded in the inquiry, its life is bound up with that of the indigenous mammalia. And this both confirms and explains the observation made by Livingstone, Selous and others, that it is constantly associated with large game, such as the buffalo, and ceases to frequent districts from which they retreat.

Fly-disease or Nagana (a Zulu term, aptly signifying to be low or depressed in spirits) is due, according to Dr. Bruce, to the presence in the blood of a flagellated infusorian. This hæmatozoon (Fig. 2) is of elongate form, about 10–20 μ long by 2 μ wide, furnished with a membrane or "fin" running along one side of the body, and a flagellum at one end.

It is intimately allied to, if not actually identical with, *Trypanosoma evansi*, the hæmatozoon of "Horse Surra." At present Dr. Lingard, the leading authority on that Indian animal-disease, hesitates to regard the two complaints as the same, because Surra does not attack cattle. But when it is recollected that Nagana pursues a much slower course in cattle than in horses, and that wild game are immune to it, just as African sheep are to anthrax, the objection does not seem very formidable.

The hæmatozoa of Nagana make their appearance, which is signalised by a rise in temperature, in the blood after an incubation period of 7 to 20 days, swimming actively among, and apparently "worrying" the corpuscles. With the progress of the disease they increase in numbers and, at the time of their host's death, may amount, in the dog, to 310,000 per cub. mm. of blood! Neither reproductive nor any other stages of the parasite are yet known, nor has it been found in the blood of any wild animal, inoculation of which (the best test for the presence of the hæmatozoon) has hitherto failed to produce disease.

Dr. Bruce has demonstrated that it is possible repeatedly to feed Tsetse on a healthy dog without producing disease in that animal—that is, the flies possess no specific venom; but that, if allowed to draw blood from a diseased animal or the carcase of one, they will communicate Nagana to any healthy animals on which they are subsequently fed, and the same result is obtained by inoculation of diseased blood, or, in dogs, by feeding them on the flesh of an animal dead of Nagana.

[3] Osten Sacken, *Berl. ent. Zeitschr.*, 1887, pp. 17–27.

Thus far is the cause of the disease ascertained, as is the fact that the Tsetse can serve as a transmissive agent; but the natural source, other than diseased animals, which are not known to occur in a wild state, whence the flies obtain the parasite is still undetermined, nor is it proved that, unlike malaria, the disease cannot be acquired by breathing the air of the fly-country.

Repeating an old experiment of Captain Vardon's, Dr. Bruce has shown that a few hours' sojourn in a fly-district is sufficient exposure to induce the disease in a horse, which is prevented from eating and drinking there; but to complete the proof that the flies are indispensable as carriers of infection, it has further to be shown that domestic animals, if protected from their bites, can remain in such a region with impunity. As yet Dr. Bruce has not been able to make the experiment, but it may be observed that the concurrent testimony of many travellers, that animals can safely cross a fly-country on nights when the insects are inactive, goes to prove that the infection is not air-borne.

If Dr. Lingard's very voluminous report on Surra[1] be compared with the one under consideration, the points of identity between the two diseases will be found to be remarkably numerous, though not quite universal, and the fact that two such investigations are in progress by workers in touch with each other ought materially to quicken and extend the results arrived at. The complete life-history of the Surra parasite has yet to be

FIG. 2.—Hæmatozoa of Nagana in the blood of a horse (after Bruce).

published, and in discussing the ætiology of that complaint, Dr. Lingard attaches much importance to the eating of grass from swamps and marshy ground, and the drinking of stagnant water, and but little to fly-infection, which he considers to occur chiefly when healthy and diseased horses are crowded together. Such infection is, therefore, regarded as being of the purely transmissive form of fly-inoculation found in anthrax and possibly other septic diseases.

But a more intimate relationship of the fly and the parasite, at least in Nagana, suggests itself. In 1884, Dr. Manson showed[2] that the mosquito is the intermediate host of filaria, and applying his observations to the building-up of a working hypothesis as to the life-history of the malaria parasite (Laveran's hæmacytozoon) outside the body, he suggested, in 1894, that the mosquito also served as host for that form, and that the "flagellation-stage" assumed by a certain number of the parasites in drawn blood was an incipient change designed for life in the mosquito. In a course of lectures,[3] in process of being delivered as we write, for the unpublished text of which we have to return him our warm acknowledgments, this theory is developed in greater detail, and is supported by the observations of Surgeon-Major Ross, that examination of the blood imbibed from a malarial patient by mosquitoes shows, shortly after its extraction, that not a few, but the majority of parasites undergo flagellation. That the destiny of the flagella is still untraced is due to the extreme difficulty of the observations.

Dr. Manson's theory still awaits its final proof or disproof,

[3] "The Goulstonian Lectures on the Life-History of the Malaria Germ outside the Human Body," delivered before the Royal College of Physicians of London, March 1896, by Dr. Patrick Manson.

and has been developed to a stage in which, failing the latter contingency, it is likely to be widely accepted. Assuming it to be correct, man occupies to the parasite the position of what he terms an "optional host," in which parasitism is neither necessary for nor inimical to the continuance of the species.

Another case of such possible relationship may be mentioned. In 1889, it was shown by Drs. Smith and Kilborne [1] that the so-called "Red-water" or "Texas fever" of cattle is a disease of malarial type due to the presence in the red blood-corpuscles of bodies presenting a certain similarity to Laveran's parasite. In this disease the sole form of infection known is by the agency of cattle-ticks (Ixodidæ), in which, notwithstanding their undoubted transmissive part, we believe the entozoon has hitherto not been detected in any stage.

Without attempting in any way to prescribe a line of research which Dr. Bruce is unlikely to overlook, it is impossible not to foreshadow the interest which will attach to an examination of the evolutions of the parasite in the body of the Tsetse, an examination which may end by showing that the insect, even if it possesses no specific virus in the older sense, may play an essential part in the economy of the hæmatozoon.

The symptoms, course, and pathology of Nagana are treated very fully by Dr. Bruce in a series of clinical cases, accompanied by charts indicating the variations of temperature, and the percentages of red blood-corpuscles and hæmatozoa. Suffice it here to say that the red blood-corpuscles may be reduced to one-third of their normal amount, and in one dog, at the point of death, bore to the parasites the proportion only of ten to one. He finds it invariably fatal in the horse, ass and dog—perhaps not necessarily so in cattle—in which it runs a much slower course. Two graphic and painful pictures are given of a donkey and a dog in the last stage of this distressing disease, and one is glad to learn that there is little suffering, and that the appetite rarely fails up to the last.

Of the new facts contained in this report, perhaps the most welcome is that Dr. Bruce finds that arsenic, so far as he has been able to try it, has a marked action on Nagana, causing disappearance of the hæmatozoa, reduction in temperature, and maintenance of the normal number of red blood-corpuscles. That it is a complete cure or prophylactic remains to be shown. The same result has been found in Surra, though the proportion of cases mentioned by Dr. Lingard as cured by treatment with arsenic is but small. This appears to be due partly to the extreme debility of many animals at the time of its first administration, and to the large and sometimes poisonous doses required. Its effects, nevertheless, are so remarkable as to give good ground for hoping that, when the limits of utility and safety of the drug, especially as a preventive, or in the early stages of disease, are determined, the trivial addition of a supply of arsenic to the traveller's outfit will free the African colonist of, perhaps, his greatest source of anxiety.

In Surra attempts have been made to treat the disease by inoculation or injection of filtered serum from affected animals. They have not proved successful, nor, while admitting the importance of the fact that the range of forms attacked by it and Nagana is limited, is there any *à priori* reason why they should succeed. The class of diseases here noticed, of which malaria may be taken as the type, is not caused by bacteria; and though it is known that the vitality of hæmatozoa is affected by alterations in the medium in which they live, as by the administration of quinine or arsenic, the ordinary methods of research and antitoxic treatment employed in bacteriology do not appear to be applicable to them.

In view of a tendency in the reports, both of Dr. Bruce and Dr. Lingard, to dwell in detail upon the clinical features of the respective diseases, it cannot be too strongly urged that, when once the pathogenic nature of the hæmatozoon has been established, these inquiries, in order to progress to a fruitful issue, must be conducted on zoological lines. The mode of reproduction, distribution and general bionomics of the hæmatozoon, and, in the event of its possessing more than an accidental connection with the Tsetse, the economy of that insect, these are the essential subjects of research: and little light will be thrown on them by any amount of laboriously-compiled clinical and pathological details.

It is to be desired that Surgeon-Major Bruce's further and more complete reports shall be republished in England, or at least made easily accessible to the many persons interested in African colonisation.

WALTER F. H. BLANDFORD.

[1] *Ann. Rep. U.S. Sec. Agric.*, 1889, pp. 38-91: 1890, pp. 92, 93, and 105-110; and following year.

THE ACTION OF LIGHT ON THE IRIS, DEMONSTRATED BY A NEW PUPILOMETER.

BROWN-SÉQUARD observed that, in the iris of batrachians and fishes, separated from the rest of the eye, the pupil contracts at the approach of a candle, a fact which he attributed to the direct action of the light on the muscular tissues of the iris, the nervous elements having already lost, as he thought, at the times of his experiment, all irritability. We may also ask if the iris of the living eye responds to the direct action of light.

This problem cannot be approached directly, because of the mobility of the eye and the extreme variability of the pupil.

My new pupilometer, constructed by the well-known engineer, Mr. Ph. Pellin, consists of a series of three tubes of increasing diameter, commencing with the ocular tube; the first is provided with a screen perforated by a very small hole, and with an adjustable frame which may be removed or brought near in a manner to fix the eye at the required distance (12·8 mm.), of the anterior focus of the eye. The last tube is closed by a ground glass, 10 cm. in diameter; on the surface of this glass appear black and white circles with numerical graduations. All the peripheric zones of the ground glass which are not perceived by the retina illuminate the iris. In this manner I am able to distinguish the effect produced upon the pupil by suppressing the illumination of a portion of the iris by means of opaque rings of blackened copper successively arranged upon the glass, the apertures of which are precisely equal to the apparent surfaces of the pupil, and then suddenly removed. For the retina nothing is changed by changing these rings, since the opening of each ring equals precisely the apparent surface of the luminous admission; for the iris, on the contrary, all is changed, since the opacity of the interposed rings prevents the luminous rays from reaching it.

The experiment made under these conditions proves that there is almost always a dilatation of the pupil when the iris is withdrawn from the light. The process may be described as follows. The subject is requested to indicate the largest concentric circle that he is able to distinguish on the luminous background, whereupon I place against the background an opaque ring, the opening of which equals precisely the said concentric circle; after a few moments I remove the ring, and then the subject generally remarks the coincidence of the apparent surface of his pupil with a concentric circle of much greater diameter. I have noticed but two exceptions to this rule where the result was a contraction instead of enlargement. The dilatation varies from $\frac{1}{8}$ to $\frac{1}{18}$ of 1 mmq. for 1 mmq. of iris withdrawn from the light, and such dilatation has generally been observed to be greater for the dark than for the light iris.

The great majority of dark eyes which prevails in southern latitudes is perhaps a provision of nature to thus protect the eye from the effect of too abrupt changes of luminous irritation.

In any case the variations of dimensions of the iris are much less when it is the iris alone which is subjected to light than when the iris and the retina are influenced together. It may be shown, for instance, that if 1 mmq. of the centre of the retina be withdrawn from the light, the iris is capable of increasing in size from 1 to 16 mmq.

If, with the pupilometer of Robert Houdin, we observe the pupil of one eye while the iris of the other is obscured, we remark on the said pupil a dilatation from half to quarter of a millimetre in diameter; this goes to prove that the action of light on the iris is due, in part at least, to a reflex of cerebral origin; but, on the other hand, we do not yet possess sufficient knowledge of the anatomy of the iris to enable us to say whether these variations are due to the direct action of light on muscular elements (as supposed by Brown-Séquard) or to the action of nervous centres yet unknown belonging to the iris.

I have studied the influence of a coloured disc on the pupil, allowing the coloured light to strike the retina, in which cases I remarked that the more luminous the colours the less the dilatation of the pupil: yellow and green, for instance, cause a greater dilatation than red or blue. Again, I have remarked just the contrary. The same contradictions, which may be explained by the fatigue of the eye, are manifest when we examine the isolated action upon the iris of rings cut from the same block as the aforesaid coloured disc.

I have also endeavoured to find with the new pupilometer the

relation existing between the pupillary contraction and the illumination of the retina.

The discovery of the direct action of light upon the iris leads to a number of curious deductions.

1. We are now able to explain the cause of the intense photophobia which characterises the iritis, and it is probable that the examination of the iris by the new pupilometer from the point of view of its proper excitability will be very useful in the diagnosis of diseases of the eye.

2. It shows that our photometric measurements must involve a systematic error, although slight. When the eye is directed towards the most luminous of two lights of different intensities the iris contracts, tending thus to equalise for the retina the two lights. It is in this movement of the iris perhaps that we should seek an explanation of the contradictions which we meet continually between the data of our photometric processes and the data furnished by sensitive plants employed in the measurement of light. We know, for instance, that a branch of *vitia sativa* placed between two lights equal for our eye and equidistant from each other tends invariably to incline towards one of them.

CHARLES HENRY.

IMMUNISATION AGAINST SERPENTS' VENOM, AND THE TREATMENT OF SNAKE-BITE WITH ANTIVENENE.[1]

I.

FROM a remote period of antiquity, there has been enmity between the human race and serpents, and, in a literal sense, man has bruised the head of the serpent, and the serpent has bruised the heel of man. This long-continued feud has not yet resulted in victory for either side. Venomous serpents still annually destroy the lives of tens of thousands of human beings, and, in self-defence, tens of thousands of serpents are annually slain by man.

The progress of knowledge has greatly increased the means for protecting mankind against the death-producing effects of many diseases; and, although these means have been liberally employed in the contest against venomous serpents, none of them has hitherto been found sufficient.

The reality of the contest is appreciated when we find pervading medical literature from its earliest beginnings—from the time of Pliny and Celsus—to the present time, disquisitions on the treatment of the bites of venomous serpents, and lengthy descriptions of the numerous remedies, organic and inorganic, that have been used for this purpose. Although extended experience and the application of the scientific methods of the present day, have resulted in showing that each of these remedies had been recommended on insufficient grounds, we may hesitate in pronouncing their recommendation to have been premature, in view of the impossibility of waiting, in the presence of imminent dangers, until accurate demonstration has been obtained by the usually tardy and laborious processes of science.

Let me pause here for a few minutes to indicate the practical importance of a scientific demonstration of the value of any remedy that is used in the treatment of snake-poisoning.

When a serpent inflicts a wound, I need scarcely say that it is not the wound, but the venom introduced into it which causes the symptoms of poisoning, and the death that may result. This venom is now known to be a complex mixture, containing several non-poisonous as well as poisonous substances. The latter are not ferments and have no power of reproducing themselves in the body, but they are substances that produce effects having a direct relationship to the quantity introduced into the body. This quantity in the case of each serpent varies with its size and bodily and mental condition; with the nature of the bite—whether both fangs or only one have been introduced, whether they have penetrated deeply or only scratched the surface; and with other circumstances related to the serpent, such as whether it had recently bitten an animal or not, and thus parted with a portion or retained the whole of the venom stored in the poison glands.

A bite may, therefore, result in very little danger, or it may be rapidly fatal; but, in order to produce death, there must have been introduced into the tissues at least a certain quantity of venom, which is spoken of as the minimum-lethal quantity or dose. The minimum-lethal quantity for the animal bitten, again, is different for different species of animals, and different also for different individuals of the same species, the chief cause of difference between animals of the same species being the body weight of the individual, the quantity required to produce death being very exactly related to each pound or kilogramme of weight.

If even a minute fraction below the minimum-lethal has been introduced into the tissues by an effective bite, death will not follow, although serious and alarming symptoms will be produced of exactly the same kind as those which follow a bite which terminates fatally.

How then can we be assured, in any case of snake-bite in man, that a quantity of venom sufficient to produce death has been introduced? It is impossible to answer this question except by the result. If a quantity less than the minimum-lethal has been introduced, although the gravest symptoms may be produced, the patient will recover whatever remedies are administered, provided, obviously, that the remedies have not been so injudiciously selected or used that they themselves, and not the insufficient quantity of venom, produce a fatal termination. The recovery of a patient after the introduction of less than the smallest quantity of venom capable of producing death, has thus too often been attributed to the remedies that have been administered; and consequently, as, indeed, is exemplified in the treatment of many diseases, a large number of substances have acquired an unjust reputation as antidotes. The list of antidotes has, accordingly, become a very large one; but when their pretensions have been subjected to sufficient tests, the verdict is that all of them are valueless to prevent death when even the smallest quantity of venom required to produce death has been received by an animal.

Without entering into details, I will content myself with reproducing the opinion of Sir Joseph Fayrer, that, "after long and repeated observations in India, and subsequently in England, I am forced to the conclusion that all the remedies hitherto regarded as antidotes are absolutely without any specific effect on the condition produced by the poison."

But while medical practice and science, in each period of its development, has thus failed to protect man against this ancient enemy, legendary traditions, the tales of travellers and of residents among nations and tribes existing outside of the civilisation of the time, at least suggest that, by means apart from the use of remedies, some measure of success may actually have been obtained.

Many of these legends and statements are probably of great significance, and, in connection with facts derived from experiment, which to-night I have to describe, they possess a deep interest.

We learn from these legends that from a remote period of time the belief has existed that a power may be acquired by man of freely handling venomous serpents, and even of successfully resisting the poisonous effects of their bites.

The Psylli of Africa, the Marsi of Italy, the Gouni of India, and other ancient tribes and sects, were stated to have been immune against serpents' bites, and this immunity has been explained on the supposition that serpents' blood was present in the veins of the members of these tribes and sects.

In more modern times and, indeed, at the present day, the same belief is expressed in the writings of many travellers. In "A New and Accurate Description of the Coast of Guinea," by William Bosman, published in 1705, an account is given of the great "reverence and respect" of the negroes for snakes, worshipped by them as gods; in connection with which the following statements are made. "But what is best of all is that these idolatrous snakes don't do the least mischief in the world to mankind; for if by chance in the dark one treads upon them, and they bite or sting him, it is not more prejudicial than the sting of millipedes. Wherefore the natives would fain persuade us that it is good to be bitten or stung by these snakes, upon the plea that one is thereby secured and protected from the sting of any poisonous snake" (p. 379).

At Southern Africa, the Rev. John Campbell, in 1813, observed that it was "very common among the Hottentots to catch a serpent, squeeze out the poison from under his teeth, and drink it. They say it only makes them a little giddy, and imagine that it preserves them afterwards from receiving any injury from the sting of that reptile" (p. 401).

Drummond Hay, in his work on Western Barbary, pub-

[1] An address delivered at the Royal Institution of Great Britain, on Friday, March 20, by Prof. Thomas R. Fraser, F.R.S.

lished in 1844, gives a description of the performances by members of a sect of snake-charmers, called the Eisowy, who freely handled, and allowed themselves to be bitten by serpents proved to be venomous by a rapidly fatal experiment performed on a fowl. At the termination of the exhibition, the Eisowy, apparently as a usual part of the performance, "commenced eating or rather chewing" a poisonous snake, "which, writhing with pain (to quote Mr. Hay's words), bit him in the neck and hands until it was actually destroyed by the Eisowy's teeth." He states that, on another occasion, at Tangier, a young Moor, who was witnessing the performances of a snake-charmer, ridiculed his exhibition as an imposture, and having been dared by the Eisowy to touch one of the serpents, the lad did so, was bitten by one of them, and shortly afterwards expired. In connection with my subject, a special interest is attached to the account given by Mr. Drummond Hay, and repeated in its main features by Quedenfeldt in the *Zeitschrift für Ethnologie* of 1886, of the origin of this Eisowy sect, and of the immunity which they claim. The founder, Seedna Eiser, was being followed through the desert of Soos by a great multitude, who, becoming hungry, clamoured for bread. On this, Seedna Eiser became enraged, and turning upon them he uttered a common Arabic curse, "Kool sim," which means "eat poison." So great was their faith in the teaching of the saint, that they acted upon the literal interpretation of his words, and thereafter ate venomous snakes and reptiles; and from that time they themselves and their descendants have been immune against serpents' bites (p. 65).

Dr. Honigberger, in his "Thirty-five Years in the East," published in 1852, relates the incident of a faqueer who was bitten by a serpent, and to whom he at once sent medicines which he judged likely to prevent the ill-effects of the venom. "On the same afternoon," he writes, "I visited him and found him in good spirits. I at first attributed the circumstance to the effect produced by the remedies I had sent him, but was surprised on hearing that he had not taken them, he being of opinion that the venom of the serpent was incapable of affecting him, inasmuch as he had often been bitten by serpents without having sustained any injury." On the suggestion of the faqueer, the same serpent, which had been caught and retained, was allowed to bite him again, and afterwards to bite a fowl. This fowl was taken home by Dr. Honigberger, and he found it dead on the following morning, "although the faqueer, who was bitten first, was quite well" (p. 135).

Nicholson, in his work on "Indian Snakes" (1875), and Richardson, in his "Landmarks of Snake-poison Literature" (1885), also narrate instances, the latter with obvious disbelief in their reality, suggesting that snake-charmers may possess some means for protecting themselves against the bites of venomous serpents.

Many other examples might be quoted in which this suggestion is made. The attention which has been drawn to the subject during the last twelve months has prompted the publication of other instances, such as that related by Dr. Bawa, of a Tamil snake-charmer who, in the course of his performances, was bitten by a cobra without any effect, while an onlooker, foolishly repeating the performance, was bitten by the same cobra, and died in three hours; and the description given by M. D'Abbadie, in a recent issue of the *Comptes rendus*, of the custom, recently prevailing at Mozambique, of inoculating with serpents' venom, under the firm conviction that protection is thereby produced against the effects of serpents' bites.

It may be instructive to associate with these statements the belief that venomous serpents are themselves protected against the effects of bites inflicted upon them by individuals both of their own and of other species. On mere anatomical grounds, it is difficult to understand how serpents could escape the absorption of their own venom through mucous surfaces, even admitting that absorption of venom does not occur in normal conditions of these surfaces. Venom must, however, be so frequently introduced into their bodies, in situations where absorption could not fail to occur, by the bites inflicted upon them by other serpents, that the conclusion seems inevitable that they possess some protective quality, without which, probably, no venomous serpents would now be in existence. Not only have many general observations been made in favour of this belief, but it has been supported by direct experiments, such as those made by Fontana of Tuscany more than a century ago, and by Guyon, Lacerda, Waddell, Kaufmann, and Sir Joseph Fayrer.

This, and other evidence, pointing to the existence of protection against venom, not only in serpents themselves, but also, in certain exceptional circumstances, in human beings, several years ago originated a wish to investigate the matter. It was obviously suggested that if protection occurs, it must be caused by some direct result of the absorption of venom; and, therefore, that its existence could be proved or disproved by experiment. In the former event, the first steps would already have been taken to obtain, by further experiments, results likely to be of value in the treatment of poisoning by serpents' venom, and, indeed, likely to be of suggestive importance in even the wider field of general therapeutics.

The general plan to be followed in the first stages of the investigation was obviously suggested by some of the statements I have reproduced; for they indicate that individuals might become accustomed to, or protected against the effects of serpents' bites, by the introduction into their bodies of a succession of doses of venom, no one of which, necessarily, at the beginning of the process was so large as the minimum-lethal. A consideration also of the facts, proving the possession of protection on the part of venomous serpents themselves, indicated the same plan of procedure; for, equally obviously, these serpents, from an early period of their existence, must absorb venom from their own gradually-developing poison-glands, until, in the course of time, they had acquired sufficient protection to remain unaffected by the larger quantities which the now fully-developed glands would introduce into their bodies.

My first supplies of cobra venom were obtained in 1869, from the late Dr. Shortt, of Madras, and in 1879 from Surgeon-Colonel Moir, of Meerut. They were in very small quantity, but with them I was able to satisfy myself that, by a succession of minute doses, animals became able to receive the minimum-lethal dose without any distinct injury. At this point, however, the supply of venom failed, and the observations could not then be carried further. It became evident that until large quantities of venom had been obtained, definite results could not be hoped for.

It was not until several years afterwards that a sufficient supply had been gradually accumulated, by further small quantities received from Sir Joseph Fayrer, the Thakore of Gondal, and Dr. Phillips; and by larger quantities from Sir William Mackinnon, Director-General of the Army Medical Department, and especially from Surgeon-Colonel Cunningham, of Calcutta, who for many years has been engaged with much success in the study of venoms and their antidotes. Within the last few months, and subsequently to the publication of some of the experimental results which had by this time been obtained, the India Office has also placed at my disposal a considerable quantity of venom, which had been collected by Dr. Hankin, of Agra, at the request of Dr. Cleghoorn, Surgeon-General with the Government of India.

But, besides these specimens of the venom of the cobra of India, I have also been fortunate in obtaining specimens of venoms from other parts of the world.

From America, Dr. Weir Mitchell, of Philadelphia—whose work on the chemistry and physiology of serpents' venom constitutes the great advance of the century on the venom of viperine serpents—has supplied me with the venom of three species of rattlesnakes, viz. *Crotalus horridus*, *C. adamanteus*, and *C. durrisus*, and also with a specimen of the venom of the Copper Head (*Trigonocephalus contortrix*).

From Australia, Dr. Thomas Bancroft, of Brisbane, has at various times sent specimens of the venoms of the black snake (*Pseudechis porphyriacus*), the brown snake (*Diemenia superciliosa*), and of a large unidentified snake of the Diamantina district of Queensland (probably a new species of Diemenia).

From Africa, the kindness of Mr. Andrew Smith, a distinguished naturalist of Cape Town, of Dr. Brook, of the Orange Free States, and of Dr. John Murray and Mr. Van Putten, of Cape Colony, has placed at my disposal small quantities of the venom of the puff adder (*Vipera arietans*), the night adder (*Aspidelaps lubricus*), the yellow cobra (*Naja haie*), and the "Ring Hals Slang" or "Rinkas" (*Sepedon hæmachates*).

In the meantime, however, the results of experiments on the inoculation of the toxines of diseases, as well as of proteid toxines of vegetable origin, had suggested to several observers that serpents' venom, because of its chemical analogies with several of these substances, might possibly be found capable, like them, of producing immunity against the effects of poisonous doses; and

further important evidence has thus been obtained in favour of the reality of the protection to which I have referred.

Sewall, in 1886, undertook an investigation with the object of determining if immunity against the fatal effects of rattlesnake venom could be produced by the inoculation of repeated doses, each too small to produce ill-effects. The experiments were made on pigeons, and he succeeded in proving that immunity could be secured to the extent, at least, of protection against seven times the minimum-lethal dose. Kanthack made a similar series of experiments in 1891, which allowed him to conclude that rabbits may be accustomed to resist lethal doses of cobra venom. Working with the venom of vipers, Kaufmann in 1891, and Phisalix and Bertrand in 1893, obtained experimental evidence of the possibility of producing a definite, though not high degree of resistance against the toxic effects of this venom. In the following year, Calmette, continuing some earlier observations which had led him to express the opinion that protection against snake venom could not be produced, published evidence confirming the results of previous investigators, but also showing that a higher degree of protection could be secured than they had obtained, for he succeeded in administering to each of several rabbits, within a period of eight months, a total quantity of from 30 to 35 milligrammes of venom.

In 1894, also, both Phisalix and Bertrand and Calmette obtained evidence of the power of the blood-serum of protected animals to counteract the effects of venom. Calmette at the same time claimed that hypochlorite and chloride of calcium were antidotes of considerable value; and in a later publication, he showed that the blood-serum of animals immunised by the administration of venom possesses a certain degree of antidotal efficacy against the toxines of several diseases.

In the case of many of the venoms which I have had the good fortune to obtain, the quantity at my disposal was not sufficient for experimental examination on the plan that seemed desirable, and, besides, the examination of each of them would require several months of work. The venoms that have as yet been used are four in number, those, namely, of the cobra of India (*Naja tripudians*), of the *Crotalus horridus* of America, of a large colubrine snake, probably a species of *Diemenia* from Queensland, Australia, and of the *Sepedon hæmachates* of Africa. They are, therefore, those of the most deadly of the poisonous serpents of Asia, America, Australia, and Africa, respectively; and, further, they are representative of the chief differences that occur in the composition and action of venoms, for they are derived from members af the two great groups of the colubrine and viperine serpents. My supply of cobra venom, however, being much larger than that of any of the others, this venom was chiefly used in the experiments.

An essential preliminary to exact investigations with active substances must always be the determination of the activity of the substances. The only convenient method for doing this is to define the smallest dose capable of producing death for any given weight of animal—that is, the minimum-lethal dose. The venoms in their natural liquid state are unstable, and they are also inconstant in activity, mainly because of variations in the quantity of the water which they contain. Dried venoms have therefore been used in all the experiments. The cobra venom has, however, nearly always been received in the form of a dry solid; but when this was not so, it has been dried *in vacuo* over sulphuric acid.

Experiments were made with it on several animals—as the frog, guinea-pig, rabbit, white rat, cat, and the innocuous grass snake of Italy (*Tropedonotus natrix*). Very considerable differences were found to occur in the minimum-lethal dose for each of these animals. For the guinea-pig, the minimum-lethal dose per kilogramme was ·00018 grm.; for the frog, ·0002 grm.; for the rabbit, ·000245 grm.; for the white rat, 00025 grm.; for the cat, somewhat less than ·005 grm.; and for the grass snake, the relatively large dose of ·03 grm.[1] Cobra venom thus takes a position among the most active of known substances, rivalling in its lethal power the most potent of the vegetable active principles, such as aconitine, strophanthin or acokantherin.

These facts having been ascertained, attempts were next made to render animals proof against lethal doses, by administering to them a succession of gradually increasing non-lethal doses. These were, for the first few doses, in some of the experiments, one-tenth of the minimum-lethal, in others one-fifth, in others one-half of the minimum-lethal, and in others almost as great as the minimum-lethal. At varying intervals, the doses were repeated, and by-and-by gradually increased, until the actual minimum-lethal had been attained. The subsequent doses, by gradual increments, exceeded the minimum-lethal, and after five or six times the minimum-lethal had been reached, it was found that the increments could be increased so that each became twice, four times, and latterly even five times the minimum-lethal, and still the animal suffered little, and, in many cases, no appreciable injury.

This brief statement, however, does not represent the experimental difficulties that were encountered. It describes the course of events in the altogether successful experiments. Non-success, however, was frequent, and many failures occurred before experience indicated the precautions and conditions that are necessary for success.

Serpents' venom exerts what may broadly be described as a duplex action. It produces functional disturbances unassociated with visible structural changes, and it also produces obvious structural changes. The latter are of a highly irritative character, causing intense visceral congestions in the lungs, kidneys, and other organs, and when the venom is given by subcutaneous injection, on all the structures of the skin and subjacent parts. There are apparently also some definite changes produced in the blood, with regard to which several important facts have been discovered by Dr. Martin, of the University of Sydney, and by Surgeon-Colonel Cunningham, of Calcutta. Irritative effects are obviously produced by cobra venom, even in non-lethal doses, and with greatly increased virulence by doses that exceed the minimum-lethal: but, in respect to this action, the other three venoms used are greatly more active than the venom of the cobra. Evidence was obtained to indicate that in the process of immunisation a diminution occurs in the intensity of these local actions; but this diminution does not proceed so rapidly as that in the unseen functional or other changes which are the more direct causes of death; and, further, the local irritative changes, after having been produced, are slower to disappear than the unseen functional disturbances. Until these facts had been appreciated, and, indeed, even with the adoption of precautions suggested by them, frequent failures occurred. The apparently contradictory results, accordingly, were obtained of the production, by gradually increasing doses, on the one hand, of a protection against quantities much above the minimum-lethal, so perfect that no apparent injury was caused; and, on the other hand, when the intervals of time separating successive doses had been too brief, of an intolerance so decided that death was produced by the last of a succession of gradually increasing doses, no one of which was so great as the minimum-lethal. The latter unfortunate event was frequently displayed in frogs and guinea-pigs, and attempts to carry immunisation in them to a high point usually resulted in failure.

Notwithstanding these difficulties, however, such gratifying results have been obtained as that rabbits could at last receive, by subcutaneous injection, so much as ten, twenty, thirty, and even the remarkable quantity of fifty times the minimum-lethal dose, without manifesting any obvious symptoms of poisoning.

Almost the only observable phenomena were a rise in the body temperature, which continued for a few hours after the injection, and which contrasts with the fall that occurs after the administration of even non-lethal doses, in non-protected animals; and a loss of appetite, which usually, though not invariably, occurred, and was probably the cause of a temporary fall in weight during the day or two days succeeding each injection. On the other hand, during the process of successful immunisation, the animals increased in weight, fed well, and appeared to acquire increased vigour and liveliness (Fig. 1).

It is marvellous to observe these evidences of the absence of injurious effects, and even of the production of benefit in an animal which, for instance, has received in one single dose a quantity of venom sufficient to kill, in less than six hours, fifty animals of the same weight, and in the course of five or six months a total quantity of venom sufficient to destroy the lives of 370 animals of the same species and weight.

With the cobra venom, I have also immunised cats and white rats, both by subcutaneous and by stomach administration; but the significance of the latter method of administration will be afterwards considered. A horse has also been immunised; and I have to express my obligations to Principal Williams and Prof. W. Owen Williams for granting me the accommodation of their

Grass snake,		3 centig.

establishment, and to Mr. Davis, also of the New Veterinary College, for much valuable assistance.

Following the same plan of research with the three other venoms, it was found that for rabbits the minimum-lethal dose per kilogramme of the Diamantina venom is ·0015 grm.; of the venom of *Sepedon hæmachates*, ·0025 grm.; and of the venom of Crotalus ·004 grm.[1] The Crotalus venom is, in its purity, altogether comparable with the cobra venom; and the determinations, therefore, show that cobra venom is sixteen times more powerful than Crotalus or rattlesnake venom. This venom, as well as the two others, however, much exceed cobra venom in the intensity of their local action. When death is produced by Crotalus venom, the subcutaneous tissues become extensively infiltrated with a large quantity of blood and of blood-stained serum, the underlying muscles are reduced to an almost pulpy blood-stained substance, and post-mortem decomposition occurs very soon after death. Similar changes in the subcutaneous tissues, but to a rather less degree, are caused by the Diamantina venom, and in addition, hæmaturia, or more probably hæmoglobinuria, was invariably produced by lethal and by large non-lethal doses. I mention these circumstances to indicate the perfection of the protection which is produced by the administration of successive gradually increasing doses: for they can be so adjusted that a dose of the Diamantina venom, even fifteen times larger than the minimum-lethal, may be administered without producing more than an inconsiderable degree of local destructive effect.

Experiments have also been made by which it has been demonstrated that when an animal has acquired a resistant power over the minimum-lethal dose of one venom, that animal is also able successfully to resist the lethal action of a dose above the minimum-lethal of other venoms. To a rabbit protected against cobra venom, a dose above the minimum-lethal of Sepedon venom has been administered; to rabbits protected against Crotalus venom, doses above the minimum-lethal of Diamantina and of cobra venoms have been given; to rabbits protected against the Diamantina venom, doses above the minimum-lethal of Crotalus and Sepedon venoms have been given, and in each case the animal has recovered, and but few symptoms of injury were produced. At the same time, in other experiments, indications were obtained that animals protected against a given venom are capable of resisting the toxic effect of that venom more effectually than the toxic effect of other venoms.

The experiments have not yet proceeded sufficiently far to show for what length of time the protection conferred by any final lethal dose may last. It has been discovered, however, that protection lasts for at least a considerable period of time, even when the last protective dose has not been a large one. For example, to a rabbit which had last received four times the minimum-lethal dose of cobra venom, twice the minimum-lethal dose was administered thirty-four days subsequently; while to another rabbit, which had last received twice the minimum-lethal dose of Crotalus venom, the same dose of this venom was administered twenty days subsequently, and in each case the second dose failed to produce any toxic symptom.

Having thus succeeded in producing a high degree of protection in animals against the toxic effects of serpents' venom, the blood-serum of these animals was, in the next place, collected for the purpose of testing its antidotal properties. In this portion of the investigation, the method followed was essentially the same as that described in a communication made by me to the Royal Society of Edinburgh in 1871, on "The Antagonism between the Actions of Physostigma and Atropia," as it appeared to be the most direct method for obtaining accurate knowledge of the value of an antidote.

A few preliminary experiments were, however, early made with the serum of animals in whom the protection had not been carried to a high degree, and they were sufficient to show that antidotal properties are possessed even by this serum. It soon became apparent that in order to obtain some reasonable approximation to constancy in the conditions of the experiments, it was necessary that the serum should be in such a state that it would remain unchanged during at least several weeks. It was found that this could be insured, without any appreciable loss of antidotal power, by drying the freshly-separated serum in the receiver of an air-pump, over sulphuric acid.

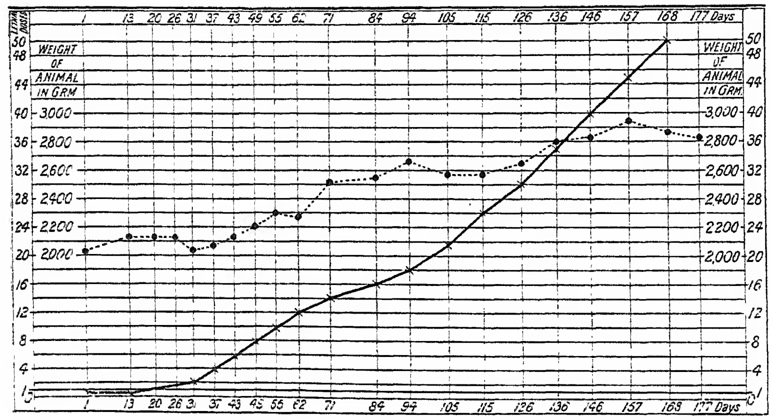

Fig. 1.—Immunisation of a rabbit against 50 times the minimum-lethal dose of cobra venom. The crosses connected by the continuous line represent administrations of venom. The dots connected by the interrupted line represent the weights of the animal.

A perfectly dry and easily pulverisable solid is thus obtained from which a normal serum can readily be prepared as required, by dissolving a definite quantity of the dry serum in a definite quantity of water. The dry substance is on the average equivalent to about one-tenth of the weight of the liquid serum. I have found that, without any special precautions, it retains its antidotal power unimpaired for at least a year, and it is probable that it may be kept unchanged for an unlimited period of time.

To this antidotal serum, whether in the dry form or in solution, I have given the name "Antivenene," a name which, notwithstanding etymological objections, has the advantages of brevity and freedom from ambiguity.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

At the graduation ceremony of the University of Glasgow on Tuesday, the honorary degree of LL.D. was conferred upon Mr. Thiselton-Dyer, F.R.S., and Prof. Andrew Gray.

Prof. J. Perry, F.R.S., Professor of Applied Mathematics and Mechanical Engineering at the Finsbury Technical College, has been appointed to the vacant chair of Mechanics and Mathematics at the Royal College of Science, London.

At a meeting of the Court of Edinburgh University on Tuesday, it was announced that the trustees of the late Earl of Moray have allocated the sum of £20,000 as a capital endowment fund for the promotion of original research in that university. The Court resolved to record their deep sense of the munificence of the gift and their cordial approval of the purpose towards which it is to be applied.

In the House of Commons on Thursday last, Sir A. Rollit asked the Vice-President of the Committee of Council of Education whether it was intended to introduce a Bill in pursuance of the recommendations, with or without modifications, of the Gresham Commission for the reorganisation of the University of London; and, if so, when and in which House. In reply, Sir J. Gorst said he could not give any definite answer to the question. The matter is however under consideration, and we are informed that Lord Playfair's Bill will be reintroduced shortly with small changes.

[1] Diamantina venom, 1½ milligramme.

Crotalus horridus, 4 ,,

THE *Calendar* for 1895–96 of the Queen's College, Galway, contains an alteration in the statutes referring to scholarships. We notice that from the beginning of the Session 1896–97, all scholarships and prizes will be open to students of either sex; junior scholarships in arts of the second year will be tenable for one year only. After the close of the Session 1897–98, the third year's scholarship in law and the senior scholarship or exhibition in the same subject will be abolished.

THE tenth summer meeting of the Edinburgh University Extension Movement will be held at University Hall, Edinburgh, from August 3 to August 29. Among the courses of lectures which have been arranged are philosophy and social science, by Prof. Patrick Geddes; the relation between science and philosophy, by Dr. R. M. Wenley; African scenery as influenced by climate, by Mr. Scott Elliot; psychology, education and physiology, hygiene, biology, geography and geology. There will also be several conferences for the discussion of educational problems of the present day. The comprehensive character of the programme should attract a large number to the meeting.

IN the House of Commons on Tuesday, Mr. Carvell Williams asked the First Lord of the Treasury whether the Parliamentary grant to King's College would not only be restored, but considerably increased; and, if so, whether provision was made for such increase in the present Estimates or whether it would be otherwise provided. In reply, Mr. Balfour said no increase was proposed this Session in regard to King's College. In accordance with an undertaking given by the Chancellor of the Exchequer to a deputation which waited upon him, he has appointed three gentlemen, Mr. T. H. Warren, President of Magdalen College, Oxford, Prof. D. G. Liveing, and Mr. Chalmers, of the Treasury, to visit the colleges sharing in the grant made to universities and colleges in Great Britain, and to investigate the character and quality of the university work done, and to inquire generally into the position which each college occupies both financially and in other respects. When their report is received, which the Chancellor of the Exchequer expects will be some time in the autumn, he will be in a position to judge whether a case has been made out for recommending Parliament to increase the sum to each of the colleges sharing in the grant.

FROM *Science* comes news of a notable extension of the University of Pennsylvania, by the establishment of a large number of graduate scholarships and fellowships. Provost Harrison gave 500,000 dols. to the university last June, "for the encouragement of liberal studies and the advancement of knowledge." The specific purposes of the fund are as follows: (1) The establishment of scholarships and fellowships intended solely for men of exceptional ability. (2) The increasing of the library of the university, particularly by the acquisition of works of permanent use and of lasting reference to and by the scholar. (3) The temporary relief from routine work of professors of ability in order that they may devote themselves to some special and graduate work. (4) The securing of men of distinction to lecture, and for a time to reside at the university. Our contemporary states that in pursuance of the end in view in the foundation, definite action has been taken in the establishment of a considerable number of graduate scholarships and fellowships. The recommendations which were made regarding these have been approved and will now go into force. There are eight graduate scholarships giving free tuition and 100 dols. open to those coming from the liberal courses in the college of the university; and there are, with the Hector Tyndale Fellowship in Physics, now fifteen fellowships, fourteen of which, coming from this foundation, are open to students of any university. The amount of the tuition deducted from the full value of the fellowship (600 dols.) does not go into the general funds of the university, but may be used for the purchase of books or apparatus which will aid the student in his work, or may be used in the publication of theses. A somewhat unusual feature is the establishment of senior fellowships, open only to those who have taken the Doctor's degree in the University of Pennsylvania. This amounts to the introduction, in a modified form, of the "Docent" system of German universities, the object being not at all to use the Senior Fellow as a teacher for the sake of the value he may be to the university, but to test him and give him an opportunity to do a little teaching in the direct line of his special work. From the Senior Fellowships there is no reduction for tuition. This gives eight Graduate Scholarships, fifteen Fellowships, and five Senior Fellowships, making twenty Fellowships in all. Fourteen of the Fellowships are open to men from other institutions, but the Senior Fellowships are limited to those having taken the Doctor's degree from the university in order that some of the best men may be kept in residence there as long as possible, and their influence felt among the students.

SCIENTIFIC SERIALS.

American Journal of Science, March.—Trinidad pitch, by S. F. Peckham and Laura A. Linton. This paper gives an account of the physical and chemical properties of pitch from the Pitch Lake of Trinidad, together with a map of the lake itself. A dry sample of the true lake pitch contained 34·2 per cent. petrolene, 18·8 per cent. asphaltene, 11·4 per cent. of other organic matter, and 35·6 per cent. of inorganic matter. The pitch as it occurs is a unique substance found nowhere else in nature. It consists of a mixture of bitumen, water, sand, decayed vegetation, and gas in such definite proportions that within certain limits the composition of the entire mass is uniform.—Proofs of the rising of the land round Hudson Bay, by Robert Bell. The old shore-lines in the provinces of Ontario and Quebec slope upward in a north-easterly direction at rates varying in different regions from a few inches to a foot and even two feet per mile. Many former landing-places about the bay are now high and dry. The rising is apparently still in progress.—Experiments upon the kathode rays and their effects, by A. W. Wright. In developing "shadowgraphs," it is better not to use any alkaline accelerator at all until just at the end of the process. Röntgen rays passing through glass walls do not show magnetic deflection or mutual repulsion; but when they are made to pass through gold-leaf instead, they show traces of these phenomena, probably owing to the fact that they carry with them small portions of volatilised and electrified metal.—Triangulation by means of kathode photography, by John Trowbridge. The principle of triangulation may be applied to kathode photography when determining the situation of metallic particles in the body. By using two vacuum tubes in different positions, two pictures of, say, a bullet embedded in a hand may be obtained, and their distance apart gives the depth at which the bullet may be sought.—Notes of observations on the Röntgen rays, by H. A. Rowland, N. R. Carmichael, and L. J. Briggs. Some photographs of a coin obtained by Röntgen's method showed no penumbra when the coin was 2 cm. from the plate. In a very high vacuum tube the source of the active rays was distinctly traced to the *anode*.

THE *Meteorologische Zeitschrift* for March contains some interesting results of meteorological observations made at Boroma, on the Zambesi, lat. 16° S., long. 33° 12′ E., in the years 1891–92. The most prominent feature of the climate is the contrast between the dry and the wet seasons. The approach of the rainy season is announced by lightning in the north and north-east during October; rain commences in November, and continues, on and off, for about five months; hail also occasionally occurs during thunderstorms. The dry season commences in April, and until the following November no measurable quantity of rain falls. It is noteworthy that during seven dry months, under a tropical sun, vegetation is not arrested, although even slight dew is very rarely observed. The daily barometric range is very regular, and amounts to about 0·15 inch. The atmospheric waves are so similar that the barometric curves overlie each other as nearly as possible; depressions such as are frequent in our latitudes do not occur at any part of the year; even the passage of thunderstorms is not shown upon the barograph traces. The absolute maximum temperature recorded was 109°·9, in November, and the minimum 54°·5, in August. The annual rainfall amounted to 29·6 inches, of which 10 inches fell in December. The greatest amount observed in twenty-four hours was only 1·9 inch.

THE last fascicule of the Memoirs (*Travaux*) of the St. Petersburg Society of Naturalists (vol. xxv. livr. 2), which is entirely given to the works done in the zootomical laboratory of the St. Petersburg University, contains an interesting monograph, by B. Sukatchoff, on some new forms of sponges from Lake Baikal. The dredgings were made in the south-western part of the lake, near the issue of the Angara, by means of an apparatus similar to the one used by the *Challenger* expedition, the greatest depth reached being 492 feet. The greatest depth at which sponges were found was 273 feet. Most of the sponges obtained belong to already known species of *Lubomirskia*, described by

Dybowski in 1880; but some of them must be considered as new varieties, or as new species of the same genus. Thus the author describes and figures the new varieties: *Lubomirskia baicalensis*, Pall., var. ϵ, and *Lubomirskia intermedia*, Dyb., var. β, and the new species, *L. Tcherskii* and *L. fusifera*. The paper is fully summed up in French. The same number contains a note on *Polyzonium germanicum*, Brandt, by M. Rimsky Korsakoff; a paper, by W. Schimkevitch, on some new species and varieties of *Pantopoda* from the Arctic Ocean (Barents's Sea), in which the new forms *Ammothea borealis*, *Nymphon rubrum*, var. *intermedium*, *Nyphon grossipes*, var. *armatum*, *Tanystylum hœkianum*, *Phoxihilus bœhmii*, are described and figured. The author also gives the plates which are intended to show that the two species, *Phoxihilus vulgaris* and *Ph. charybdæus*, are different. M. Eugéne Schultz describes the new species *Loxosoma harmeri*; and A. Yaschenko gives a catalogue of the fishes in the museum of the St. Petersburg University.

SOCIETIES AND ACADEMIES.

London.

Royal Society, February 27.—"A Method for rapidly producing Diphtheria Antitoxines." Preliminary note. By Dr. G. E. Cartwright Wood.

In this preliminary communication[1] a method was described by means of which, firstly, an animal can be rendered immune towards large quantities of diphtheria poison; secondly, such animals can be made to produce powerful diphtheria antitoxines. The distinctive feature of the method consists in the use of the products produced by the growth of the diphtheria bacillus in albuminous fluids made by the addition of serum to ordinary peptone broth. This fluid is, after three or four weeks' growth at 37° C., filtered through a Chamberland candle and heated for an hour at 65° C. This liquid, which is described as "serum" toxine, probably depends for its action on the presence of the diphtheria albumoses described by Sidney Martin. It gives rise on injection to little or no local reaction, but to a marked rise of temperature, which is still more pronounced when the injection is repeated. The ordinary toxine obtained by the growth of the diphtheria bacillus in fresh peptone broth, or in putrid broth (Spronck's method), was also made use of, and this is referred to in the paper as "broth" toxine.

In the first experiment (Horse No. 1) 380 c.c. of serum toxine was injected during the first fourteen days for the purpose of immunising the animal, and thus protecting it against the subsequent introduction of the much more irritating and deadly broth toxine. During the next fortnight it then received 310 c.c. of broth toxine in three injections without being markedly affected, and was then bled at the end of this period. The antitoxic value of the serum was then found to be ten normal units, 1-100th of a c.c. protecting against ten lethal doses of broth toxine, a result obtained by the ordinary method only after ten weeks treatment.

In the second experiment (Horse No. 2), the animal received 1350 c.c. of serum toxine mixed with 51 c.c. of antitoxine during the first fortnight. During the next two weeks it received 950 c.c. of broth toxine mixed with 350 c.c. of serum toxine. When the animal was bled at the end of a month, 1/1000th c.c. was found to protect a guinea-pig against ten lethal doses of broth toxine.

In the third experiment (Horse No. 3), the horse received the serum toxine without the addition of antitoxine, and, as will be seen from the following table, the results were even more striking.

	Antitoxic value of serum.		Amount of toxines injected.
7th day ...	$\frac{1}{300}$ c.c.	...	1200 c.c. serum toxine.
14th day ...	$\frac{1}{500}$ c.c.	...	980 c.c. serum toxine.
21st day ...	$\frac{1}{850}$ c.c.	...	650 c.c. serum toxine and 1050 c.c. weak broth toxine.
28th day ...	$\frac{1}{1250}$ c.c.	...	1100 c.c. serum toxine and 1200 c.c. stronger broth toxine.

The high antitoxic value of the serum obtained from horses Nos. 2 and 3 suggested that the serum toxine might be made use of at a later stage, as well as for the purpose of rapidly immunising the animals. When mixed with the ordinary toxine, and injected as usual, although the results obtained were better, they were not so striking as one might have expected. On examining more in detail the protocols of the horses in which the best results had been obtained, it was observed that these had been under more or less continuous treatment with the toxines, both toxines being injected in as large amounts, and as frequently as possible, so that the animal was kept in a chronic condition of local and constitutional reaction. For the purpose of determining whether the favourable result was due to this "cumulative" action of the toxines, four horses, which had been under the ordinary treatment for periods varying from nine months to a year, were treated in the following way. They received one evening each 300 c.c. of serum toxine prepared by Spronck's method, and on the following morning an injection of weak broth toxine, the latter being usually repeated daily during the rest of the week. This treatment was continued during the following week, and the serum then tested for its antitoxic value. The results are seen in the following table.

	Strength of serum before treatment.		Strength of serum after 16 days' treatment.		Amounts of toxines injected during the 16 days.
Horse No. 4 ...	$\frac{1}{600}$ c.c.	...	$\frac{1}{2000}$ c.c.	...	650 c.c. serum toxine and 2350 c.c. weak broth toxine.
Horse No. 5 ...	$\frac{1}{400}$ c.c.	...	$\frac{1}{1500}$ c.c.	...	600 c.c. serum toxine and 1800 c.c. weak broth toxine.
Horse No. 6 ...	$\frac{1}{300}$ c.c.	...	$\frac{1}{750}$ c.c.	...	650 c.c. serum toxine and 2350 c.c. weak broth toxine.
Horse No. 7 ...	$\frac{1}{400}$ c.c.	...	$\frac{1}{750}$ c.c.	...	650 c.c. serum toxine and 2350 c.c. weak broth toxine.

These results indicate clearly that the rapid productions of anti-toxine depended on the increased sensitiveness of the animal, owing to the injections being repeated before the previous ones had had time to pass off. Some preliminary experiments have indicated that this cumulative action may be produced in an even more marked degree by the use of other toxines than those produced by the diphtheria bacillus.

It is claimed for this method that powerful diphtheria antitoxines can be easily produced in a shorter space of time than has hitherto been possible, and that, as a consequence, the amount of serum necessary to be injected is greatly reduced, while its greater strength will permit of the patient receiving at the beginning of treatment a sufficient quantity of the serum at one injection, when, as is universally recognised both by animal experiment and clinical experience, its curative action is exerted most markedly.

March 19.—"On the Relations of Turacin and Turacoporphyrin to the Colouring Matter of the Blood." By Prof. Arthur Gamgee, F.R.S.

In a recent paper read before the Royal Society, the author has shown that the intense absorption band in the extreme violet, which is observed in the spectrum of highly diluted solutions of hæmoglobin and its compounds, is (with slight changes in its position) exhibited by certain of the derivatives of the blood colouring matter, *e.g.* by hæmochromogen and the compounds of hæmatin, and by that remarkably interesting coloured but iron-free derivative of the latter body, hæmatoporphyrin.

Having found that no organic body which he had examined exhibits an absorption band occupying the position, or possessed of the remarkable intensity, of the extreme violet band under discussion, it seemed as if the latter owed its origin to a group of atoms existing in, and perhaps characteristic of, the blood colouring matter, which group remains intact in certain of the products of decomposition of the complex hæmoglobin molecule, whereas it does not exist in certain other of the derivatives of the hæmochromogen or hæmatin moiety of the molecule, such as bilirubin and urobilin. It appeared interesting to determine whether turacin, which, as Prof. Church first showed in 1869,[1] presents two absorption bands in the visible spectrum, which have a remarkable resemblance to those of oxy-hæmoglobin,

[1] The investigation has been carried out in the laboratories of the Royal Colleges of Physicians and Surgeons, and I should like here to express my great indebtedness to the Laboratories Committee for the facilities there afforded to me. I must also thank them and, through them, the Honourable Goldsmiths' Company, from whose Research Fund a grant was placed at my isposal.—G. E. C. W.

[1] A. H. Church, "Researches on Turacin, an Animal Pigment containing Copper," *Roy. Soc. Proc.*, vol. xvii. (1869) p. 436; *Phil. Trans.*, vol. clix. (1869) pp. 627-636.

would exhibit in the extreme violet or the ultra-violet, an absorption band similar to that of the compounds and certain of the derivatives of the blood colouring matter. It was found that solutions of turacin in caustic soda or ammonia, so dilute as to be almost colourless, and to exhibit, when a stratum 10 mm. thick was examined, only a faint shading in the position of the stronger of the two turacin bands in the green, absorbed the extreme violet and ultra-violet rays of the spectrum *precisely as* highly diluted solutions of the acid compounds of hæmatin (*e.g.* hæmatin hydrochloride dissolved in glacial acetic acid). The earlier observations were made by allowing the spectrum of a beam of sunlight reflected into the dark room from the mirror of the heliostat, and which had passed through the solution of turacin, to fall upon a fluorescent screen of the double cyanide of platinum and barium, when an intense absorption band at the commencement of the ultra-violet was visible to the naked eye. This observation was subsequently confirmed by taking a series of photographs of the spectrum, employing solutions of turacin of various degrees of concentration.

It thus appears that turacin, like the acid compounds of hæmatin, exhibits an absorption band, which is exactly on the boundary of the ultra-violet proper, and which extends further and further into the ultra-violet, as the concentration of the solution increases.

The identity of the spectrum of turacin with that of the hæmatin compounds was so complete that it led the author to surmise the existence of a close relationship between the copper-containing body and the iron-containing colouring matter of the blood. Without any knowledge of Prof. Church's second investigation, published in 1892,[1] in making an oral preliminary communication of his first results to the International Physiological Congress at Berne, in September, 1895, the author expressed his conviction that turacin contains the same atomic group which is the cause of the extreme violet and ultra-violet absorption band in the spectrum of highly dilute solutions of hæmoglobin and its derivatives, and predicted that by removing the copper from turacin, it would be possible to obtain a turaco-porphyrin similar to the body (hæmato-porphyrin) which results from the removal of the iron from hæmatin. It was only after the completion of the experiments necessary for the elucidation of this point, that the fact of his having been anticipated in this matter by Prof. Church was brought under the notice of the author.

The results of the present work offer, however, an independent and additional confirmation of Prof. Church's results.

The facts placed on record in this paper point to the essential identity of turaco-porphyrin and hæmatoporphyrin, and when taken in connection with the identity of the ultra-violet spectrum of turacin, and of the acid hæmatin compounds, appear to establish that turacin contains the atomic group, which is the cause of the characteristic extreme violet and ultra-violet absorption exerted by hæmoglobin, its compounds, and principal derivatives.

Entomological Society, April 1.—Prof. Meldola, F.R.S., President, in the chair.—Mr. Champion exhibited, on behalf of Mr. Blatch, specimens of *Quedius riparius*, Kellner, captured in February last on the banks of running streams at Porlock, Somerset. He remarked that the insect was an interesting and unexpected addition to the British list, and the second recent novelty from the west country, the other being *Ochthebius lejolisi*, Muls. and Rey, found at Ilfracombe in June last by Mr. Bennett. He added that Mr. Waterhouse had informed him that he had seen specimens of the Quedius from Wales and Scotland. Mr. Champion also exhibited a small collection of Coleoptera made by Mr. O. V. Aplin in Southern Tunis during various expeditions inland from Gabes. The collection included some interesting Tenebrionidæ of the genera *Pimelia* and *Adesmia*. Mr. Aplin noticed specimens of these insects impaled by shrikes.—Mr. Goss exhibited, for Mr. Cameron, an apterous male of *Mutilla contracta* taken at Barrackpore, India. The specimen was stated to be the first recorded instance in this species of a wingless male, and was also abnormal in having the thorax incised laterally.—Dr. Sharp, F.R.S., called attention to the fact that at a recent meeting of the Society (March 20, 1895) a specimen of a supposed dimorphic form of one of the species of *Dytiscus* was examined, and Prof. Stewart inquired whether any anatomical examination had been made of the sexual organs. He said that in the *Comptes rendus* Soc. Bordeaux, 1894, there was an account of the examination of the sexual organs of the supposed second form of *D. marginalis* by M. Peytoureau, who came to the conclusion that it was really a distinct species.—Prof. Poulton, F.R.S., exhibited examples of the type labels now in use in the Hope Collection at Oxford, and illustrated their employment by projecting on the screen, by the lantern, a photograph of the Westwood types of African *Eusemiæ* described in F. Bates' "Matabele Land" (London, 1881). He said that such labels, having been once set up in type, could be reproduced in electrotype very cheaply and efficiently. Mr. Verrall said he was of opinion that no species should be described from a single type, but from many specimens, and he wished every so-called "type" could be destroyed as soon as a species had been described from it. Mr. Blandford explained the system of labelling types in the Brussels Museum. Dr. Sharp, Prof. Meldola, Mr. McLachlan, and Prof Poulton continued the discussion.—Mr. Blandford exhibited a series of lantern slides showing the uses to which photography could be put in entomological illustration. The photographs shown included various *Saturniidæ*, *Vanessidæ*, species of *Mamestra*, *Tipula*, *Ophion*, *Carabus*, *Lucanus*, *Sitones*, &c., as well as one or two examples of insect-injury, and a view in Windsor Park showing oaks defoliated by *Tortrix viridana*. Prof. Meldola expressed surprise that photography had hitherto been so little employed in the illustration of works on entomology.—Prof. Poulton read a paper entitled "On the Courtship of certain European Acridiidæ." He said that these observations upon the courtship of Swiss Acridiidæ were made in exceedingly favourable weather at the end of August and beginning of September last year. He was much indebted to Mr. F. Jenkinson and Mr. V. F. Dickins for many independent observations and valuable confirmation. The observations were almost all made in the neighbourhood of the Weisshorn Hotel, high above Vissoye, in the Val d'Anniviers. Prof. Meldola expressed great interest in the paper, and said that the observation of the habits of insects in the field seemed to be much neglected by many entomologists. Dr. Sharp remarked that there was a greater variety in the organs capable of producing sound in the Orthoptera than was generally supposed.—Mr. G. F. Hampson read a paper entitled "On the Classification of Three Subfamilies of Moths of the Family Pyralidæ: the *Epipaschiinæ*, *Endotrichinæ*, and *Pyralinæ*."

PARIS.

Academy of Sciences, April 7.—M. A. Cornu in the chair.—Applications of the theory of divergent series capable of summation, by M. E. Borel.—Some remarks on the X-rays, by S. P. Thompson. An account of the phenomena observed with a fluorescent screen in a Crookes' tube during the gradual production of a vacuum. At a very high vacuum, the rays penetrate bones as well as flesh, and hence there is a certain degree of exhaustion for which the difference between the transparency of the bone and flesh is a maximum.—On electrified Röntgen rays, by M. A. Lafay.—A condition for the maximum power of Crookes' tubes, by MM. J. Chappuis and E. Nugues. The radiation of a Crookes' tube, as measured by the rate at which its rays discharged an electrometer, was found to vary with the rate of vibration of the commutator of the Ruhmkorff coil employed. For the coil used by the authors, ten breaks per second produced the maximum effect; rates higher or lower than this were less effective.—Thermal studies of some oxybromides, by M. Tassilly. Determinations of the heats of solution of the hydrated oxybromides of the alkaline earths.—Action of hydrobromic and hydriodic acids upon phosphoryl trichloride, by M. A. Besson.—At a temperature of 400°–500° in presence of pumice, hydrobromic acid acts upon phosphoryl trichloride giving the complete set of substitution derivatives $POCl_2Br$, $POClBr_2$, $POBr_3$, and PBr_5. Hydriodic acid acts somewhat differently, a solution of the gas in phosphoryl trichloride slowly reacting at the ordinary temperature giving phosphorus triiodide and metaphosphoric acid.—On a sample of rice over a century old, by M. Balland. The sample on analysis differed from ordinary rice only in a lower percentage of fat.—Elongation of the lower limbs due to castration, by M. Lortet.

BERLIN.

Meteorological Society, March 3.—Prof. Börnstein, President, in the chair.—Prof. Hellmann spoke on Indo-Germanic superstitions as to weather, which are still widespread among the people, and are based upon a belief in the importance of the twelve days from Christmas to Epiphany, or

[1] A. H. Church, "Researches on Turacin, an Animal Pigment containing Copper," *Phil. Trans.*, vol. 183 (1892), A, pp. 511-530.

from January 1 to 12, as determining the weather forecasts for the whole ensuing year. These rules are contained in a work, "Die Bauernpraktik," of which the first German edition appeared in 1508, and having attained a wide circulation over western and northern Europe, was translated into English, French, Danish, Swedish and Bohemian, and passed through numberless editions in the sixteenth and seventeenth centuries. There is no known author of this work, but the speaker had succeeded in tracing out manuscripts of the thirteenth century, and the writings of the Venerable Bede in the ninth, as the source of the book. From Bede's writings—which deal not only with weather forecasts, but contain also a "Thunder-book," which is still popular in Sweden—it is evident that the author had translated a Greek manuscript. Certain passages in Pliny refer to Democritus as the source of some of the forecasts, and of the significance of the twelve days mentioned above. But the superstition as to these days is of still older date, for statements which, although incomplete, are, on the whole, similar to those in the "Bauernpraktik," are found on the Babylonian tablets, and the speaker hence concluded that the superstition is of Babylonian origin.

Physiological Society, March 6.—Prof. du Bois Reymond, President, in the chair.—Prof. Zuntz read a communication by Messrs. Asher and Lüscher, in Bern, in which they describe the first results of an investigation of the electrical changes in the œsophagus during deglutition. Using german-silver wire electrodes and a capillary electrometer, they observed a movement of the mercury whenever a wave of contraction passed over the portion of the œsophagus included between the electrodes.—Dr. Rothmann spoke on secondary degenerations of the pyramidal tracts resulting from unilateral extirpation of the cortical centres for the extremities.—Prof. Zuntz spoke on the results of his investigations on metabolism, which had shown that the performance of 1 kgm. of work requires the consumption of 28 kgm. of chemically equivalent energy, whether it be derived from proteids, from fats, or from carbohydrates. Chauveau had recently come to the conclusion, based on experiments, that sugar alone is used up in a muscle doing work, and that when the animal is fed with fat the latter is preliminarily changed into sugar by the liver. The speaker showed that this assumption involves the occurrence of a very complicated chemical process, during which a large part of the energy of the food must be set free in the liver and remain unused. Chauveau had also stated that the same amount of energy is used up in positive as in negative work, and against this view the speaker advanced the results stated above for positive work, while, on the other hand, during the negative work of descending an incline with the lesser declivity, less chemical energy is consumed, thus corresponding to the lessened work. As the declivity becomes gradually greater, the amount of chemical energy increases, at a certain stage is equal to the work done, and then increases rapidly beyond the ratio given above for positive work.—Dr. Rawitz reported on an investigation of the well-known statement made by Darwin that imperfect albinos—animals with white hides and blue eyes—are deaf. Having become possessed of a white dog with blue eyes, he had found, by experiments lasting over three weeks, that this dog really was deaf. After killing the dog, he found that the cortical auditory centres of both sides were atrophied, being on one side reduced to half the normal amount, and on the other to one-third. The cochlea of the inner ear was also wasted away, and the auditory ossicles ankylosed.

March 20.—Prof. du Bois Reymond, President, in the chair.—Dr. René du Bois Reymond discussed Stieda's theory of the homology of the limbs, in detail with reference to the bones and muscles, and briefly as to the blood-vessels and nerves.—Dr. Epstein demonstrated a new turbine, a new perimeter, and a new kymograph constructed for the purpose of experimenting on the influence of colour-perception on blood-pressure.—Prof. Thierfelder reported on two further experiments, made in conjunction with Dr. Nuttall, on animals free from bacteria. In one of these, two guinea-pigs were fed for thirteen days, in the other for ten days, aseptically with milk and biscuit. The animals remained in every respect normal, and gained in weight to the same extent as others fed with ordinary milk and biscuit. Their urine contained ethereal sulphates, although the alimentary canal was free from bacteria.

Note.—In the report of the Physiological Society on p. 503 of Nature, column 2, line 37 from the top, for "height of circulation" read "height of contraction."

Philadelphia.

Academy of Natural Sciences, March 10.—A paper entitled "Summary of New Liberian Polydesmoidea," by O. F. Cook, was presented for publication.—General Isaac J. Wistar made a communication on the apparent capricious distribution of iron oxide as colouring matter in the rocks of the anthracite coal region. At several points, apparently, the accessible supply of iron was exhausted by complete distribution in the strata under process of deposit with intermediate and subsequent periods during which new supplies appear from some source not yet clearly explained. Prof. A. P. Brown stated that it had been suggested by Russell that the red colour of certain formations may have originated from the subaërial decay of iron-bearing rocks, and the subsequent deposit of this material as sediment forming the red rock. As far as the ash of coal is concerned, it is probable that the colour is due to the way in which pyrites is contained either in the coal itself or in the slate adjoining. Coal containing separable pyrites would give white ash, while if the pyrites is intimately mixed in the coal the ash will be red.—Mr. James Willcox and Prof. Angelo Heilprin commented on the evolutionary value of the large collection of fulgurs presented to the last meeting, the former claiming that about twenty-five species had been reduced by the presence of complete series of intermediate forms to three or four.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—The Heart of a Continent: Captain F. E. Younghusband, 2nd edition (Murray).—Argon and Newton: Lieut.-Colonel W. Sedgwick (Whittingham).—British Sea Birds: C. Dixon (Bliss).—Les Rayons X: Dr. C. E. Guillaume (Paris, Gauthier-Villars).—Report of the Commissioner of Education for the Year 1892-93, Vol. 2 (Washington).—Queen's College, Galway, Calendar for 1895-96 (Dublin, Ponsonby).

Pamphlets.—Prof. Röntgen's "X" Rays, and their Applications in the New Photography (Glasgow, Bauermeister).—Die Denkschöpfung, &c.: A. Bastian (Berlin, Dümmlers).—The Magnetic Circuit: Dr. H. du Bois, translated by Dr. Atkinson (Longmans).

Serials.—Journal of the Royal Statistical Society, March (Stanford).—Engineering Magazine, April (Tucker).—Journal of the Franklin Institute, April (Philadelphia).—Science Progress, April (Scientific Press).—Imperial University, College of Agriculture, Bulletin Vol. ii. CONTENTS.

THURSDAY, APRIL 23, 1896.

A NEW BOOK ON MAN.

Ethnology. By A. H. Keane. "Cambridge Geographical Series." Pp. xxx + 442. (Cambridge: University Press, 1896.)

A HANDY but comprehensive work on ethnology has long been required alike by the student and general reader, and it is with pleasure and interest that we welcome the appearance of a book which is claimed by the author to be a synthesis and a trustworthy guide.

Mr. Keane's book is divided into two parts: (1) Fundamental Ethnical Problems; and (2) The Primary Ethnical Groups. After a definition of terms, which is rather unsatisfactory, as is also the title of the book itself, the author deals with the physical evolution of man, and here as elsewhere the evolution doctrine is accepted. In this chapter, there is the inevitable phylogenetic tree; but in this instance it is furnished with a bunch of unexplained roots. Whatever truth this scheme may illustrate, we fail to see the conclusion that "from this diagram it is made evident that the ascent of the Hominidæ is in an independent line from some long extinct generalised form," &c. When will people learn that a phylogenetic tree does not *prove* anything! The treatment of the mental evolution of man in a short chapter is somewhat inadequate for that most important subject. The antiquity of man is dealt with in various chapters; in the prefatory general considerations, "Croll's last two glacial epochs" are "accepted in all their fulness," and the author decides in favour of interglacial man, who "specialised not less, probably much more, than half-a-million years ago." The chapters on Palæolithic and Neolithic man are useful summaries, but with several questionable statements. Geographers will scarcely admit that "the explanation," of the attractiveness of Denmark to Neolithic men, "lies in the physical and biological conditions of a region washed by the warm waters of the Gulf Stream." The argument for the specific unity of man will prove of service to many readers. It is strange that, though the meaning of the terms genus, species, and variety "is clearly defined in a way that gives rise to no misunderstandings," Mr. Keane attributes to Linnæus the erection of "four species" of the group *Homo sapiens* (p. 164), whereas these were evidently regarded as varieties of that species by the great Swedish naturalist. On p. 25 we find a paragraph commencing thus: "HOMINIDÆ. (Linné's Genus *Homo*), with no specific divisions, but four primary varieties"—a system of nomenclature that no biologist would recognise. Somehow or other, in spite of his statement that the meaning of the terms species, &c., is so fixed as to give rise to no misunderstanding, the author does not appreciate the rules for zoological nomenclature; apparently his view is that the single species of *Homo* differentiated in early times into four varieties, which he calls *Homo Æthiopicus*, *Homo Mongolicus*, *Homo Americanus*, and *Homo Caucasicus*, so that we now have four varieties in the genus, but no species.

In the chapter on the physical criteria of race, Mr. Keane gives an account of the data utilised in classifying the different groups of man, and a selection of the various systems of classification that have been adopted; the ingenious system of Deniker deserves a more detailed description than is accorded to it. The remarkable statement on p. 171, that the greater abundance of pigment in the skin of the negro "seems due to the stimulating action of the solar heat combined with moisture and an excess of vegetable food, yielding more carbon than can be completely assimilated, the character being then fixed by heredity," must not pass unchallenged. It is true that Waitz adduces many examples to show that "hot and damp countries favour the darkening of the skin," and though this may be a factor, there are too many exceptions for it to be a sufficient cause; evidently this has also struck the author, but the fixation of black carbon through an excess of vegetable food is a theory that is decidedly comical, though it is doubtless offered in good faith. Mr. Keane devotes nearly the whole of the section on the mental criteria of race to a disquisition on the evolution of language. He asserts that monosyllabism is not the first but the last stage in the growth of a language; if this be true, then the German language must be in its infancy. Several of his views on linguistic evolution are, to say the least of it, heterodox, and will probably lead to further discussion.

The second part, which deals with the main divisions of mankind, is a most useful summary of a vast range of reading, and will prove of great utility to all interested in the subject, although there are many statements which will not approve themselves to every specialist. Mr. Keane argues in favour of the evolution of the pliocene precursor of man in the Indo-African Continent, which has replaced Sclater's Lemuria. This continent extended from South India to Africa and Madagascar, including the intermediate islands, and also was in biological relation to the hypothetical Austral Continent, which extended from New Guinea and Tasmania to the islets of St. Paul and Amsterdam. "Thus when the pliocene precursor, wherever evolved, began to spread abroad, he was free to move in all directions over the eastern hemisphere."

One or two examples will illustrate Mr. Keane's views on certain problems. Besides the Negritoes who extended along Malaysia to New Guinea, there was a primitive population of Melanesian Papuans, who also spread over the whole of Oceania as far as Hawaii, Easter Island, and New Zealand. These were also the aborigines of Australia, who thence passed over into Tasmania; Australia also received a contingent of "Caucasian Melanochroi" (*i.e.* the Dravidian element in Australian ethnology), and also a Malay infusion, "while the Neanderthal characters persisting here and there would be traceable to the *Ur-Einwanderung* of the pliocene precursor from the Indo-Austral Continent."

"The Melanesian language [which Dr. Codrington has shown to be the most primitive existing form of the Malay-Polynesian group] is not indigenous in its present home, but must have been introduced and imposed upon the Papuan natives by some foreign people in remote prehistoric times. This people is none other than the Eastern Polynesians, a branch of the Caucasic division, who possibly in the Neolithic period migrated from the Asiatic mainland to Malaysia and thence eastwards to the remotest islands of the Pacific Ocean."

Mr. Keane, as we have seen, is not particularly happy

when attempting to explain the effect of environment on man, as the following extract will also prove.

"It has been shown that the precursor was most probably furry, with a woolly under and a sleek outer coat, and it is conceivable that in a volcanic environment like that of Java, it might have been advantageous to shed the wool and retain the sleek hair, together with all the other physical characters of the primitive Negrito."

The white race (*Homo Caucasicus*, as Mr. Keane delights to term it) is held by the author to have evolved in, and dispersed from, North Africa; but he strangely omits to refer to Dr. D. G. Brinton, who, in his "Races and Peoples" (1890), had already promulgated that view.

It is evident that Mr. Keane is a very diligent and widely-read literary man, but he is decidedly weak on the scientific aspects of his subject. Lastly we must criticise those figures which were copied from the author's "Types of the Races of Mankind," in Longmans' New Atlas. The process-blocks from these lithographs have a very coarse appearance, and offer a marked contrast to those taken from photographs. On the whole, the selection of the illustrations of racial types is well made.

Although there is a good deal of what may be termed contentious matter, besides numerous errors, in Mr. Keane's book, we can recommend it as a most useful introduction to a very complicated study; and as the author has brought together and abstracted a large number of references, the student can use the book as a point of departure, and thus it will serve as a base for a more extended or detailed survey of this really important branch of science. A. C. HADDON.

RIGID DYNAMICS.

An Elementary Treatise on Rigid Dynamics. By W. J Loudon, B.A., Demonstrator in Physics in the University of Toronto. Demy 8vo, pp. ix + 236. (London: Macmillan and Co., 1896.)

THERE are few mathematicians who do not vividly recollect the difficulties they experienced when reading "Rigid Dynamics" for the first time. Mr. Loudon's treatise does much to smooth away these difficulties; and if it still leaves undone much that might have been done in simplifying the subject for beginners, it nevertheless fills a gap the existence of which has long been felt among teachers.

From a purely mathematical standpoint, we have none but praise to offer. As a digest of the earlier matter of Dr. Routh's treatise up to, but not including, Lagrange's generalised equations of motion, it will be welcomed by all students whose primary object is to master the equations of motion of a rigid body without diving too far into higher applications.

The order of treatment is essentially based on "Routh," with the exception that Mr. Loudon gives no separate chapters on "Motion in Two Dimensions," "Momentum," and "Vis Viva." Thus the first two chapters deal with "Moments of Inertia" and "Ellipsoids of Inertia," and are followed by chapters on "D'Alembert's Principle" and on "Motion about a Fixed Axis." After the latter problem has been considered both for finite and "impulsive" forces, the same is done for motion about a fixed point. In this connection, the equations of motion of a top, and of a body moving under no forces, are discussed as far as they can adequately be treated without using elliptic functions. The book concludes with a chapter on the "Gyroscope," in which the experimental proof of the earth's rotation is figured and described at some length.

One very commendable feature is the large number of diagrams. To represent on paper three planes at right angles in a rigid body is a task which previous writers have shirked; but Mr. Loudon's large and bold figures will do much to assist the reader in forming a concrete idea of the motions he is dealing with. We might instance more especially Fig. 50, illustrating the motion of a top spinning on a horizontal plane, and Fig. 58, illustrating how the motion of a rigid body under no forces is completely represented by the rolling of the momental ellipsoid on a fixed plane.

To our mind the book's chief drawback, considered as an *elementary* treatise, lies in the author having, no doubt unconsciously, followed Dr. Routh's analytical methods too closely instead of striking out in simpler lines of treatment. That it is a useful exercise to start every problem by writing down the fundamental equations

$$\Sigma m\frac{d^2x}{dt^2} = X, \quad \Sigma m\left(y\frac{d^2z}{dt^2} - z\frac{d^2y}{dt^2}\right) = L$$

cannot be doubted, but the ordinary beginner often finds it hard to proceed from these equations to the final solution. What he now chiefly requires is a thorough grasp of the nature and significance of "angular momentum." We by no means wish to overrate the educational value of the familiar type of Tripos rider, whose solution merely involves writing down the equations of conservation of angular momentum and energy, and eliminating between the two; at the same time, we do think that much may be learnt from problems of this class, especially by the beginner. For a similar reason we are sorry not to find "Motion in Two Dimensions" treated earlier. Again, in deducing Euler's equations of motion, it seems a pity that the author has adopted Dr. Routh's laborious proof, a proof which is always found very hard to grasp. Its difficulty is largely due to the necessity of proving the relation

$$\frac{d\omega_1}{dt} = \frac{d\omega_x}{dt}$$

connecting the rates of change of the angular velocities about fixed and moving axes respectively. The author gives two proofs of this identity, occupying four pages of difficult mathematics; but the result is, after all, only a particular case of the general property of moving axes, which, when applied to any *other* vector quantity (angular momentum, for example), assumes the far more intelligible and suggestive form

$$\frac{dh_x}{dt} = \frac{dh_1}{dt} - h_2\omega_3 + h_3\omega_2$$

and thus leads to a far shorter proof of Euler's equations.

In a few respects the book slightly lacks in finish. A tyro might easily complete the chapter on "D'Alembert's Principle" without having his attention drawn to what that principle really is, or might even mislead himself into the impression that the principle consisted in the mere equations

$$\Sigma(f_1) = \Sigma(f_2) = \Sigma(f_3) = 0.$$

Again, on p. 127, the author commences to explain the "sleeping" of a top, but stops short after briefly indicating that the effect is due to friction. It would require considerable mathematical ability to prove the phenomenon by actually integrating the equations of motion, taking account of friction in the manner suggested.

Most people find it easier and quite as effectual to explain the observed results from general principles.

Such difficulties would mostly disappear in the hands of an accomplished teacher. Moreover, the volume is exceedingly rich in examples, both illustrative and otherwise, and, in addition to those contained in the text, there is a collection of 300 problems at the end. As a class-book, or for use in the lecture-room, Mr. Loudon's treatise may therefore be safely recommended. G. H. B.

OUR BOOK SHELF.

Our Country's Butterflies and Moths, and how to know them. A Guide to the Lepidoptera of Great Britain. By W. J. Gordon, author of "Our Country's Birds," "Our Country's Flowers," &c. With a thousand examples in colour by H. Lynn, and many original diagrams. Crown 8vo, pp. vii + 150, plates 32. (London: Day and Son, 1896.)

ONE remarkable circumstance noticeable in the present plethora of works on British butterflies and moths, is that almost every new one is composed on a different plan. The present book reminds us a little of Wood's "Index Entomologicus," except that the figures are not reduced; and it will be very useful to schoolboys commencing a collection. All the *Macro-Lepidoptera* are figured, to the *Geometridæ* inclusive, and all the genera of *Micro-Lepidoptera*, except in the *Tineæ*, where the selection is limited to typical specimens of each family. The execution, though unequal, is fairly good on the whole, and most of the species figured will be easily recognised, though the want of figures of undersides, and of both sexes in the butterflies will be severely felt in many cases. One or two of the figures are, however, so unlike the insects they are supposed to represent, that our first impression on opening the book was that they were intended to represent some foreign species. We may specially instance the figure of *Sphinx pinastri* on plate 7, while that of *Smerinthus populi* is not much better. But this matters less in the case of conspicuous and easily identified species; and where accuracy is really needed, as in the smaller *Geometridæ*, the execution is much better. The letter-press largely consists of indices and tables, and contains much useful information relating to *Lepidoptera*, and even to insects in general. The main characteristics of the families, genera and species are briefly noticed, as well as their sizes and times of appearance, but nothing is said about localities or comparative rarity. Notices of the larvæ are limited to those of the butterflies; English as well as Latin names are used throughout. It is only fair to the author to say that we have rarely seen a book in which so much information was compressed into so small a space.

Handbook for the Bio-Chemical Laboratory. By Prof. John A. Mandel. Pp. 101. (New York: John Wiley and Sons. London: Chapman and Hall, Limited, 1896.)

IN this handbook will be found detailed descriptions of the methods of preparation of the most important substances which enter into the composition of the fluids and tissues of the animal body, and a synopsis of the tests for such substances, arranged in alphabetical order. Students of physiological chemistry will find the volume a handy laboratory manual.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Buried Celluloid.

IT has occurred to many people, that perhaps celluloid migh be useful as an insulator for electric cables. I feared it migh deteriorate. I have made an experiment of 4½ years duration which may be of use in connection with the subject. On August 15, 1891, I took four photographic quarter-plate celluloid plates, with the gelatine removed, and treated them as follows:—

No. 1 was nailed to an outhouse, and became rotten in a year.
No. 2 was 1 foot deep in garden soil.
No. 3, 1 foot deep in gravel.
No. 4, 1 foot deep in a rubbish heap.

The last three were dug up on April 6, 1896. Nos. 2 and 4 were in as perfect condition as ever. No. 3 has some sand rubbed in, but is perfectly sound.

The experiment was made at Pitlochry, N.B. The specimens can be seen at my office. GEORGE FORBES.

34 Great George Street, Westminster, S.W., April 16.

Suggested Photography by Transmitted Heat Rays.

I AM no chemist, and may be mistaken, and what I propose would be more curious than useful; but I believe it would be possible to get a visible shadow of a small object which was concealed from sight by being enclosed within an opaque material. There are substances opaque to light, but which transmit the rays of heat; most readily, I suppose, those from the sun, and these are substances on which such heat rays inpinging would cause some visible change.

If the heat-transmitting substance allows the rays to pass without dispersion, preserving their rectilinear direction, then these rays falling upon a duly prepared screen would cause a visible change upon a portion of its surface; and any ordinary opaque object placed within the heat-transmitting substance would cast a shadow, dark, or bright, as the case may be.

Penzance. REGINALD COURTENAY.

Influence of Terrestrial Disturbances on the Growth of Trees.

As the subject of forestry has recently been much under discussion, and appears to be exciting more interest in this country than it was, I trust I shall not be trespassing upon your space in calling attention to a peculiar case of timber growth which I have noticed, and in soliciting the opinions of those of your readers who are likely to be well-informed upon foreign woods, as to its true cause.

There is in the British Museum of Natural History the cross-section of a large Douglas fir grown in British Columbia, and stated to be more than 500 years old at the time it was felled, which was, I believe, in 1885. An attractive feature in the section is that the annual rings have been marked off chronologically, and some historical event, contemporaneous with the growth of the ring to which the date is attached, is given.

A glance, however, at one part of the surface of the wood, which is polished, reveals a very remarkable modification of the annual rings, which appears to have taken place towards the close of the first century of the tree's existence. About twenty of the rings are there crowded so closely together as to present, at a short distance, the appearance of a zone about three-quarters of an inch wide running round the trunk, and differently coloured from the rest of the wood. It is also to be particularly observed that the change to ordinary growth on either side of the zone is abrupt; and, further, that no such phenomenon is afterwards presented during the many centuries of the tree's subsequent development.

The suddenness of the changes puts out of court the idea that the check to growth might have been due to overcrowding in the forest during the period of the struggle for supremacy over its fellows, which the tree would undergo, because any effect from this cause would only come on gradually, and diminish in the same manner.

The supposition that twenty bad seasons occurred in succession, is unlikely under any climatic conditions with which we are

familiar. It is true that two or three rings of growth in a tree are often very close together in consequence, perhaps, of adverse seasons, or insect depredations upon the leaves; and this is easy to understand.

It seems therefore not easy to say what can have occasioned this apparently abrupt cessation of vigour in a tree which had previously made good progress, and which again as suddenly renewed its former healthy condition.

Would any extraordinary convulsion of nature be likely to account for the facts of the case? But might we not expect to see evidence of similar catastrophes at various epochs in a tree of such great age? Nothing, however, afterwards appears but ordinary average growth, becoming gradually less with increasing age.

Now the dates given on the part of the section about where the thinning occurs run up comparatively close to, but do not quite correspond with a very remarkable period of the world's history, viz. towards the middle of the fourteenth century. If the tree had ceased to grow for a few years before it was cut, the correspondence would be very close indeed.

About this period many extraordinary particulars are given in Hecker's "Epidemics of the Middle Ages." In this work details occur of the appalling convulsions, terrestrial and atmospheric, to which the world was subjected for some years prior to the outbreak of the Black Death.

Amongst others of a similar tendency the following passages appear.

"Mighty revolutions in the organism of the earth of which we have credible information had preceded it (the Black Death). From China to the Atlantic the foundations of the earth were shaken; throughout Asia and Europe the atmosphere was in commotion, and endangered by its baneful influence both vegetable and animal life."

"Before the earthquake (that of Cyprus) a pestiferous wind spread so poisonous an odour that many were overpowered by it, and expired in dreadful agonies. This phenomenon is one of the rarest that has been observed, for nothing is more constant than the composition of the air."

"Earthquakes were more general than had been within the range of history. In thousands of places chasms were formed from whence arose noxious vapours."

"It is probable, therefore, that the atmosphere contained foreign and sensibly perceptible admixtures to a great extent, which at least in the lower regions could not be decomposed and rendered ineffective by separation."

"The order of the seasons seemed to be reversed—rains, floods, and failures in crops were so general that few places were exempt from them."

"In the inmost depths of the globe that impulse was given in the year 1333, which in uninterrupted succession for six-and-twenty years shook the surface of the earth even to the western shores of Europe. From the very beginning the air partook of the terrestrial concussion. Atmospherical waters overflowed the land, or its plants and animals perished under the scorching heat." (Hecker's "Epidemics of the Middle Ages," trans. Babington.)

Particular mention is made of the fearful natural calamities then visited upon China, which seems to have suffered more than any other place recorded. Now this points to the special activity of subterranean forces on the Pacific sea-board; and, consequently, British Columbia is not unlikely to have come in for a heavy share of the physical disturbances of that period. If so, is it not very probable that as strong an impression would be made upon the plants and animals of that part of the globe as upon those of other countries that are mentioned? Now trees are the only beings at present living which could possibly have been contemporary with these calamities; and, as it is not difficult to determine their age approximately, it would be very interesting to carry out investigations in other instances, and thus ascertain if nature has recorded in the giants of the forest some impress of events which were fraught with such dire consequences to the human race. HENRY J. COLBOURN.

Woolhampton, Reading, April 4.

Carib Pottery.

LAST year in St. Kitts, in a cliff fresh cut by a wash, a gentleman found what were apparently the contents of a Carib grave—fragments of pottery, two complete utensils, and pieces of human bones. The whole is now in the possession of Dr. W. J. Branch.

This is the first discovery, as far as I can ascertain, of either bones or pottery in the Leeward Islands, though Carib pottery is common in some of the Windward Islands. Since then, however, I have found a kitchen-midden, and procured plenty of small fragments, along with crab-claws, broken shells, fish-bones, &c.

The human bones above mentioned are the shafts, without the ends, of a femur, tibia, and fibula, a fifth metatarsal, a phalanx of the thumb, and several chips of the other fibula and

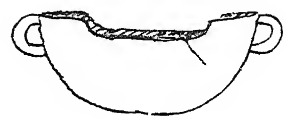

FIG. 1.

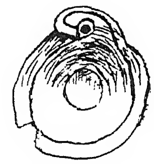

FIG. 2.

tibia. The tibia is curious as being very flat—almost two-sided, the interosseous border being merely a ridge on the outer surface.

The pottery consists of an oval bowl (Fig. 1), which the finder unhappily broke, a small plate (Fig. 2), and a number of fragments. The bowl is mended so as to be now entire; it measures 9¼ in. by 6 in. and 3¾ in. in depth; and was probably made in St. Kitts, where there is no good clay, for it is of a coarse dark earth, soft and badly baked. The plate, size 8 in. by 7 in., is nearly complete; it is of the same material, and is ornamented with an

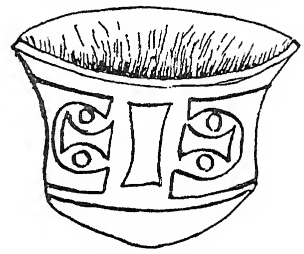

FIG. 3.

incised line winding round and ending in the curious spirally curved handle; there is a small perforated knob on the outside opposite the handle, apparently for a string to hang up the vessel. About fourteen of the fragments have been pieced together, making part of a large jar. From this I have restored the jar as in the sketch (Fig. 3). The dimensions were:—Diameter at brim 13¼ in., diameter at bulge 10½ in., depth 12½ in. It is of the red Nevis clay, apparently turned on a lathe, and well baked. The pattern is in white lines, and fired.

St. Kitts, W. I., March 30. C. W. BRANCH.

The New Education Bill and Local Museums.

I DESIRE to call the immediate attention of those solicitous for the progress and improvement of local museums to the opportunity afforded by the Education Bill now before Parliament for obtaining some public recognition of their value in any scheme for the encouragement of secondary education. By some County Councils the Technical Instruction Act has been construed as permitting grants being made from the "Customs and Excise" funds to local museums, but other Councils have not so acted, and it is very desirable that this point should be definitely settled. All that would be required is the insertion in Section 12 (page 8 of the Bill as printed), and perhaps best at the end of Clause 2, of words giving power to the "Education Authority" to aid in the establishment and maintenance of museums, whether the property of a public body or a private society, provided that such museums are devoted to the instruction of the public, and are, of course, under such regulations and control as might be deemed necessary.

There can be little doubt, I think, of the valuable services which well-arranged local museums could afford to the work of technical instruction, more particularly in calling forth and encouraging a taste for natural science studies. But the great

need of most of these small museums is an adequate and settled annual income sufficient to defray the cost of intelligent management. Capital sums for building, fittings, &c., would flow in, and donations of good local collections would often be made, if the fear of "want of permanence" could be allayed. It is this which is the difficulty in the management of local museums in the vast majority of cases, and a moderate grant of "technical instruction" funds in a county would often give far better results, educationally considered, than many of the objects to which this money is now applied.

The matter is by no means political or controversial—such grants would benefit many deserving institutions; and I hope that all well-wishers of museums will use their influence to get such a clause as that above indicated inserted in the Bill when before Committee. I commend the subject to the Museums Association and to the Secretaries of local scientific societies as one in which their energies would be most usefully exercised.

C.

A Bright Meteor.

We had the good fortune to witness a splendid meteor here on Sunday evening, the 12th of this month. The sky was perfectly clear, the hour 8 p.m. The lady with whom I was walking, by an exclamation called my attention to it, so that I did not see it on its first appearance, but it must have started from the neighbourhood of α Draconis; it then pursued a south-easterly course, passing nearly parallel to ζ and η Ursæ Majoris and α Böotis or Arcturus, and disappearing at last behind a hill to the east. We did not, therefore, see its termination; but I hear from others who did, that there was no explosion. It must have taken several seconds in its flight, as there was time for my companion to make several remarks. Its size was very considerable, and its light intermittent. Three or four times it seemed as if about to be extinguished, but again blazed forth; the colour was a fine yellow, changing to crimson; a train of sparks followed it of about 5° in length. The whole path traversed could not have been less than 50°. In the evening twilight not many stars were visible, so that I was unable to determine its exact course as accurately as I could have wished.

J. D. La Touche.

Stokesay Vicarage, Craven Arms, Shropshire, April 14.

It may be of interest to record the appearance of a fine meteor, the finest I remember to have seen, on the evening of Sunday, April 12, about 8.6 p.m. I was standing in a field in the parish of Mathon, on the extreme western border of Worcestershire, when a friend who was with me drew my attention to it. The meteor was then about 20° E. of N., and roughly half-way between horizon and zenith. It passed downwards and eastwards, very slowly as it seemed to us, till it reached a spot about 30° N. of E., and perhaps 20° above the horizon, when it disappeared. Its course was right underneath the Bear, which, lying east of the pole-star, was just becoming visible at the time. The time during which we watched the meteor I should estimate at from 10 to 15 seconds. The meteor consisted of a bright head appearing many times as large as Jupiter, and a train like a rocket's, but much shorter in proportion. The night, in the intervals of fierce north-westerly squalls, was exceptionally fine and clear.

West Malvern, April 16. A. G. Tansley.

A Daylight Meteor.

At 7.25 a.m., April 18, a meteor was observed by an inmate of my house. The sun was shining clearly in an almost unclouded sky when, in looking up, three bright stars were seen in rapid succession shooting over the trees in a northerly direction. The person who made the observation was much excited with the sight, never having witnessed fire-balls of such brightness and rapidity before.

James Shaw.

Tynron, Dumfriesshire.

"Rana esculenta" in Kincardineshire.

When on a brief visit to Kincardineshire last month, I was surprised to find *R. esculenta* in considerable numbers at a few places which I visited. I found the frogs in pools beside the Bervie, and also in places several miles away. One of these was a small isolated bog. Mr. George Sim, of Aberdeen, who is well acquainted with the fauna of Kincardineshire, was unaware of the existence of this frog in the county until I called his attention to it. In 1837 and 1842 large numbers of these animals were introduced into England, but I have not heard of a similar introduction into Scotland. It does not seem probable that the frog should itself have migrated so far north. When a thorough examination of the district has been made, it may be found that the animal is widely distributed.

University College of North Wales, Bangor.

THE RÖNTGEN RAYS.

The investigations of M. Henri Becquerel on the radiation emitted by certain salts of uranium have shown the existence of a kind of radiation intermediate in its properties between light and the Röntgen rays. These investigations are exceedingly interesting on account of the differences as well as the analogies they disclose between the uranium radiation and the Röntgen rays. M. Becquerel has shown that the radiation from the double sulphate of uranyle and potassium is analogous to Röntgen rays, inasmuch as it can affect a photographic plate after penetrating substances such as aluminium, copper, wood, &c., which are opaque to ordinary light; it also resembles these rays in being able to discharge an electrified body, whether the charge be positive or negative. On the other hand, it differs from Röntgen rays and resembles ordinary light, inasmuch as it can be refracted and polarised. It is also much more easily reflected than Röntgen rays. The radiation from the uranium salts is thus intermediate in properties between ordinary light and Röntgen rays; and as there can be no question but that this radiation consists of transverse vibrations, inasmuch as it can be polarised, it affords strong presumptive evidence that the Röntgen rays are also due to transverse vibrations.

The persistence of the radiation from the potassium uranyle sulphate is very remarkable. M. Becquerel found that crystals which had been kept in the dark for 160 hours continued to radiate vigorously. This radiation is absorbed almost equally by aluminium and copper, so that it does not show the same dependence upon the atomic weight of the absorbing medium as that of the Röntgen rays; on the other hand, the radiation resembles Röntgen rays in not being homogeneous.

With respect to direct evidence of the Röntgen rays being due to transverse vibrations, such as would be afforded by a difference between the absorption by two plates of tourmaline (1) with their axes parallel, (2) with their axes crossed, the results are somewhat conflicting. On the one hand, Prince Galitzine and M. de Karnojitsky get a greater absorption through two plates of tourmaline when their axes are crossed than when they are parallel; while, on the other hand, M. H. Becquerel, M. Sagnac, and the writer get no appreciable difference between the two cases. It is just possible that as tourmaline is a mineral which varies greatly in chemical composition, those varieties which contain abnormal quantities of the heavier metals may show this effect, whilst in other specimens it may be too small to be appreciable.

A considerable number of experiments have been made to find the part of the tube where the Röntgen rays originate. Perrin, using pin-hole photography, came to the conclusion that they arise at the places where the kathode rays strike against a solid obstacle. Rowland, Carmichael and Briggs, on the other hand, using a very highly exhausted tube with the terminals only one millimetre apart, located the origin of these rays at the extremity of the *anode*. Prince Galitzine and M. de Karnojitsky place the origin inside the tube some millimetres behind the glass. The writer, with the assistance of Mr. McClelland, investigated this point by measuring the rate at which electricity leaks through an air space of fixed length at different distances from the bulb; the Röntgen rays passing through a small hole in a thick plate of metal. The rates of leak were found to vary inversely as the square of the distance from a point, but

the position of this point with respect to the tube varied with the shape and character of the tube used to produce the rays. When the bulb was pear-shaped, with the negative electrode in the narrow part of the tube, the point was near the place where the bulb began to widen out; while with bulbs containing metallic plates to reflect the rays, this origin of the rays was on the metal plate whatever might be the position of the negative electrode. But in no case did the origin of the rays fall on the part of the tube nearest to the air space through which the leakage was measured, though this was the part of the tube which was most brightly phosphorescent. The origin, however, in these experiments was always at a place where some kathode rays struck against a solid obstacle. In these experiments the rays came through a small hole, so that the want of coincidence between the origin of the rays and the part of the tube where the phosphorescence was brightest, could hardly be explained by supposing that the direction of emission of these rays is practically almost confined to the normal to the phosphorescent surface, so that the apparent source of the rays would be the locus of intersection of the normals to this surface.

The results of the various investigations as to the source of the rays seem to show that this is most commonly at a place where some kathode rays strike against a solid obstacle; they also prove that there are regions in the tube where, though many kathode rays are stopped, very few Röntgen rays are produced. The experiment of Rowland previously mentioned, as well as the one by Lord Blythswood, where the rays were produced at the negative terminal of a Wimshurst machine without a bulb at all, suggest that there are other sources of these rays besides places where solids are bombarded by kathode rays. Judging from analogy with the behaviour of an ordinary discharge tube giving a luminous discharge, there seems nothing unreasonable in the idea that these rays may sometimes originate in the gas itself by the splitting up of its molecules under the electric discharge. When the discharge is luminous there is, as Dr. Schuster has pointed out, generally a peculiar spectrum emitted by the negative glow outside the negative dark space; there is thus in this region, under the comparatively feeble electric field which can exist when the discharge is luminous, some process going on which is favourable to the emission of radiation. Now, when the tube is emitting Röntgen rays the dark space reaches to the walls of the tube, and the intensity of the electric field is enormously greater than when the discharge is luminous. (It is most interesting to connect a voltmeter to the terminals of a tube while it is still on the pump, and observe the way the readings go up when the tube is getting into a fit state to emit Röntgen rays.) It would seem likely that under this very intense electric field the gas in the tube would be more thoroughly split up than under the feeble field which accompanies the luminous discharge, and that this finer subdivision of the gas would cause the emission of radiations of much smaller wave-length. It would be interesting to investigate whether the nature of the gas in the bulb has any effect upon the character of the Röntgen rays emitted by it; it would, however, be necessary to use other pumps as well as mercury ones to try this experiment.

The existence of a definite metallic reflection, which is considerable at grazing incidences, has been proved by Dr. Joly; while Lord Blythswood and other experimenters have published accounts of investigations which confirm Röntgen's observation of a copious diffuse return of rays from a solid obstacle. The definite metallic reflection gives us hope of arriving at the wave-lengths of these rays by interference experiments with metallic mirrors inclined at a small angle, though before this experiment can be successfully attempted it will be necessary to study more closely the want of homogeneity in the Röntgen rays, and to devise methods of producing monochromatic rays. From an interference experiment with negative results, M. Sagnac concludes that the Röntgen rays he was using must have had a wave-length less than 4×10^{-8} centimetres.

A very remarkable experiment has been made by M. Lafay, in which effects are produced similar to those which would occur if under certain circumstances the Röntgen rays were absorbed, and rays having the property of being deflected by a magnet emitted. The experiment is as follows: a photograph of a needle is taken through a thin piece of silver-foil; the Röntgen rays, after passing through the foil, traverse a magnetic field. If the foil is not electrified, the magnetic field produces no effect on the position of the shadow of the needle; when, however, the foil is electrified (by a source quite independent of the one used to work the coil), the shadow is deflected when the magnetic field is on, the direction of deflection is reversed when the sign of the electrification of the foil is reversed. Only a preliminary account of this experiment has yet been published, and in this it is not explicitly stated whether or no the width of the shadow cast by the needle is affected by the magnetic field. The point is an important one in the interpretation of this experiment, for the Röntgen rays, falling on the charged silver foil, will discharge its electrification and produce electric currents in the air; these currents, probably in this experiment flowing somewhat in the direction of the rays, would, when they passed through the photographic plate, probably affect it. Now these currents will be deflected by a magnet, the magnet driving some of them on to the part of the photographic plate previously occupied by the shadow of the needle. They would thus encroach on one side of the shadow; they would not, however, affect the other side unless the Röntgen rays were stopped by the charged plate; as though these currents can obliterate a shadow, they could not produce one where the Röntgen rays are present. Thus the effect of the currents would be to cut a piece off the shadow, and the piece would be cut off from one side or the other, according as the silver-foil was positively or negatively electrified. These currents, however, could not, with the presence of the Röntgen rays, explain a simultaneous shifting of both sides of the shadow of the needle.

Röntgen's discovery of the close connection between the absorption of these rays and the atomic weight of the absorber, has been confirmed and extended by many observers. This is a most interesting result, and it may be remarked is what would occur on Prout's hypothesis of the constitution of the elements, if each little primordial atom furnished its quota to the absorption of these rays.

The rate of leakage of electricity through different gases under the influence of these rays has been measured by Mr. McClelland and the writer. We find that in general the rate of leakage increases with the atomic weight of the gas, although there are exceptions to this rule. The rapidity with which electrification leaks through the halogens is very remarkable; it is interesting to find that the gas through which the rate of leak was greatest was mercury vapour, although the ordinary electric discharge only passes through this gas with great difficulty. When leakage takes place between two platinum plates in a gas exposed to these rays, the plates show strong polarisation.

The connection between the rate of leak through a gas and the potential difference is very remarkable. When the potential difference does not exceed two or three volts, the rate of leak is proportional to the potential difference. Then increasing the potential difference, we arrive at a stage where the rate of leak increases more rapidly than the potential difference. Increasing still further the potential difference, we soon arrive at a stage where the

rate of leak is almost independent of the potential difference. Thus in chlorine we found that the rate of leak was practically the same when the potential difference was 278 volts as when it was ten. The relation between the rate of leak and the potential difference thus exhibits the same general features as that between the magnetisation of a piece of soft iron and the magnetising force.

This result seems to throw light on the manner in which the electricity passes through the illuminated gas, and may perhaps be extended to conduction through ordinary electrolytes.

M. Stoletow has observed a somewhat similar relation between the potential difference and the rate of leak from a negatively electrified surface illuminated by ultra-violet light.

Mr. McClelland and I also investigated the connection between the rate of leak and the potential difference in the case of solid dielectrics, such as paraffin and sulphur exposed to the Röntgen rays. We found that this obeyed Ohm's law up to the highest potential difference (278 volts) used in our experiments, so that the potential difference required to "saturate" solid delectrics is evidently very much greater than for gases. The polarisation is also much greater for paraffin and sulphur than for gases, and it can be locked up, as it were, in the dielectrics for any length of time by screening them from the rays

J. J. Thomson.

THE EXPERT WITNESS.

We are rejoiced to see the daily press at last calling attention to the need of reform in the present system of expert witnesses, indicating that public opinion is coming round to the view which we have advocated for the past twenty-five years. The fact that scientific men, some of them even of high standing, can be procured to sustain the most contradictory views is, we have no hesitation in saying, hurtful to the interests of science, and tends to degrade science in the opinion of the public.

An easy way to secure perfectly unbiassed opinion is to insist that a scientific expert should not be called by a particular side in a case, but should be nominated by the Judge. We have urged the expansion of this system from the Admiralty Court, in which it is constantly employed, and within the past few days our opinion has been echoed by the daily press.

Commenting upon the judgments in two actions brought by the Incandescent Gas Light Company against rival companies for infringement of Dr. Welsbach's patent, the *Times* says:—

"One reflection is likely to occur to any who has watched the progress of these cases. The substantial question to be determined was one of chemistry and chemical history. The principle of law to be applied was clear and simple. A cloud of scientific witnesses was in attendance, and men of great eminence, such as Sir Henry Roscoe and Prof. Dewar, were called on both sides. The objection to this course is not perhaps very serious when the litigants are wealthy companies and the patent is of great value. But it must strike any impartial mind that the length of such inquiries would be curtailed, that the expert would be more in his true place than he often now is, and that there would be fewer exhibitions of startling conflicts between the opinions of high scientific authorities, if the Court frequently did what it is not customary to do—namely, took the evidence more into its own hands, nominating one expert, or it may be two, to report for its guidance on some of the matters of controversy. An expert reporting as the delegate of the Court would sometimes express himself very differently from one paid for his evidence, and many cases would occupy as many hours as they now occupy days."

The *Globe* also has something to say in condemnation of the present state of things, and its plain words will not be pleasant reading to men imbued with the true scientific spirit. Referring to the same cases as the *Times*, it remarks:—

"From the conflict of expert testimony, which is almost invariable in these cases, an idea has grown up that such evidence is not very valuable to the plain man, and the average juryman is much disposed, when he hears the eminent experts contradicting one another, to pay little or no attention to either side. The fact is that our whole system of taking expert evidence is founded on a wrong basis, except in the Admiralty Court, where the Judge has the advantage of professional opinion from persons occupying a quasi-judicial position. The expert who is called in an ordinary case receives a fee which varies according to his reputation, and also according to the length he is prepared to go in supporting the case of those who call him. Naturally, a plaintiff, whose case depends upon, say, a doubtful point in chemistry will search for an expert witness who takes that view of the question which is most favourable to his contention, and the defendant on his side, will look for one who does exactly the reverse. Hence there is a continual pressure being exerted upon the expert witness to go further in his evidence than would be the case if he could be impartial, and testimony becomes bewilderingly contradictory. A simple remedy for this state of things would be for the Judge to select the expert himself. There are few departments of science in which he would not know of some recognised authority, and, even if he did not, he could always obtain the information. An expert so chosen would, of course, receive his fees from the suitors, but he would give his evidence as the assessor of the Court instead of as the witness of one litigant, the truth would be much more easily got at, and cases that now take weeks would be settled in a few days."

As in most matters with which science is concerned, Germany is able to show us the best mode of action. Experts are appointed by the State at the discretion of the Judge; these may be men not suggested by either of the litigants, or chosen by both of them.

It has been legal in England for some years for a Judge to select an expert to report to the Court upon a particular matter in dispute, and this practice is occasionally followed. There is thus little difference between the status of the official English expert and the expert of the Imperial Courts in Germany. All that is needed is the substitution of official experts entirely for those called by the parties concerned. Under such a system, no question of bias could be raised, and science would not be scandalised from time to time as it is now by those who are content thus to trade on their scientific reputation, and give rise to such unpleasant insinuations as those in which the *Times* and *Globe* are pleased to indulge.

H. C. LEVINGE.

Botanic science has sustained a loss by the death, in the full vigour of middle life, of H. C. Levinge, of Knock Drin Castle, Mullingar, late Secretary to the Government of Bengal (Public Works). During his Indian career he devoted all the time he could spare from official labour to natural history, and especially to the vascular cryptogams. His collection of Indian ferns was the largest and finest hitherto made; he had himself explored more particularly Sikkim, Kashmir, the Neilgherries, and the mountains south therefrom. At the very time when, on retiring home, he was preparing to work on his superb collection, the larger and finer part of it was destroyed in the fire of Whiteley's fire-proof warehouse. From this cause, and perhaps from the excellence of the late work of Colonel Beddome on Indian ferns, Mr. Levinge, at Knock Drin Castle, devoted himself chiefly to the Irish flora. He contributed several papers to the *Irish Naturalist*, and to the *Journal of Botany*; and added no less than seventy-seven additional species to area vii. of the *Cybele Hibernica*. Most of these were from West Meath, many from the im-

mediate neighbourhood of Knock Drin. They are mainly critical or easily overlooked species as *Chara denudata*, Braun (new to the British Isles); he also discovered new localities for many very rare plants, as for *Neotinea intacta*, Reich, f.; for which see his paper in *Journ. Bot.*, 1892, p. 194. Among his Sikkim collections he found a small undescribed *Selaginella*, in which the macrospores are covered with hairs (perhaps only extensions of the tubercles frequently present) exceeding the breadth of the macrospore—an extraordinary morphologic example of the possibilities of unicellular development, and also of interest to the student of fossil botany, where similar, possibly Lycopodiaceous, spores occur.

Botanists, strangers to Mr. Levinge, who called at Knock Drin Castle, were received with domestic and scientific hospitality at once; they were instructed by the beautiful gardens; they were expedited to all the best collecting grounds in Westmeath and neighbouring counties, and the interesting plants put in their hands. His friends will unanimously agree that no more delightful man remains behind him. It is understood that he has bequeathed his collection to the Dublin Museum of Science and Art. C. B. C.

NOTES.

The French Academy of Medicine has decided to divide between Dr. Roux and Prof. E. Behring the 250,000 francs prize, founded by M. and Mdme. Victor Saint Paul as a reward to whomsoever should first discover a remedy for diphtheria.

We regret to have to record the death of the Moscow Professor of Zoology and Anthropology, Anatoly Petrovich Bogdanoff. He was born in Southern Russia in 1834, and after studying at the Moscow University, and writing, in 1858, his first dissertation on the colours of birds, he became Professor of the same University in the year 1863. In connection with this work he wrote an excellent text-book of zoology, and a still better work, unique in its kind, namely, a "Chrestomathy of Zoology," in three volumes, in which the reader obtains a thorough scientific acquaintance with the different classes of the animal kingdom by means of admirably chosen abstracts from the best authors, considerable attention being given to purely biological questions, and especially to the lowest animals, as well as to their manners of life. A couple of generations of Russian zoologists have been indebted to this admirable work. In the sixties, Prof. Bogdanoff founded, at Moscow, the well-known "Society of Lovers of Natural Sciences, Anthropology and Ethnography," whose numerous quarto volumes of *Memoirs* rank among the best scientific publications in Russia; and whose expeditions included the well-known Turkestan expedition of the late Fedchenko and Madame Olga Fedchenko. The chief anthropological work of A. P. Bogdanoff was on the inhabitants of the grave-mounds of the Moscow region. The full list of his nearly forty anthropological, and nearly thirty zoological works is given in the most valuable publication, "Materials for the History of Zoology, pure and applied, in Russia, chiefly for the last Thirty Years," of which he was the editor, and of which three volumes have already been published. His works for popularising biology, especially on Darwin's ideas, and for extending the interest in anthropology, are also numerous.

The sixty-eighth meeting of German Naturalists and Physicians will be held this year at Frankfort-on-Main, from September 21 to 26.

Our American correspondent writes, under date April 10: "Mrs. Elizabeth Mary Ludlow, mother of the late Robert Center, has given his estate, valued at 150,000 dols., to Columbia College as an endowment of 'The Robert Center Fund for Instruction in Music.' An anonymous friend has given 10,000 dols. to be expended in the purchase of books for the library. The Havemeyer family have given to Columbia College a fund as a memorial to Frederic Christian Havemeyer, with which the finest building in America for the study of chemistry will be erected, at a cost of nearly 500,000 dols. on the new site of the college. The building will be 80 × 208 ft., and four stories high. It will be finished in hard enamel, with floors of asphalt; and the corners of all rooms will be rounded so as to prevent accumulation of dust and disease germs, and the drainage system will permit every room to be washed out with a hose. Work is rapidly progressing on the other buildings, the library, the hall of physics, and Schermerborn Hall, which is devoted to natural sciences. Plans for the hall of engineering have been approved, and ground broken. The site of the chemistry building will be dedicated on May 2."

The conditions of the 1100 guineas road carriage competition have now been settled by the proprietors of the *Engineer*, and are announced in the current number of our contemporary. An arrangement has been made with the Crystal Palace Company, who have offered facilities at the Crystal Palace for showing the carriages in work there, and for holding the subsidiary trials. The judges will be Sir Frederick Bramwell, F.R.S., Mr. J. A. F. Aspinall, and Dr. John Hopkinson, F.R.S. The competition is to be international. The vehicles will be divided into four classes and one supplemental class, in each of which a prize will be given, as follows:—(*a*) For the best mechanically propelled vehicle constructed to carry (including the driver) four or more persons, the total weight, when fully loaded, not exceeding two tons, a prize of 350 guineas; (*b*) for the best mechanically propelled vehicle constructed to carry either one or two or three persons, the total weight, when fully loaded, not exceeding one ton, a prize of 250 guineas; (*c*) for the best mechanically propelled vehicle constructed to carry, in addition to the driver, not more than one ton of goods or parcels, the total weight, when fully loaded, not exceeding two tons, a prize of 250 guineas; (*d*) for the best mechanically propelled vehicle constructed to carry, in addition to the driver, five hundredweight of goods or parcels, the weight, when fully loaded, not exceeding one ton, a prize of 150 guineas. (Supplemental).—For the vehicle, whether for passengers or goods, propelled solely by a motor actuated by the vapour of oil or spirit, having a lower specific gravity than 0·8, or a flashing-point lower than 73° F., Abel's test, and constructed to satisfy the requirements of any Act of Parliament, and the rules to be made thereunder for the time being respectively in force, which, in the opinion of the judges, best satisfies the purpose for which it is built, a prize of 100 guineas. Any method of propulsion other than muscular power may be employed, provided it be contained in the vehicle. Entries are to be made on printed forms (to be obtained at the offices of the *Engineer*) at any time prior to 6 p.m. on the last day of July, 1896. Preliminary runs will be made in the grounds of the Crystal Palace with each of the vehicles in succession. The practical working run will consist of a run on the public roads of not less than 100 miles out and 100 miles home, or a total of not less than 200 miles over a course to be announced three days prior to that fixed for the run. It will probably be arranged for Monday, October 12. Any vehicle which does not complete the "practical working run" at a *minimum* average speed of five miles an hour, to include all stoppages, to be disqualified.

In reference to the article on "The Tick Pest in the Tropics," contributed by Mr. C. A. Barber to these columns last June (vol. lii. p. 197), Dr. M. Francis, Veterinarian of the Texas Experiment Station, has drawn our attention to an account by

him of the method of destroying ticks on the cattle of Texas, and, as the study of the tick pest is one of his principal duties, this description is of great value. After several unsuccessful attempts to destroy the pest by various means, the dipping process has been adopted at Texas with very gratifying results. A large vat of five thousand gallons capacity is used, and the cattle are forced to swim through it. Various carbolic and arsenical sheep-dips were employed as solutions in the vat, but the results were not satisfactory; either the cattle had to be kept in the dips for too long a time in order to kill all the ticks, or they were irritated by the solutions. This led Dr. Francis to try the effect of oil in destroying the ticks. It is well known that grease or oil, of almost any kind, is fatal to insects, lice, &c., and known facts as to the life-history and structure of ticks gave presumptive evidence that oil might be successfully substituted for the various commercial dips which had been employed. A layer, from three-quarters to one inch in thickness, of crude cotton-seed oil on the water in the vat was first used, the cattle being forced to swim through the vat, so that when they emerged they were covered perfectly with oil. This had no apparent effect on the cattle, but was found to be exceedingly fatal to the tick, and was very much superior to any other treatment tried. Dips of different nature were experimented with, but none as yet used have given such satisfactory results as the cotton-seed oil. Kerosene emulsion was found to have no practical value; crude petroleum irritates the skin, and emulsifies with water; resin oil is useless for the purpose; corrosive sublimate is too dangerous and is not very fatal to ticks even in solution 1 : 250 in water; and tobacco sheep-dips have no practical value. Dr. Francis is at present studying the effects of other oils, the most promising being West Virginia Black, a mineral oil. A full description of the construction of the vat and pen enclosure used will be found in the *Texas Farm and Ranch* of March 14.

Carnation-lovers will read with much interest a *Bulletin* just issued from the Agricultural Experiment Station of Purdue University. It is entitled "Bacteriosis of Carnations," and describes in great detail an elaborate investigation which Messrs. Arthur and Bolley have carried out on a disease with which carnations are very frequently afflicted. That this disease is caused by true parasitic bacteria, these researches appear to prove beyond doubt, and Messrs. Arthur and Bolley have succeeded in isolating the specific microbe, which they have named "Bacterium Dianthi." Although this bacillus grows readily in artificial culture media when rendered acid, producing a yellow pigment, it has only been found in nature in leaves of the carnation-pink, and infection experiments seem to indicate that it is parasitic only upon pinks, and produces no effect on the shoots, leaves, or tubers of potatoes, or on other non-caryophyllaceous plants. The disease seems to be started by these bacteria entering the plant from the air through the stomata, or occasionally by means of punctures made by aphides; whilst their passage from one cell to another is due, in the opinion of the authors, to the secretion of an enzyme, by means of which the microbe "dissolves for itself a passage-way." Although no varieties of carnation are exempt from the disease, yet they differ greatly in their susceptibility towards it. Delicate varieties and poorly-grown plants are more readily affected than vigorous and well-grown varieties. It is satisfactory to learn that such a simple precaution as keeping the foliage dry, and preventing the presence of aphides, may practically banish this disease from our carnation-houses.

A correspondent of the *Times* says:—"Within the last few weeks there has been in connection with the Dover Coal-field a transition from the experimental to the practical stage. In the last week of March the Kent Coal-fields Syndicate was formed, the capital of which was fixed at £200,000, and last week the whole of that capital was subscribed, a board of directors chosen, and a contract entered into for the sinking of two shafts as near as practicable to the Shakespeare's Cliff boring, it being stipulated that these two shafts are to be carried down to 2 ft. in. seam (1138 ft.) within eighteen months, and equipped with the most approved machinery capable of winding 2500 tons per day."

A "record" has been accomplished in measuring geodetic base lines by the Swedish surveyor Jäderin. The French staff officers, using double bars of two metals and microscopes, consider 400 metres per day good work. Hatt, in Corsica, using an encased steel ribbon 20 metres long, stretched on stands by two weights of 8 kilogrammes, advanced 500 to 600 metres per day. But Jäderin, by employing successively two wires, one of steel and the other of bronze, stretched by spring dynamometers at a tension of 10 kilogrammes, and supported on ten tripods, succeeded in measuring up to 3 kilometres in one summer-day—whether at midsummer, north of the Arctic Circle, we cannot say. From the notice which appears in the current number of the *Physical Society's Abstracts*, we learn that Jäderin's paper has not been printed.

In a valuable paper (*Atti e Memorie della R. Accad. di Scienze* in Padova, vol. xii., 1896, pp. 89–97), Prof. G. Vicentini has presented an interesting summary of his investigations on earthquake pulsations. The instrument employed is the microseismograph designed by himself (see Nature, vol. li. p. 540), and now erected in the Universities of Siena and Padua. The motion of the paper on which the pulsations are recorded is unusually rapid, and this has allowed a detailed examination of their nature to be made. Prof. Vicentini distinguishes, as a rule, three phases in each disturbance. The first consists of rapid vibrations and small oscillations; the second of large, and more or less irregular oscillations, with several maxima which begin and end abruptly; in the third phase the pulsations become more regular, and are longer in period. Throughout nearly the whole movement, but especially during the last two phases, the mean position of the pendulum generally undergoes a continuous change, showing that with the more rapid oscillations there coexist long, slow waves with a period of at least twenty seconds, which result in a gentle tilting of the surface of the ground. If the earthquake is a severe one, and the origin at a great distance from the place of observation, the three phases are separated from one another. But, as the distance of the epicentre diminishes, the first two phases partly coalesce, and the rapid vibrations are superposed on the earlier long-period oscillations. When the earthquakes are weak and of local origin, the tilting of the ground is still observed. During the slight Rovigo earthquake of May 25, 1895, for instance, the tilting at Padua took place nearly in a straight line, slowly in the first ten seconds, but more rapidly in the next twelve, when it reached a maximum of about 6″. After this, for ten seconds, an equally rapid tilt took place in the opposite direction, and this was succeeded by several smaller oscillations, of about twenty seconds each, before the motion became imperceptible.

From the Horticultural Department of the Cornell University Agricultural Experiment Station we have a "Geological History of the Chautauqua Grape Belt," a narrow plain in the State of New York, extending north-eastward from the Pennsylvanian State line, bounded on the north by Lake Erie, and south by a high range of hills, well adapted for the culture of the vine.

The Department of Entomology of the U.S. Department of Agriculture has issued an account of the San José Scale, its occurrences in the United States, and the remedies to be used against it, by Mr. L. O. Howard and Mr. C. L. Marlatt. As

many as twenty-eight different kinds of trees and shrubs are enumerated as being liable to the attacks of this pest, including most of the common fruit trees, a few varieties of pear only being exempt.

The "jack-rabbits" of Southern California and the adjoining States appear to be nearly as great a nuisance in America, as the ordinary rabbit in Australia and New Zealand. A lately published number of the *Bulletin* of the U.S. Department of Agriculture is devoted to a report, prepared by Dr. T. S. Palmer, on the jack-rabbits and their ravages, and on the best manner of getting rid of them, which is said to have become of late years a serious question in California, Colorado, Idaho, Oregon, and Utah. The so-called "jack-rabbits" belong to five species of the genus *Lepus*, which are spread over Western America from the plains of the Saskatchewan down to Mexico. They live on the open prairies, and, as they do not burrow, are compelled to trust for safety on their quickness of hearing and speed. Their ears and hind legs have been developed accordingly to an extraordinary degree. In some places they multiply to such an enormous extent that the damage done to the crops in one single county in California has been estimated at 600,000 dols., and one county in Idaho has expended more than 30,000 dols. in bounties paid for their destruction. The most effective mode of getting rid of jack-rabbits appears to be by driving them over a large tract of country into a "coral." On each side of the coral two long wings of wire-fencing are run out, and in some cases are extended to a length of six or seven miles on each side. The whole population of the country is then collected on a special day and a line formed, in order to drive the rabbits between the wings of fencing into the coral. In some cases these drives are carried out on a gigantic scale, and the number of rabbits destroyed on a single occasion runs up to 20,000. Upon the appointed day large numbers of people turn out, armed with sticks and clubs, and, scattering over a considerable area, start the rabbits and drive them towards the mouth of the coral. Every available vehicle is pressed into service, but the larger part of the throng is usually on foot. The lines gradually close in, and the frightened rabbits, urged on by blows and shouts, rush blindly into the opening between the wings, and are gradually despatched with clubs. The *Bulletin* contains a table, which shows that upwards of 370,000 "jack-rabbits" have recently been destroyed in this manner.

Result of the Grand Army Rabbit Drive at Fresno, California—20,000 Jack Rabbits killed.

The last *Bulletin* received (vol. ii. No 6) of the Imperial University College of Agriculture (Tōkyō) contains important papers (in German), all relating to the culture of Conifers, by Prof. O. Loew and Dr. Seiroku Honda.

Messrs. Henry Holt and Co. announce, among their forthcoming works, "Electricity," by Prof. Charles A. Perkins, of the University of Tennessee, and "A Problem Book in Elementary Chemistry," by E. Dana Pierce, of the Hotchkiss School, Lakeville, Ct.

The Field Columbian Museum has issued a Flora of West Virginia, by Mr. C. F. Millspaugh and Mr. L. W. Nuttall. Besides Flowering Plants the list includes the Vascular Cryptogams, Muscineæ, and Fungi; a considerable number of new species of Fungi being described. While commending the activity of this energetic Western station, we would venture to suggest, in future publications, a somewhat more careful revision of the press. Such names as *Equisitæ*, *Lycopodæ*, and *Impomæa* do not look well in a scientific publication.

We have received the Summary Report of the Canadian Geological Survey, for 1895. Although strict economy has

been rendered necessary, much good exploring work appears to have been done. The deep boring for oil at Athabasca Landing has now been continued down to over 1700 feet, with every prospect of early success when work is resumed this season. Students of Graptolites will welcome the announcement that Prof. Lapworth's work on the Canadian forms is now approaching completion.

IN a communication made before the St. Petersburg Society of Naturalists (*Proceedings*, November 1895), Prof. Borodin described some interesting species of plants which he had discovered during his last summer's exploration of the lakes of the Valdai plateau, namely, the *Isoëtes echinospora* and the *Isoëtes lacustris*, the *Lycopodium inundatum*, *Botrychium virginianum*, and *Luzula angustifolia*, Garcke, var. *albida*, which last seems to have been imported, and now grows in masses along the embankment of the Moscow Railway. He especially mentioned the simultaneous occurrence, in Lake Bologoye, of the two species, *Caulinia fragilis*, W. (*Najas minor*, All.) and *Caulinia flexilis* (*Najas flexilis*, Rostk.), which, Prof. Borodin remarks, never occur together. The former is known from many localities of Southern and, partly, Middle Russia; but the second, which is altogether a rare northern species, has only been found until now in the lakes of Finland and Olonets.

THE presidential address, delivered last December to the Geological Society of Washington, by Dr. G. K. Gilbert, has been published by the Society. It is entitled "The Origin of Hypotheses," and illustrates the methods of scientific investigation by reference to a particular problem—the origin of the peculiar crater-structure in limestone known as Coon Butte (Arizona). Involving as it does a consideration of all possible methods of the formation of a non-volcanic crater, it will be found to have a more special interest for geologists than the title might suggest.

THE Rugby School Natural History Society is one of the best of the scientific societies attached to our public schools. The report for the year 1895 has just come to hand, and we recognise in it a spirit of devotion to science worthy of the fullest encouragement. It is no small matter for a school society to spend £270 upon the purchase of objects, cases for a new museum, and for the rearrangement of the specimens; yet that is what the boys at Rugby have done. A rigid economy of many years enabled the Society to meet the entire expenses of the removal and cleaning of the objects, without appealing for help from outside, but as a consequence its resources are entirely exhausted. Funds are needed to be devoted to new cases for the entomological collection in the museum, but, we understand from the report, unless material assistance beyond the ordinary income is received, it will be a long time before the Society's exchequer will be sufficiently replenished to warrant any expenditure. We cordially commend the position of the Society to philanthropists, believing that any assistance given would work for the increase of scientific investigators. The papers contained in the report are on the flight of birds, by Mr. W. T. Loveday; the contents of the Rugby School Museum, with suggestions for their improvement and enlargement, by Mr. W. E. Collings; the functions of a school natural history museum, by Mr. L. Cumming; and on earth-worms, by the Rev. Hilderic Friend. There are also the usual reports of the various scientific sections of the Society.

THE additions to the Zoological Society's Gardens during the past week include a Red-faced Ouakari (*Brachyurus rubicundus*), from the Upper Amazons, presented by Mr. Ernest E. Austen; a Black-eared Marmoset (*Hapale penicillata*), a Common Marmoset (*Hapale jacchus*) from South-east Brazil, presented by Mr. R. H. Biddle; two Ring-tailed Coatis (*Nasua rufa*) from South America, presented respectively by Captain Hyde and Mr. James Green; a Lion (*Felis leo*, ♂) from Africa, deposited; an Indian Civet (*Viverricula malaccensis*) from India, a Nankeen Night Heron (*Nycticorax caledonicus*) from Australia, twenty Midwife Toads (*Alytes obstetricans*) European, purchased; a Weka Rail (*Ocydromus australis*) from New Zealand, received in exchange; two Maholi Galagos (*Galago maholi*), four North African Jackals (*Canis anthus*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

URANUS AND ITS SATELLITES.—As part of his work at Mount Hamilton during 1894 and 1895, Prof. Barnard took up the measurement of the positions of the four moons of the planet Uranus, and his results have just been published (*Astronomical Journal*, No. 370). Even with the 36-inch telescope the two inner satellites were usually difficult objects, while Titania and Oberon were also difficult if there was any wind to disturb the telescope. Ariel seems to be generally about half a magnitude brighter than Umbriel, and is the more easily visible notwithstanding that it is nearer to the planet. The compared brightnesses of Titania and Oberon seemed at first to show a variation of their relative light, amounting to a whole magnitude, but it is by no means certain that a real change occurs in the brightness of either; a consideration of the circumstances under which the comparisons were made has led Prof. Barnard to the curious conclusion that his eye has a tendency to make the lower of two equal lights appear the brighter, and he therefore thinks it probable that the two outer satellites are of constant and nearly equal brightness.

Apparently without being aware of the earlier observations of Schiaparelli and others, Prof. Barnard noticed a very decided ellipticity of the disc of Uranus, and found that the orbits of the satellites deviate some 20 or 30 degrees from the equatorial plane indicated by the major axis of the disc. For the polar and equatorial diameters, the measured values are 3"·93 and 4"·150 respectively, when reduced to the mean distance of Uranus from the sun equal 19·18329 astronomical units. The polar compression appears to be greater than that of Saturn, which fact indicates a rapid axial rotation. The mean diameter of the planet derived from the measures is 34,900 miles.

COMET SWIFT.—A telegram received from Kiel on April 17 announces the observation of Swift's comet at 8h., Echo Mountain mean time, on April 13 in R.A. 3h. 39m., Decl. 15° 40′ N. The comet is stated to have a tail, and was moving slowly westward. It is a little south of the Pleiades, so that it can only be observed for a short time after sunset.

A later telegram states that the comet was observed at the Lick Observatory at 8h. 26m. mean time on April 16; it was then in R.A. 3h. 38m., Decl. 18° 20′ N.

THE ASTRONOMICAL AND PHYSICAL SOCIETY OF TORONTO.—Judging by the sixth annual report, which we have just received, this Society is doing good work in popularising the study of science in Canada. The volume contains reports of the semi-monthly meetings and a series of papers read before the Society. For the most part the papers give popular accounts of various astronomical and physical researches, among which "the spectra of nebulæ," "celestial photography," and "electrical radiation" may be specially mentioned. One of the communications, by A. Harvey, describing the behaviour of minerals at very high temperatures, is very suggestive. His experiments were made by means of a Barton electrical furnace, in which the current proceeds through water to the negative pole, so that an arc is formed where the mineral at the negative pole is brought to the surface of the water. The mineral in this way becomes surrounded by an intensely heated gaseous envelope, and its surface is quickly melted, while a brilliant light is produced. When removed from the water, the crust on the surface of the mineral greatly resembles that seen in meteorites. Different minerals give out light of different colours, and usually glowing particles are detached in very much the same way as those which give rise to the trails of shooting-stars. The volume also reports the proceedings of the Committee on the "unification of time." It appears that of the nine nations publishing ephemerides, six have formally given their assent to the proposal that on and after the first day of January 1901, the astronomical day should begin at mean midnight.

PHYSICAL PHENOMENA OF THE HIGH REGIONS OF THE ATMOSPHERE.[1]

THE first and decisive cause of nearly all physical phenomena occurring in the terrestrial atmosphere is the solar heat. The atmosphere may therefore be considered an immense heat machine, of which the sun is the focus; the boiler is represented by the soil or the clouds heated by its rays, and the condenser by the radiation towards the interplanetary space.

The means by which physicists and meteorologists study the various regions of the atmosphere are very limited; they are obliged to content themselves, more often than not, with very indirect observations, and to proceed by induction. In fact, the most interesting phenomena occur in the high regions—that is to say, at almost inaccessible heights. The object of this lecture is to show by some experiments that meteorological physicists are beginning to approach very closely the real explanation of natural phenomena. You will see, in fact, that in certain cases, not only an exact image of these phenomena is obtained, but often a veritable synthesis of them may be produced by the employment of processes entirely analogous to those which really operate in nature.

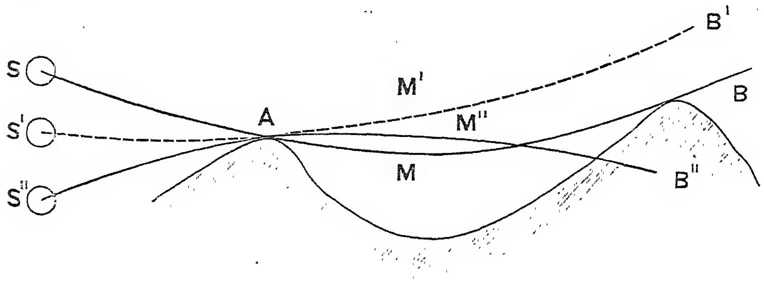

Fig. 1.

I will begin by enumerating the means in use amongst meteorologists for studying the different regions of the atmosphere.

The most direct method is the use of the aerostat; the aerostat or balloon makes it possible to take instruments of measurement to the very heart of the atmospheric regions one wishes to study. Unfortunately the method is difficult, expensive, and also dangerous; it is therefore only used in exceptional cases. The balloon ascents which have resulted best are those of Gay-Lussac (1804), of Glaisher (1862), and recently of Dr. Berson, of Strassfurt (1894), who ascended more than 9000 metres.

The most important facts observed in the balloon were very unexpected; here is the *résumé* of them:

(1) There exist very frequently clouds formed of *crystals of ice;* they constitute the cirrus, which float at very great heights.

(2) The *direction* of the *wind changes* at different heights.

(3) The temperature does not always diminish regularly with the altitude; very often *cold layers* and *hot layers* are met with *alternately*.

The second direct method for studying the atmosphere is the constructing of mountain observatories, as much as possible on isolated peaks. In these observatories the reality is daily verified of these unforeseen *inversions* of *wind* and *temperature* at different altitudes.

As for the clouds of ice, they are too high to be attained directly by the mountain observatories.

It will, perhaps, be interesting for you to know the principal mountain observatories constructed in France.

[Projection of the photographs of the following observatories:

Pic du Midi	(altitude	2800 metres)	in the Pyrenees.
Mont Ventoux	,,	1900	,,	in Provence.
Puy-de-Dôme	,,	1900	,,	in Auvergne.
The Eiffel Tower	,,	330	,,	in Paris.

[1] Discourse delivered by Prof. Cornu, at the Royal Institution. (Translated by Winifred Lockyer.)

This last observatory, owing to the lightness of its construction, entirely in open work, may almost be considered a captive balloon, permanent and fixed, 300 metres above the ground.]

Halos.—We have said that mountain observatories do not attain the region of the clouds of ice (6000 to 10,000 metres in altitude); it would, therefore, be only possible to observe them in a balloon. Fortunately these crystals of ice reveal themselves by an optical phenomenon, *the halo*, which is even seen from the low levels. It is a brilliant circle, with radius of about 22°, which encircles the sun or moon; it has a reddish tint inside, and slightly bluish tint towards the exterior. It is explained, as well as many appearances of the same kind, by the refraction of the light of the body through ice crystals; in fact, the crystals of ice are hexagonal prisms, of which the faces are in pairs inclined at 60°. These crystals, disseminated in the air, and pointing in all directions, refract the light, but the refracted rays cannot exceed the slant of 22° which the *minimum deviation* discovered by Sir Isaac Newton imposes on them; the limit of the refracted rays is, therefore, a cone of 22° round the line which joins the eye with the sun or moon.

[*Experiment imitating the Halo.*—Crystals are produced in a transparent medium, consisting of a mixture of appropriate liquids; in this way the mixture of hot and damp layers of the atmosphere is reproduced precisely, with the cold layers, which form the crystals of ice.

For this purpose a saturated aqueous solution of potash alum is placed in a glass cell, and through this cell a stream of light is made to pass, projecting the image of a circular opening representing the sun on a dark sky. Then a quarter of the total volume of rectified alcohol is added; the alum, insoluble in alcoholised water, is precipitated in very small crystals which float about in the liquid. The image of the sun is at first indistinct, as in a mist, but soon a brilliant circle, with delicate rainbow tints, appears, and represents exactly the appearance of the halo. The experiment is brilliant and instructive.]

This phenomenon is well known by country people; it is a sure sign of rain when it appears on a hot day, even if no other indications predict a metereological disturbance.

Alternation and Inversion of Temperatures.—In neighbouring observatories situated at very different altitudes, such as that of Puy-de-Dôme and Clermont, the existence of hot currents are often noted in the high regions. It is to successive inversions of the same nature that Mr. Amsler, of Schaffhousen, attributes that beautiful phenomenon known in Switzerland as "Alpenglühen," and which consists of a second illumination of the snowy caps of the Alps some minutes after they had become dark by the setting of the sun.

[Projection of a photograph of the summits of the Bernese Oberland, the Jungfrau, the Mönch, the Eiger; the view having been taken from St. Beatenberg, close to the lake of Thun. Picturesque imitation of the phenomenon by a coloured glass and proper diaphragms.]

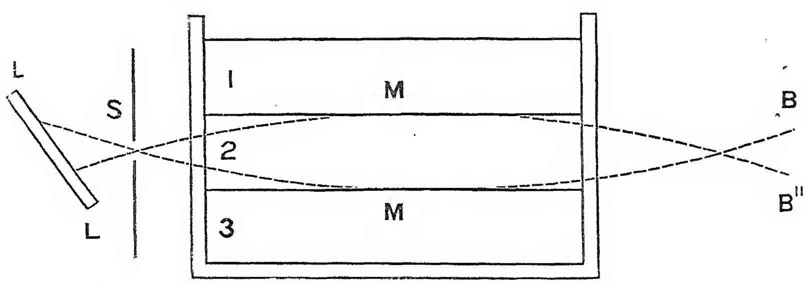

Fig. 2.—(1) Glycerine $\frac{1}{3}$, water $\frac{2}{3}$; (2) glycerine $\frac{2}{3}$, water $\frac{1}{3}$; (3) anhydrous chloride of zinc, $\frac{1}{3}$, water $\frac{2}{3}$.

Mr. Amsler's explanation is founded on the change of the direction of the curvature of the trajectory of the luminous rays depending on whether the air at the bottom of the valleys is warmer or colder than that of the higher regions.

Before the setting of the sun the ground warmed by the solar heat imprints on the trajectory a curve analogous to that of the

mirage S A M B, that is to say, convex towards the earth (Fig. 1); the sun in going down, at S′, throws the shadow of the summit A on summit B, which should therefore afterwards remain in shadow, as the sun continues to set, and as the last ray is S′ A M′ B′. But if in the interval the air of the valley gets sufficiently cold, the trajectory takes an inverse curve, S″ A M″ B″, and summit B is again illuminated.

[*Experimental Realisation of the Inversion of the Curves of the Luminous Trajectories.*—With a little care it is possible to superpose in a transparent cell of about 20 centimetres thickness three layers of liquid, of which the composition is given under Fig. 2. A movable mirror, L L, throws a stream of light through the opening, S, of a diaphragm. This beam of light, sent under different inclinations, is reflected either by the inferior layer of chloride of zinc (dense, but less refracting), or by the layer of diluted glycerine (lighter and also less refracting than the intermediate layer).

A little fluorescene illuminates the trajectory of the streams of light, and renders their curves visible; the Alpenglühen can thus be represented with a few accessory arrangements.]

Scintillation of Stars.—This phenomenon is also a proof of the alternation of the temperature and of the movement of the layers of air in the high regions. Spectrum analysis shows that the scintillation is produced by a disappearance following a regular order (in accordance with the variation of the zenith distance of the star) of the successive colours of the spectrum.

[*Imitation of the Phenomenon.*—It is obtained by a very brilliant experiment, which consists in throwing the image of a luminous opening, O, with the help of a lens, L, on a little silvered ball, B, of 3 or 4 centimetres in diameter, resting on black velvet. Thus the aspect of a fixed star is obtained, with remarkable brightness (Fig. 3).

But the luminous opening, O, is made in a card, on which is thrown the spectral image of a slit, F, which is dispersed by a direct vision prism, P.

In fact, it is the transformation of the solar energy into mechanical energy which is the fundamental phenomenon; it brings all others with it. It is the only transformation which, for shortness, I shall deal with here.

The simplest mechanical phenomenon which is produced in the atmosphere is the wind. The origin of the wind is the difference of pressure between two points more or less distant; since the time of Pascal, it is known that the pressure of air is measured by the barometer. It might be thought, according to this property, that the direction of the wind is always determined by the indications of this instrument; that is to say, that the wind must go from the point where the barometric pressure is strongest to the point where the barometric pressure is feeblest.

Well, this is hardly ever the case; the real direction of the wind is always oblique to this theoretical direction. This fact has only been known a very few years; it is the general meteorological maps, suggested by Le Verrier about thirty years ago, and so universally known at the present day, which have put this fact beyond doubt.

The direction of the wind seems to *turn round* the point of the map where the *minimum* pressure is to be found, in the *opposite direction* to the hands of a watch; or, rather, in a *direct sense* round the point of maximum pressure. Such is the direction of the phenomenon in the *northern hemisphere*; it is contrary in the southern. In fact, the most ordinary movement of the atmosphere is a *gyratory* movement, which is called a cyclone.

The whirling movement of the air has been observed for a long time; we often see it produced around us. The dust, the dead leaves are lifted by the wind in a whirlwind resembling eddies in rivers. Sailors know of *cyclones* and *water-spouts*, and fear their dangerous effects. On the American continent there are terrible hurricanes called *tornados*. These gyratory movements seem only to belong to great stormy perturbations; but the more the study of the atmosphere is followed in detail, the more it is seen that this kind of disturbance is met with in all

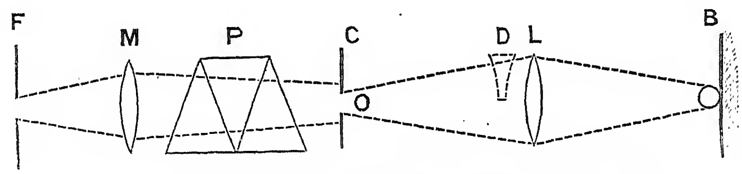

Fig. 3.—Arrangement for imitating the phenomenon of the scintillation of stars.

In truth, the card, C O, is not in the focus of the spectrum, which focus is formed further off, in the plane of the lens L. The result is that the rainbow image of the slit on the card has a white part in its centre; it is there that the opening, O, is placed. Also the light thrown on the ball, B, is entirely colourless. But the beam of light, on coming out of the opening, expands into spectrum on the lens of projection L, which recomposes it in B, as in a celebrated Newtonian experiment.

Then by placing a screen with large meshes before the lens L, certain radiations are taken away, and the star, B, appears coloured.

A *divergent half-lens*, D, with same focus as L, cancels its effect, and the spectrum of the star, with the artificial bands created by the screen, appears on a white screen by the side of the ball. This is the imitation of the spectrum analysis of the scintillation of stars.]

It is seen by these few examples that the study of the *optical phenomena* of the atmosphere, aided by physical analysis and *synthesis*, can, and must, teach much about the calorific phenomena of the regions beyond our reach.

Dynamic Phenomena of the Atmosphere.—The phenomena studied up till now are due to conditions of almost perfect equilibrium in the atmospheric layers; they might be called *static*. But the calorific action of the sun, combined with the cooling action of radiation in space, can produce phenomena of movement representing every degree of intensity, from the feeblest to the most violent: we call these phenomena *dynamic*. They make themselves apparent in very different ways.

(1) Under the form of *mechanical energy*: winds, whirlwinds, cyclones, water-spouts, &c. (2) Under the form of *calorific energy*, which makes itself felt by the formation of clouds, rain, hail corresponding to different changes of state of water, the element of the atmosphere which is continually varying. (3) Under the form of *electric energy*: lightning, thunder, &c.

manifestations of displaced air. It is therefore concluded that the gyratory movement is to some extent the *normal* condition of agitated air; it would hardly be possible to employ force on a gaseous mass without developing more or less rapid rotations, which tend to acquire for themselves a permanent condition.

Experimental Proofs.—Every time a rapid jet of gas is produced, one or more cyclonic movements are formed at the side of the jet. If the projected column is of a cylinder shape, the cyclonic movement will take the form of a ring; for example, the rings of smoke which are observed after the explosion of cannons, guns, &c.

[Repetition of the well-known experiment of smoke-rings, produced by striking the canvased end of a box filled with vapour of hydrochlorate of ammonia, with a circular opening on the opposite side. The smoke-rings are rendered visible by throwing them in the line of a beam of electric light.]

Multiple Origin of the Gyratory Movements of the Atmosphere.—Nearly all the general causes which act on the movement of the atmosphere are gyratory influences; when once the movement is set going, it continues of itself, and sometimes increases in amount; in the first place, the movement of the rotation of the earth must be cited, which always brings with it a small component of rotation for a displacement of a gaseous mass in *latitude* or *altitude*; in the second place, and as decisive cause, the solar heat, which warms the air near the surface, or the clouds. As the ascending tendency of the heated gas cannot be equal over the whole surface exposed to the rays of the sun (as much because of the nature of the ground as because of its inequalities), the equilibrium is upset in certain parts, and gaseous columns ascend. This is, therefore, the same case as the jets, quoted above, and consequently under favourable circumstances for gyrations round horizontal axes. When once the gyration is established, the causes which have produced it keep it up and augment it.

The existence of whirlwinds with horizontal axes in hail-storms, particularly in that of May 20, 1893, at Pittsburg, has been observed by an American meteorologist, Mr. Frank W. Very, and has furnished him with a very ingenious explanation of the formation of hail. Indeed, such a whirlwind (if it has sufficient dimensions) takes the hot and damp air of the surface of the ground to high and cold regions; the vapour condenses, freezes, and crystals of ice are brought into the gyratory movement; they ascend and descend alternately, following the spirals of the whirlwind, and increase at every passage in the inferior regions, which are charged with humidity. This explanation accounts for all the peculiarities which are observed in a fall of hail: zoned structure, very low temperature; special sound before the fall; electric manifestations which accompany them; for a whirlwind of hail is a veritable influence electric machine, a sort of *replenisher*.

Artificial Reproduction of Natural Gyratory Phenomena.—The phenomena produced by the rapid rotation of the air are altogether unexpected in consequence of the singularity of forces put in play. The ordinary laws of mechanics, to which daily experience has accustomed us, seem entirely different to those which the cyclonic movements seem to obey; and this must not astonish us. We have reduced mechanics to its simplest elements; the material point, the constant force, the rectilinear movement: thanks to these simplifications, we have been able to understand the movement of spherical projectiles, that of a pendulum, the rotation of a fly-wheel, &c. But as soon as the solid body becomes complex as to its form, when the movement which it may take has at the same time a translation and a rotation, our imagination represents it badly; if to this complication of form we add the resistance of the surrounding medium, then we have no idea of the probable resulting effect; for example, the *boomerang*. As to the movements of fluids, they are so difficult for us to foresee, that we receive fresh surprises every time we move a vessel of water; as soon as the mass of water is at all considerable, the tumultuous movements, which we unwillingly cause, always produce some awkwardness.

We understand then how impossible it is for us to anticipate the atmospheric movements, of which the mass is so immense, for each cubic metre weighs 1,300 grs.; if the energy expended in setting in movement such masses is considerable, inversely the stability of the system is enormous, since we have to wait for the dissipation of this energy by the passive resistances, almost always reduced to friction on the earth's surface.

We will, therefore, not endeavour to analyse the forces put in play in the gyratory movements of the air. I will limit myself to repeating before you some of the beautiful experiments of M. Ch. Weyher, who has been good enough to come himself to help me arrange the apparatus now before you.

Here is a sphere composed of ten circular paddles, put in rapid motion round axis A B (Fig. 4); the air caught in the rotation produces a general whirlwind movement, symmetric in relation to the plane of the equator. On all sides the air is sucked in by the revolving sphere, which may be seen by the effect on smoke or pieces of paper brought near it. This air is expelled from the equatorial circumference, and only in the almost mathematical plane of this circumference; in fact, look at these pieces of paper which keep themselves concentrically to the equator, following an arrangement which reminds us of Saturn's ring. The tension of the paper and its vibrations show that it is the repulsion of the equatorial outflow which maintains them.

It might be concluded from this, that the revolving sphere could only produce equatorial repulsions; but the complexity of the turbulent streams baffles the most evident anticipations. If a light balloon be approached a little distance from the sphere, it is immediately attracted, and begins to revolve rapidly round the sphere in the equatorial plane; if a second or third be let loose in the same way, they will follow it at varied velocity, and represent satellites; the planetary configuration is complete.

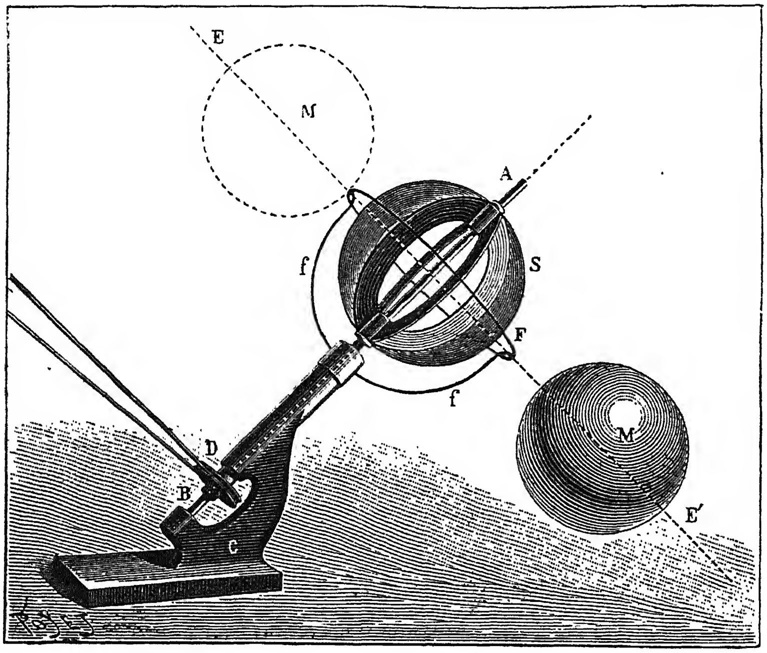

Fig. 4.—Artificial reproduction of the gyratory natural phenomena.

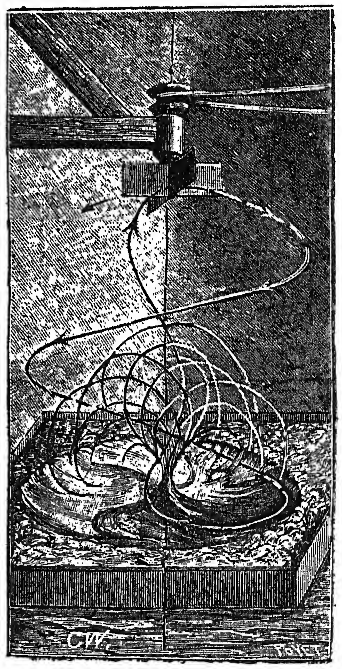

Fig. 5.

This paradox of a repulsion transformed into attraction by a change of form of the presented body, is easily solved by considering the resultant of aspiring and repelling actions on the surface of the moving body. On the greatest angular space round the revolving sphere it is the whirlwind attraction which dominates. This is easily proved by placing underneath this sphere a basin full of hot water; if the atmosphere of the room is quiet, little by little the vapour will be seen to collect in a whirl from the surface of the water to the revolving sphere (Fig. 5). This is the imitation of a water-spout. The importance of this phenomenon has led M. Weyher to reproduce it in a more striking way, and by bringing into play a much more considerable quantity of mechanical energies, thus recalling better those which constitute this natural phenomenon.

The excitement of the gyratory movement (which, in nature, has its source in higher regions of the atmosphere) is produced by a small mill, placed three metres above a reservoir of water four metres in diameter (Fig. 6). When the small mill is made to revolve (400 to 500 revolutions a minute), the aerial whirlwind sucks up little by little the surface of the water, which is

seen to be agitated and to be forming *centripetal* spirals, and producing a liquid cone several centimetres in height. Above this cone a great number of little drops accumulate, which fall back in spirals. This attraction, *at a distance*, is even more striking if the water is slightly heated; the vapour then forms a *hollow* tube, of which the hollow part is distinguished by its dark colour and its geometrical regularity; it shoots forth from the water towards the small mill, causing light objects, such as bits of straw, which are floating on the liquid, to be thrown up.

Such is the experiment which in 1887 was made in the open air at the great works of the Weyher and Richmond Company. With the reduced apparatus, now placed before you (Fig. 6), we can repeat it in conditions quite as convincing. The small mill is placed at the top of the case two metres high, closed on one side by a glass; the water, slightly warmed and containing a little soap, is placed at the bottom of the case in a basin. I set the small mill going; you see the agitation at once, the soap-bubbles precipitate themselves at the foot of the column of vapour. Soon the column takes the form already described, and represents exactly the appearance of a real water-spout; at the foot is the *buisson*—that is to say, the collection of bubbles and little drops; at the top, the expanded hollow tube of vapour.

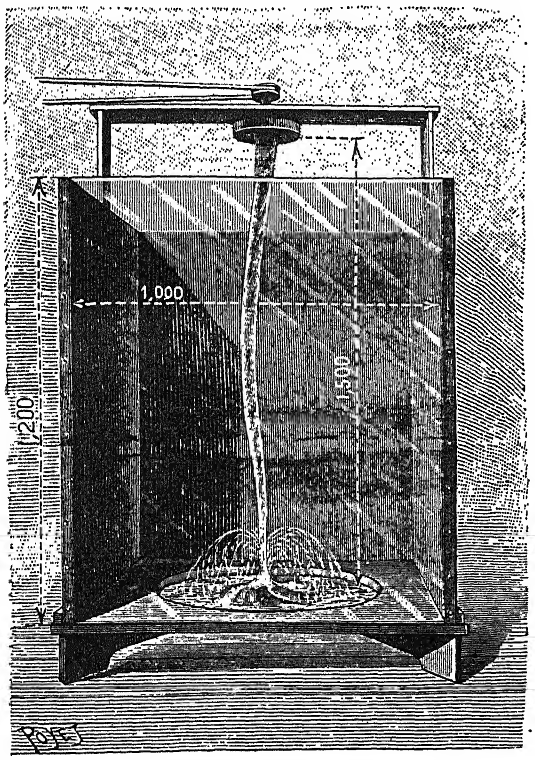

FIG. 6.—Artificial reproduction of a water-spout.

A light balloon placed at the surface of the water is first carried to the centre, and rendered captive at its foot; by quickening the rotation (which increases the power of the whirlwind) the balloon is raised by the water-spout, and sometimes follows the spiral the whole of its height.

The helicoidal movement of this light balloon, as well as the aspect of the nebulous spiral, shows well the constitution of the water-spout; one sees the superposed rolls of helicoidal currents, some ascending, others descending (Fig. 7); it is a perpetual going and coming between the mill and the surface of the water. As all the currents turn in the same direction if the ascending ones *screw* to the *right*, the descending ones *screw* to the *left*. It is the absence of having recognised this double movement of ascent and descent which is at the bottom of the misunderstanding between the partisans of ascending water-spouts and those who maintain that they are only descending phenomena.

The ascending movement of the light balloons caught up by the water-spout, shows well the ascending velocities; it is more difficult to put in evidence the descending region, declared in some theories to be the only existing one, because it occupies in the reduced experiment a very small space; it is confined to the interior of the nebulous sheath, of which the hollow centre is distinguished by its dark colour. I will, however, show it to you with the help of a very simple artifice. Take a body emitting smoke to the top of the water-spout; we see this aspirated smoke at once reach the interior of the sheath, roll itself into a slender cone, and descend to the surface of the water. This is exactly what is seen in nature when, in a water-spout, the clouds descend in the form of a stream which grafts itself in the middle of the *buisson* formed by the water at the surface of the boiling sea. This spiral is, so to speak, the harmless part of the water-spout; the terrible part is invisible; it is formed by the mass of air which rages round the spiral. In the experiment before us it is contrary. The raging mass is visible owing to the smoke which is supplied; the interior of the spiral remains dark; it is by the introduction of the smoke that the existence and form are recognised.

There still remains to show you that with a similar arrangement a cyclone can be produced with all its characteristics—variation of pressure at its passage, barometric minimum, central

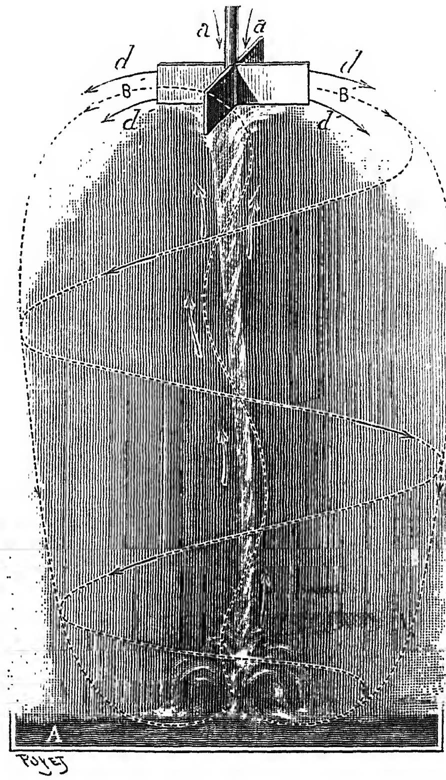

FIG. 7.—Double direction of liquid currents in a water-spout.

calm, brisk rising of wind, centre of the storm, &c.—which has also been attained by M. Weyher.

The following remarks have been subsequently added to the lecture at the Royal Institution:—

We will conclude by describing with some detail that experiment which reproduces so accurately all cyclonic phenomena. In reality a cyclone is nothing else than an immense aërial whirlwind; it only differs from a water-spout by its proportions, and principally with respect to the height and the diameter; in a water-spout the diameter is very small in relation to the height, whereas in the cyclone it is the contrary. But in both cases the general movement is the same; the aërial currents descend all around, to remount immediately on the interior spirals, with a diameter more or less great, but leaving, as in a water-spout, a central region free, in which the descending movement is equally to be found.

Here is a flat rotating disc, about 1 metre in diameter, mounted on the extremity of a crane 2 metres in radius; by means

of this arrangement it is possible to make the rotating disc travel horizontally above a large table in which are fixed a great number of pins, to the head of each of which is attached a bit of wool some centimetres in length, and thus forming many flags, which will show us the directions of the wind in each point traversed by the cyclone. In the centre of the table a hole is pierced communicating underneath with a very sensitive barometer, which will show us the variations of atmospheric pressure at the passage of the meteor (Fig. 8).

We set the rotating disc in rotation after having placed it above one of the extremities of the table; you see at once all the flags situated underneath indicate the directions of the wind. Those which form the centre of the whirlwind remain flat and rest inert on the table, their extremities directed one towards the other. They represent wonderfully well the central calm.

The flags surrounding the central calm form a circumference; they imply a wind forcing them all in a direction slightly centripetal, and ascending. In the following ranges the pieces of wool place themselves again along a circumference, but scarcely showing the centripetal direction, and not at all the ascending one; then the more distant the flags are from the centre, the more they inflect towards the table, and indicate the descending wind; at the exterior circuit the wool takes centrifugal directions; it is air which escapes from all sides on the borders of the cyclone.

Now, if we make the artificial cyclone travel horizontally, by moving the crane on its pivot, you will see that the central calm shows itself every instant at a new place, which is very easily observed by the aspect of the flags occupying the centre, which fall down suddenly and rest inert on the table. On the other hand the flags immediately adjacent raise themselves quickly, caught up by the tempest, and those which but recently were

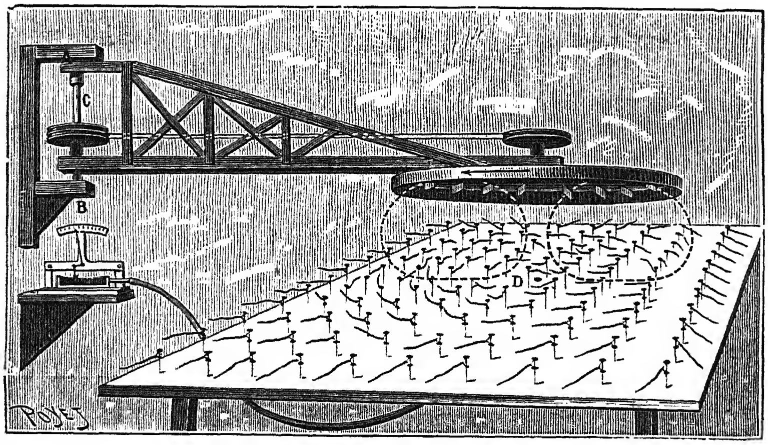

FIG. 8.—Artificial reproduction of cyclonic phenomena.

pointing in one direction, turn all at once in the opposite one, and make it possible to observe with all its sharpness the abrupt change of wind which takes place on leaving the central calm.

By making the cyclone travel with sufficient quickness, the flags permit us to take note of the dangerous and manageable sides of a cyclone, according as one looks at the semicircle in which the wind turns in the same direction as the movement of translation, or in the opposite one.

The variations of pressure are indicated by the passage of the cyclone above the hole made in the table, and communicating with the barometer; you see the needle falling little by little, indicating the minimum precisely at the moment when the centre of the cyclone passes above the hole, then rising slowly.

A thermometer sufficiently sensitive, placed in the centre of the cyclone, allows us to observe a rise of temperature.

In great cyclones, a ship on reaching the centre not only finds a general calm, but the sun or stars may be seen to shine through a great opening in the clouds; it is the eye of the storm.

In order to explain this fact, it suffices to remark that a cyclone is only in fact a water-spout of enormous diameter, in the immense sheath of which rages the storm of a descending movement, dragging down the hurricane and the clouds from the high regions to the level of the sea; but, as in the water-spout, the central nucleus remains free, and allows a clear sky to be seen.

The realisation of this eye of the storm succeeds equally well with steam or smoke by taking necessary precautions with the experiment.

Finally, as the centre of the cyclone is free of water vapour (at least in the visible form), whilst in the enveloping sheath storm and darkness reign, is it not evident that a hygrometer placed in this cloudy sheath will show a degree of moisture above that of the central nucleus?

To sum up—it may be seen that, however small the scale of the experiments in comparison to that which passes in nature, nevertheless these experiments reproduce with fidelity and with all the particularities of the great natural meteorological phenomenon.

The experiments which you have just seen will, I hope, suffice to show you how complete the experimental syntheses are, and how they represent the natural phenomena in the smallest details.

I will conclude by making the simple remark that meteorology gains in extent and certainly when we treat it as an experimental science.

A. CORNU.

IMMUNISATION AGAINST SERPENTS' VENOM, AND THE TREATMENT OF SNAKE-BITE WITH ANTIVENENE.[1]

II.

THE experiments now to be described were made with antivenene derived from a horse which had last received a dose of cobra venom estimated to be twenty times the minimum-lethal. On some previous occasions I have stated the results of observations on the antidotal value of the blood-serum of rabbits which had last received thirty and fifty times the minimum-lethal. The antivenene obtained from cats and white rats has also been examined. The special interest, however, is attached to antivenene derived from the horse, that it is more likely than any others to be used in the treatment of snake-bite in man.

The experiments were so planned as to obtain in different conditions of administration as exact a definition as possible of the antidotal power of the antivenene. In the meantime, four series of experiments have been undertaken on rabbits. In one series the venom was mixed outside of the body with the antivenene, and immediately thereafter the mixture was injected under the skin of the animal; in the second series the venom and antivenene were almost simultaneously injected into opposite sides of the body; in the third series the antivenene was injected some considerable time before the venom; and in the fourth series the venom was first injected, and thirty minutes afterwards the antivenene.

In the experiments of the *first series*, the doses of cobra venom administered were the minimum-lethal, one-and-a-half the minimum-lethal, twice, thrice, four times, five times, eight times, and ten times the minimum-lethal. In the case of each dose of venom, experiments were made with different quantities of antivenene, until the smallest quantity required to prevent death was discovered. In order to render it certain, in this and in the other series, that a lethal dose had been administered in the experiments with the so-called minimum-lethal, the minimum-lethal indicated by previous experiments was not used, but instead of it a slightly larger dose (·00025 instead of ·00024 gramme per kilogramme).

When this certainly lethal dose, capable of producing death in five or six hours, was mixed with the antivenene, and the mixture injected two minutes afterwards, under the skin, it was found that so small quantities were sufficient to prevent death as ·001 cc., ·0008 cc., ·0005 cc., and ·0004 cc. (1/1000, 1/1500, 1/2000, and 1/2500 of a cc.) for each kilogramme of the weight of animal; with ·0003 cc. (1/3333) per kilogramme, however, the animal died. The antivenene was therefore found to be so

[1] Continued from page 572.

powerful as an antidote, in the conditions of these experiments, that even the 1/2500 part of a cubic centimetre, equivalent to about the one-hundred-and-fiftieth part of a minim, acted as an efficient antidote, while even with the one-two-thousandth part of a cubic centimetre not only was death prevented, but there was almost no symptom of poisoning produced. In the experiments of this series with one-and-a-half the minimum-lethal dose, recovery occurred when the doses of antivenene were ·32 cc., ·3 cc., ·28 cc., ·25 cc., and ·24 cc. per kilogramme; but ·23 cc. and ·2 cc. failed to prevent death. In the experiments with twice the minimum-lethal dose, recovery occurred when the doses of antivenene were ·5 cc., ·4 cc., and ·35 cc.; but ·3 cc. and ·2 cc. failed to prevent death. In the experiments with thrice the minimum-lethal dose, a dose capable of producing death in less than two hours, recovery occurred when the doses of antivenene were ·7 cc. and ·65 cc.; but death occurred with ·6 cc., ·55 cc., and 5 cc. With four times the minimum-lethal dose, recovery occurred with 1·5 cc., 1·3 cc., and 1·2 cc., and death with 1 cc. With five times the minimum-lethal dose, recovery occurred with 2·5 cc., 2·2 cc., 2 cc, 1·8 cc., and 1·5 cc.; but death with 1·3 cc. With eight times the minimum-lethal dose, recovery occurred with 2·6 cc. and 2·5 cc.; but death with 2·4 cc., 2·3 cc., and 2 cc. And even the enormous dose of ten times the minimum-lethal failed to produce death, or any important symptoms, when it had previously been mixed with 3·5 cc. and 3·4 cc. of antivenene for each kilogramme of animal; and it only succeeded in producing death, although not until the lapse of several hours, when the doses of antivenene were 3·3 cc., 3·2 cc., 3 cc., and 2·5 cc. per kilogramme.

These results show a remarkable, an almost directly proportional, accordance in the increment required in the dose of antivenene for each increment in the dose of venom. In the diagram the comparatively straight direction of the oblique line separating the fatal from the non-fatal experiments is noteworthy, considering that the conditions of the experiments, in regard both to the animals and the substances used, could never be absolutely the same. Indeed, from twice the minimum-lethal dose of venom upwards, the addition of little more than ·3 cc. per kilogramme represents the addition in the quantity of antivenene required for each addition of a minimum-lethal dose of venom. Apparently the antivenene is able in this proportion to prevent death from almost any lethal dose of venom, however large it may be.

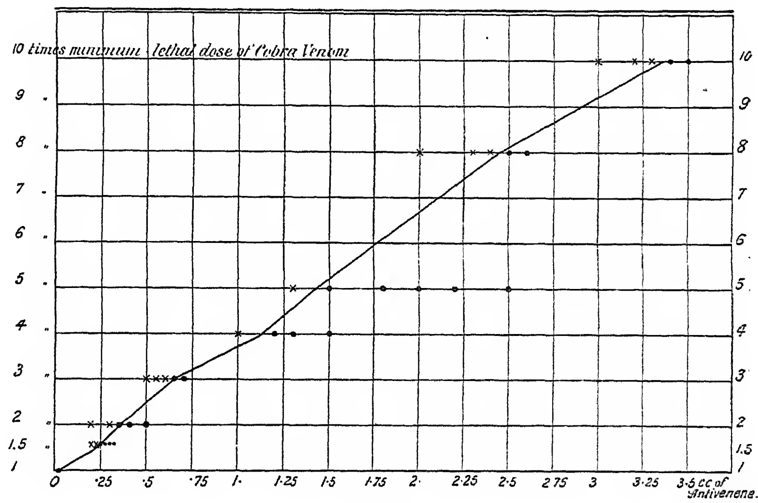

FIG. 2.

These results are in marked contrast with those that occur when an antidote acts because of its physiological properties, and they alone suggest that the antidotism is rather the effect of a chemical than of a physiological reaction. The indications obtained with doses of twice the minimum-lethal and upwards cannot, however, be carried down to the minimum-lethal dose. The quantity of antivenene required to prevent death from this dose is much less than might have been anticipated when the results of experiments with larger doses are considered. Thus, it appears that while ·35 cc. of antivenene per kilogramme is required to prevent death from twice the minimum-lethal of venom, the minute quantity of the 1/2500th of a cc., or nearly 1000 times less (·0004 as compared with ·35 cc.), is sufficient to prevent death from a little more than the minimum-lethal dose of venom. It is apparent that this minute quantity of antivenene does not render inert the whole of the minimum-lethal dose. All that is required in order that the minimum-lethal dose should not produce death being that only a minute portion of it should be rendered inert; for, if this dose be the actual mininum-lethal, the rendering inert of any portion of it, however minute, will prevent the remainder from causing death.

In the *second series*, experiments with the antivenene of the horse have been completed only with one-and-a-half the minimum-lethal dose of venom. When this dose was injected into the subcutaneous tissues of one side of the body, and, immediately thereafter, a dose of antivenene into the subcutaneous tissues of the opposite side, it was found that antivenene in doses of 3 cc. and 3·3 cc. per kilogramme failed to prevent death, but that 3·5 cc. and 3·6 cc. per kilogramme were able to do so.

In the *third series*, experiments have been made with the minimum-lethal, one-and-a-half the minimum-lethal and twice the minimum-lethal dose of cobra venom. With the first of these doses, recovery occurred with ·5 cc., ·45 cc., and ·42 cc.; but death with ·4 cc., ·3 cc., and ·25 cc. of antivenene, administered thirty minutes before the venom. With one-and-a-half the minimum-lethal of venom, 2·9 cc. and 2·7 cc. of antivenene were able to prevent death; while 2·6 cc., 2·5 cc., 2·3 cc., and 2 cc. each failed in doing so. With twice the minimum-lethal dose of venom, recovery occurred when the doses of antivenene were 5 cc., 4·5 cc., and 4 cc.; but 3·9 cc., 3 8 cc., 3·5 cc., 2·5 cc., and 2 cc. were insufficient to prevent death.

In the *fourth series*, where the results give the truest indications of the antidotal value of antivenene in the actual treatment of snake-poisoning, it was found that recovery occurred in the experiments in which ·8 cc., ·7 cc., and ·65 cc. per kilogramme of antivenene was injected thirty minutes after an assuredly minimum-lethal dose (·00025 per kilo.) of venom; but that the antivenene was insufficient in quantity to prevent death when ·6 cc. or any smaller quantity was administered. In this series, further, it was found that 3·4 cc. and 3·2 cc. per kilogramme of antivenene were sufficient doses to prevent death after one-and-a-half the minimum-lethal dose of venom, but that 3 cc., 2·8 cc., and 2·5 cc. per kilogramme were insufficient. In a corresponding series of experiments made with the antivenene derived from rabbits which had last received thirty and fifty times the minimum-lethal dose of cobra venom, it was found that 5 cc. per kilogramme of this antivenene was the smallest dose by which death could be prevented in an animal which had received twice the minimum-lethal dose of venom thirty minutes previously.

Attention is conspicuously drawn by these facts to the remarkable difference in the dose of antivenene which is required to prevent death when it is mixed with the venom before administration, as contrasted with the doses required when the two substances have not previously been mixed together. Restricting attention to the experiments in each series in which the dose of venom was the same—to the experiments with one-and-a-half the minimum-lethal dose, for instance—it appears that in order to prevent death, when this dose was mixed with antivenene before administration, only ·24 cc. of antivenene is required; whereas when both substances were injected simultaneously, but under the skin at different parts of the body, the required dose of antivenene is 3·5 cc.; when the antivenene was injected thirty minutes before the venom, it was 2·7 cc.; and when the venom was injected thirty minutes before the antivenene, it was 3·2 cc. per kilogramme.

It is impossible to consider the great difference between the dose of antivenene required when the two substances, though in

each case simultaneously administered, are, in the one case, mixed together before injection, and in the other not so mixed, without again having the suggestion originated that the antidotism is the result of chemical and not of physiological reactions.

This suggestion receives a further support from the fact, observed in several experiments, that the longer before their administration the two substances were allowed to remain together after they had been mixed, the greater is the antidotal efficiency of the antivenene. Thus, while 1·3 cc. per kilogramme of antivenene, mixed with five times the minimum-lethal dose of venom, was followed by death when the two had been mixed together five and also ten minutes before administration, this mixture was, on the other hand, followed by recovery when the interval before the administration was extended to twenty minutes. In order to obtain uniform and comparable results in the first series of experiments, it was therefore found necessary to adhere, in all the experiments made with the larger doses of venom, to a time limitation of not more than ten minutes before the mixed substances were injected.

I have also administered cobra-antivenene thirty minutes after a dose one-twelfth larger than the minimum-lethal of the venoms, respectively, of the *Sepedon hæmachates*, the *Crotalus horridus*, and the Diamentina serpent; and the animals experimented on have recovered when the dose of cobra-antivenene was not smaller than 1·5 cc. per kilogramme. This successful result is all the more remarkable when the intensely destructive effects produced by even smaller doses of each, but especially of two, of these venoms is recollected.

The antivenene derived from rabbits which had been protected to the extent that they had last received fifteen times the minimum-lethal dose of the Diamentina venom has also been tested against the Diamentina venom itself. When the two were administered together, after having been mixed *in vitro*, this antivenene in a dose of ·05 (1/20) cc. per kilogramme was able successfully to antagonise slightly less than one-and-a-half the minimum-lethal dose of the venom; but ·025 (1/40) cc. per kilogramme failed to do so.

In the experiments which I have hitherto described, and, indeed, apparently in all others made in this new subject of serum therapeutics, protection has been produced, and the antidotal properties of the antitoxic blood-serum have been tested, by the subcutaneous, or, less frequently, by the intravenous injection of the venom or other toxic substance. No endeavour seems to have been made to discover how far the same effects, or what effects, may be produced by stomach administration.

Anticipating that results of an interesting nature might be obtained by this method of administration, I have adopted it for the introduction of both antivenene and venom into the body, and the results have even exceeded my anticipations.

The plan followed was the simple one of mixing the substances, previously dissolved in water, with a small quantity of milk, and allowing white rats, which had not received any food for several hours previously, to drink this milk. In the meantime, I will briefly describe only those experiments in which antivenene was thus administered, reserving, for a few minutes, a description of the results that were obtained when the venom itself was used.

The first experiments were made with the object of determining if, by repeating the process followed in the production of immunity, with the exceptions that the administrations were by the stomach and that antivenene was substituted for venom, an animal could be protected against the poisonous effects of venom. With this object, a white rat received on alternate days during several weeks, doses of antivenene, which were gradually increased from 1 to 10 cc. per kilogramme, and then, by subcutaneous injection, one-and-a-half the minimum-lethal doses of cobra venom; with the result that death was not produced. Other white rats received 10 cc. per kilogramme on each of four days, and on the fifth day 15 cc. per kilogramme of antivenene, and still recovery took place when one-and-a-half and one-and-three-quarters the minimum-lethal dose of venom was injected under the skin. To other white rats, 10 cc. and 15 cc. of antivenene were given by the stomach, on two successive days, and on the second day, one-and-a-half the minimum-lethal dose of venom, and the result also was that death was prevented. It was thus suggested that a single administration of antivenene might be as efficacious as a succession of administrations; and accordingly, the antidotal efficiency of single doses of 7 and of 10 cc. per kilogramme was tested, in some instances three hours, in others two days, and in others three days before one-and-a-half the minimum-lethal dose of venom was subcutaneously injected; and in all cases the animals recovered. When, however, 5 cc. per kilogramme of antivenene was thus administered three hours before, and 10 cc. per kilogramme three days before, one-and-a half the minimum-lethal dose of venom, the animals died.

The experiments have not as yet been carried further, but I hope to continue them so that the limits of the antidotal power of the antivenene, and the duration of the protection after single doses of antivenene, may be defined. Enough has, however, been done to prove that the stomach administration of antivenene, equally with its subcutaneous administration, confers protection against lethal doses of serpents' venom, and to justify the use of antivenene by the former and more convenient method for the purpose of securing protection for, at least, a period of several days after a single administration of the protecting antidote.

The facts hitherto narrated are sufficient to establish that the protection acquired by animals as a result of the administration of venom is not chiefly, or even to any important degree, caused by the venom having produced a tolerance by accustoming the body, as it has been expressed, to the presence of the venom—although a certain degree of this protection may possibly be due to such accustoming—but rather to the presence in the body, as a result of the introduction into it of venom, of a definite substance having antivenomous qualities. Notwithstanding the powerful protective and antidotal action of this substance (antivenene) against serpents' venom, it is instructive to find that it is itself almost devoid of any physiological action, for even very large quantities may be injected under the skin without producing any other physiological reaction than a moderate degree of irritation in the neighbourhood of the injection. How then are we to explain the operation of this physiologically inert substance in protecting an animal against even fifty times the minimum-lethal dose of venom, or by a single administration of it, in saving an animal from death after there has been introduced into its body more than twice the quantity of venom that is required to kill it? When an answer has been attempted to be given to this question in discussions in the wider field of the serum therapeutics which deals with the toxines of diseases, the answer has been found either in the destructive power of phagocytes upon microbes and their toxines, or in the theory that the toxine elaborates from the blood the antidotal antitoxine, which, whether thus originated or separately introduced into the body, confers upon the body a resisting power which enables it to oppose successfully the injurious action of the toxines.

These answers cannot solve the problem in so far as snake venom is concerned. Phagocytosis cannot, of course, operate *in vitro* in solutions which are free from organised structures. Even when solutions of venom and antivenene, mixed together *in vitro*, have been inserted into the body, it is incredible that the increase in the quantity of antivenene by the 1/500th part of a cubic centimetre could cause such an increased proliferation of leucocytes as to prevent a lethal dose of venom from producing death, whereas a dose only the 1/500th part of a cubic centimetre smaller would be unable to do so. Further, there is no observable increase of leucocytes when much more than these infinitesimal quantities of antivenene have been administered to an animal.

In view of many of the facts that have to-night been stated, the "resistance of tissues" theory is also untenable. It is opposed, for instance, by the fact that so great a quantity of antivenene as ·42 cc., or nearly ½ of a cubic centimetre per kilogramme is required to prevent death when given thirty minutes before a lethal dose of venom, whereas, for the same dose of venom, only ·0004 cc. or the 1/2500th part of a cubic centimetre, or nearly the 1/000th part of the former dose is sufficient, when it is mixed with the venom before administration, and in circumstances, therefore, which are much less favourable for the production by the antivenene of this supposed increase in the resistance of the tissues.

As I have already pointed out, however, a chemical theory, implying a reaction between antivenene and venom, which results in a neutralisation of the toxic activities of the venom, is entirely compatible with the observed facts.

The experiments which I have described to-night indicate that, with some limitations in the largest quantities, the greater

the quantity of venom that has been introduced into the body in the process of producing protection, the greater is the antivenomous power of the blood-serum, and therefore the larger is the production of the antivenene. While not an actual proof, this circumstance is at the same time in harmony with the supposition that the antivenene may actually be a constituent of the venom itself. The difficulties encountered in the separation by chemical methods of the several constituents of venom are so great, that it is not probable that the only proof or disproof of this supposition will soon be obtained by chemical analysis. Some physiological experiments which I have made seem, however, to go a long way in supplying the demonstration, which in the meantime has not been obtained from chemistry.

With the object of determining, in the first place, if the still disputed statement is correct that serpents' venom is inert, or nearly so, when introduced into the stomach of an animal, cobra venom was administered, in a series of gradually increasing doses, to a cat, until finally it had received a single dose eighty times larger than the minimum-lethal; and to each of six white rats, single doses corresponding to 10, 20, 40, 300, 600, and 1000 times the minimum-lethal, if given by subcutaneous injection. Although no poisonous symptoms were produced in the animals by even the largest of these enormous quantities, it was found that the cat had so far been protected, that it could afterwards receive, by subcutaneous injection, one-and-a-half the minimum-lethal dose of cobra venom, without any other injury than some localised irritation at the seat of injection; and that the white rat, into whose stomach 1000 times the minimum-lethal dose had been introduced by one administration, survived perfectly, when seven days afterwards slightly more than the minimum-lethal dose of venom was injected under the skin.

It was also found that the blood-serum of the cat was definitely antivenomous, and the curious further fact was ascertained that her progeny had acquired protection through the milk supplied by the protected mother, thus supplying a scientific foundation for a half-admitted conviction, expressed by Wendell Holmes throughout his "Romance of Destiny," in regard to the heroine Elsie Venner.

These significant facts have been extended in a number of other experiments on white rats. In one group of experiments, each animal received, by stomach administration, 500 times the minimum-lethal, if given subcutaneously; and, as before, no toxic symptoms were observed. On the day following this administration, three of the animals received subcutaneously one-and-a-half the minimum lethal dose of the same cobra venom, and they all recovered. In one of the other three animals, however, death was caused by this dose, when it was injected only three hours after the stomach administration; in a second, when this dose was injected two days after the stomach administration; and in the third, when nearly twice the minimum-lethal was injected twenty-four hours after the stomach administration.

In a second group of experiments, a dose of cobra venom equivalent to 1000 times the minimum-lethal by subcutaneous injection was introduced into the stomach. On several occasions in which this had been done, an injection under the skin of one-and-a-half the minimum-lethal dose of venom made, in some experiments, two days, and in others three days afterwards, resulted in the recovery of the animals. As was anticipated, this large quantity introduced into the stomach, conferred immunity against only certain lethal doses of venom, and, for each lethal dose capable of being rendered innocuous, only within certain definable intervals of time.

The extraordinary result was thus obtained that serpents' venom introduced into the stomach in large quantity—in a quantity, which if injected under the skin would be sufficient to kill 1000 animals of the same species and weight—while it failed to produce any definite symptoms of poisoning, nevertheless produced complete protection against the lethal effect of doses of venom more than sufficient to kill the animals. There is a probable significance, further, in the general resemblance between the results of these experiments and those already described in which antivenene, and not venom, was introduced into the stomach. The bearing of these facts is obvious upon discussions relating to the production of immunisation against the toxines of diseases and to the origin of the antidotal qualities of the blood-serum used in their treatment. It is difficult to account for them otherwise than by supposing that the venom while in the stomach had been subjected to a process of analysis, by which the constituents which are poisonous had failed to be absorbed into the blood, or had been destroyed in the stomach or upper part of the alimentary canal, while the constituent or constituents which are antivenomous, or rather antidotal, had passed into the blood, in sufficient quantity to protect the animals against otherwise lethal administrations of venom. I confidently anticipate that this natural process of analysis will, by-and-by, be successfully repeated outside of the body by chemical methods.

It is further to be observed that by stomach administrations a degree of protection was acquired in a few hours against lethal doses, such as cannot be attained until after the lapse of several weeks by the method of injecting under the skin a succession of gradually increasing doses of venom. In circumstances, which are no doubt exceptional, the application of this method may therefore acquire some practical value.

Early this evening, I had occasion to point out that the leading facts connected with immunisation or protection, now being advanced as scientific novelties, had apparently been ascertained and practically applied for centuries by savage and uncultured tribes and sects in various parts of the world. In regard to the results I have last described, also, I discover that I have been anticipated by a long-existing and even now prevailing practice of unlearned savages. I have found in the *Lancet* of 1886, an interesting note by Mr. Alford Bolton, containing the following: "The most deadly snakes here are the puff-adders, the yellow cobra capellas, the horn-snakes, and the night-adders. Whilst frequently hearing of horses and cattle rapidly succumbing to the bites of these snakes, it appeared strange that the natives themselves, who mostly ramble about the Veldt almost naked, seldom or never appeared to suffer any further inconvenience from the bites of poisonous snakes than would be usual from any accident which would cause a local inflammation; and, on close inquiry, I found that the natives in Bushmanland, Namaqualand, Dumaraland, and the Kalakari, are in the habit of extracting the poison-gland from the snake immediately it is killed, squeezing it into their mouths, and drinking the secretion, and that they thereby appear to acquire absolute immunity from the effects of snake-bites." He proceeds to describe the native treatment of snake-bite, and then adds: "Having a month ago seen a native named Snellsteve, who is a snake-poison drinker and collector, put his hand into a box containing two yellow cobras, and several horn- and night-adders, in doing which he was severely bitten, and has never since suffered anything more than a little pain, such as might be caused by any trivial mishap, I feel I can no longer refuse to believe in the efficacy of the snake virus itself as a remedy against snake-poison." Among several communications which I have recently received on the subject, is one from Dr. Knobel, of Pretoria, who writes that when a boy he came into frequent association with a Bushman shepherd, who informed him that he had for years been in the habit of swallowing small quantities of the dried venom-glands of serpents, and he averred that by doing so he obtained protection against serpents' bites, for he had often been bitten without any other ill-effect than that an irritable wound was produced. He stated that the swallowed venom of the cobra produced greater protection than the venoms of less poisonous serpents; and that not only was this benefit produced by the swallowing of venom, but that there was also produced an exciting intoxication, differing from that of Indian hemp in so far that the venom always produced the same degree of intoxication with a definite quantity, however frequently it was taken, while the effects of the Indian hemp were gradually lessened by repetition. Another correspondent, Dr. Laurence, of Cape Colony, writes that a Kaffir boy, "aged about twenty-five years, frequently brings me for sale snakes of all kinds. . . . I have frequently seen this boy take hold of some most deadly snakes, especially the well-known puff-adder, which he will allow to bite him with impunity. Yesterday, I obtained from him what he states as the reason why the poison did not harm him. When a little boy, while walking in the Veldt, a puff-adder fastened on his leg. He shook it off, calling to his father, who a few minutes after killed the puff-adder and removed the poison glands. He then made small paper pellets and dipped them in the poison, and administered one occasionally to the boy, who stated that that cured him. He expressed his willingness to let any snake bite him." Several other letters I have received describe similar events, and also confirm the statement of Dr. Knobel, that serpents' venom produces intoxicating effects in man, evidences of which have been observed in many of the experiments made by me on the lower animals.

The results of the experiments in which the venom was introduced into the stomach, probably also afford an explanation of the protection enjoyed by certain snake-charmers, as well as by other individuals who claim to be protected, whether members of special sects or not; for although inoculation of the venom is apparently sometimes practised by them, and protection is no doubt assisted and maintained by the bites, which with impunity they frequently receive, they are known also to swallow the venom or the dried poison-glands containing it.

These experiments also seem to throw a new light upon the clearly established protection possessed by venomous serpents against their own venom. They suggested the importance of determining if the blood-serum of venomous serpents contains, as does that of artificially protected animals, an actual substance possessing antivenomous properties.

In order to arrive at some definite conclusions on this subject, I last year obtained from India several living specimens of the Hamadryad (*Ophiophagus elaps*), a serpent of greater size and more aggressive disposition than the cobra, and reputed to be as deadly as it. From the blood of several of these serpents a serum was separated, which when dried gave a product having the same physical characters as the antivenene from artificially protected animals. It was tested against cobra venom, both when mixed with rather more than a minimum-lethal dose, and also when injected thirty minutes after this lethal dose of cobra venom. In the former case, ·25 cc. per kilogramme of this natural antivenene prevented death; and, indeed, so perfectly antagonised this certainly lethal dose that no decided symptoms of poisoning were manifested. In the latter case, 5 cc. per kilogramme was found to be a sufficient quantity to prevent death. I hope by-and-by to extend these observations by testing the antidotal power of this serum against the venom of the actual Hamadryads from whose blood it had been separated.

A determination of this kind has, however, been made with the blood-serum and venom of the Australian black snake (*Pseudechis porphyriacus*), a deadly serpent whose bite produces intense destructive changes, not only at the place where it has been inflicted, but also in the blood and in many of the organs of the body. When the blood-serum and the venom of this serpent were mixed together outside of the body, and then injected under the skin of a rabbit, it was found that half a cubic centimetre per kilogramme of the blood-serum was sufficient to prevent death from rather more than the minimum-lethal dose of venom.

Notwithstanding the obliging co-operation of the India Office, I have not yet succeeded in obtaining the blood-serum of the cobra, but it may safely be anticipated that it also will be found to possess antivenomous properties.

It has thus been shown that venomous serpents themselves possess a definite substance in the blood-serum which is capable of protecting them against their own venom, and the venom of other serpents. The results of the experiments made by stomach administration of venom, supply at the same time an explanation of one, at least, of the methods by which this substance is introduced into the blood. This natural antivenene, however, is apparently not so powerfully antidotal as the antivenene obtained by the process of artificial protection.

The foregoing statements, although referring mainly to observations on the lower animals, have, probably in every particular, a very direct bearing upon both the prophylaxis and treatment of snake-poisoning in man.

Some little consideration of the details of the application of the antivenene and the employment of auxiliary measures may, however, be serviceable; and, equally of practical service, some consideration of the probable limitations to the capacity of antivenene as an antidote.

In the meantime, I cannot adduce any actual experience of its use in human beings, as although a considerable quantity, both in the liquid and dry state, was last summer sent to India, and a smaller quantity to Africa, no opportunity for using it as an antidote has as yet occurred in the districts to which it had been sent.

But, first, let me say in regard to the altogether unsatisfactory experience of the use of medicines, ordinarily so-called, that I am not prepared to take the extreme position that no good can be done by their employment. While the evidence shows that no one of the very large number of those that have been recommended as antidotes is able, in any conditions of administration, to prevent death after the reception of even the smallest lethal dose of venom, it still may be that, by the physiological effects which they produce, they may assist any efficient antidote, such as antivenene, in preventing death; and also, by prolonging life, increase the opportunity for a more thorough use of this antidote. In this category I would especially place medicines which increase excretion, such as diaphoritics and diuretics; many of the rapidly acting stimulants of the circulation, such as alcohol and the old snake remedy, ammonia; and stimulants of respiration, such as atropine and strychnine, the latter of which is enthusiastically championed by Dr. A. Mueller, of Sydney. And not only medicines, but also any measures that are available for these purposes, including artificial respiration, so distinctly indicated as a probably valuable therapeutical application in snake-bite by Fayrer and Brunton, which, though shown by the Indian Snake Commission to be incapable of preventing death when alone trusted to, was also shown to possess the valuable auxiliary power of prolonging life.

The first measure, however, that is usually and properly taken in the treatment of snake-bite, is to restrict, as far as possible, the absorption of the venom into the blood-vessels, from the place into which it has been injected by the poison-fangs, by separating this part from the more central parts of the body by a tight ligature. The efficiency of this measure, preventive rather than curative, is fortunately aided by the circumstance that snake-bites are most usually inflicted at parts to which a ligature can conveniently be applied; for in fifty-four cases collected by Wall, the part in nearly 89 per cent. of the cases was on the arms or legs. The ligature having been applied, whenever it is possible to do so, the next measure to adopt is to open up with a knife, to a considerable depth, the minute though deep punctures made by the fangs, and then to apply suction to the wound. Justification is found for this procedure in the fact, demonstrated by experiment, that notwithstanding the rapidity with which venom may be absorbed, a portion of it still remains for a considerable time in the tissues immediately surrounding the wound. This has been clearly demonstrated by both Kaufmann and Wall. The suction may be produced by the mouth, and in the absence of more effective apparatus this ready method would be serviceable, while it is attended with danger to the operator only in the infrequent occurrence of fissures or abrasions of the mouth. It is, however, more effectively and without any risk accomplished by a suction pump, such as the most useful pump invented by Mr. Andrew Smith, of Cape Colony, which I now show.

These steps having been taken, antivenene should be injected into the tissues at and near the wound and, also, under the skin above the ligature, and the ligature should not be removed until at least half an hour after a sufficient quantity of antivenene has been injected under the skin above it.

But the important question has yet to be answered, What is a sufficient quantity? The whole tenour of my remarks to-night has been to show how necessary it is to bear in mind that there is a definite relationship between the dose of venom received and the dose of antivenene required to antagonise it, and that this relationship also varies with the conditions of the administration of the antivenene, and, especially, with the interval of time that elapses between the reception of the venom and the administration of the antivenene.

In snake-bite in man it is impossible to estimate the dose of venom which has been injected, for the nature of the symptoms in the patient cannot give the information even approximately. In searching for a solution of this problem, several facts may be taken into consideration from which assistance may be obtained. And, firstly, what is the probable quantity of venom that a serpent injects into a wound? Some data for answering this question have, very kindly, been obtained for me by Brigade-Surgeon Lieut.-Colonel Cunningham, of Calcutta. Taking nine adult cobras, healthy and vigorous, he collected from each the venom ejected at a single bite, dried and weighed each collection separately, and sent me the weights. They are as follows;—

(1) 0·726 gramme.	(6) 0·113 gramme.
(2) 0·262 ,,	(7) 0·239 ,,
(3) 0·115 ,,	(8) 0·306 ,,
(4) 0·144 ,,	(9) 0·253 ,,
(5) 0·132 ,,	

The total venoms yield an average of 0·255 gramme for each bite; but, if the exceptionally large quantity stated in the first figure be excluded, the average for the remaining eight becomes ·195 gramme. It must also be considered that these quantities

were obtained in the most favourable conditions for securing the total quantity ejected at a single bite, whereas in actual practice the conditions are less favourable for the insertion of the total available venom into the tissues of the victim.

Reverting now to determinations of the minimum-lethal dose for the lower animals, we find that if the minimum-lethal dose for the cat be adopted as being the same as that for man, the total quantity of dry cobra-venom required to kill a man of ten stones weight would be ·317 gramme, which is considerably more than the quantity, judging from the above averages, that a cobra is usually able to eject during a single bite. It would therefore appear necessary to assume that the minimum-lethal dose per kilogramme for man is smaller than for a cat; but, as it is probably greater than for a rabbit, we may for convenience assume that it is twice that dose. In this case, the smallest quantity required to produce death in a man of ten stones would be about ·0317 gramme, which, however, seems to be considerably less than the quantity which a fresh cobra has at its disposal. Applying now the facts that have been stated in the series of experiments where the smallest quantity of antivenene required to prevent death when injected thirty minutes after twice the minimum-lethal dose was determined, it will be recollected that that quantity is 5 cc. per kilogramme of animal. Taking this as a basis for the dose of antivenene, in order to prevent death in man from the estimated minimum-lethal dose of cobra-venom, so considerable a quantity as 330 cc., or about 11½ ounces, of antivenene would be required, if the antivenene be injected not much longer than thirty minutes after the bite had been inflicted. This, though a large, is by no means an impossible dose, and it could, without much inconvenience, be introduced under the skin at several parts of the body.

On the other hand, the estimate which I have adopted of the minimum-lethal dose for man may be too high a one, and if it should prove to be nearer that for the rabbit, then the quantity of antivenene required to prevent death, if administered half an hour after the snake-bite, would be reduced to about four ounces. It is also to be recollected that if dry antivenene be used, it may be dissolved in a much smaller quantity of liquid than is required to restore it to its original bulk.

As to the probability, in a fatal snake-bite, of the quantity of venom received by the victim being only about, and not much in excess of, the minimum-lethal dose, it would appear that, in many cases, even so large a dose is not introduced; for general experience indicates that the majority of persons who are bitten actually recover, whatever treatment is adopted. Sir Joseph Fayrer also shows, in his classical "Thanatophidia," that in 64 per cent. of fatal cases of snake-bite in India, the victims survived the infliction of the bite for periods of from three to twenty-four hours; and this duration of life implies that the dose of venom received, could not have been much greater than the minimum-lethal.

It must be admitted, however, that even for the minimum-lethal dose of venom, the quantity of antivenene required to prevent death in man is probably inconveniently large, especially if, in the treatment, reliance is placed solely upon the administration of antivenene, to the exclusion of all or several of the auxiliary measures to which I have referred. It is desirable, also, that the antivenene treatment should be a practical one, not only for doses of venom which do not much exceed the minimum-lethal, but also for the considerably larger doses that are occasionally introduced in snake-bite.

To attain this object, further work is required in order that there may be obtained an antivenene even more powerful than that whose antidotal capabilities I have described.

I am not sanguine that this will be accomplished by carrying to a higher degree the process of artificial protection in animals. A comparison of the antivenene of rabbits which had last received thirty times the minimum-lethal dose of cobra venom with that of other rabbits which had last received fifty times that dose, has shown that the latter has but little antidotal advantage over the former, and has suggested that, in the process of artificial protection, the saturation point of the blood for antivenene is reached before the possible maximum non-fatal dose of venom has been administered.

I would anticipate with more hope the results of endeavours to separate the true antivenomous principles from the inert constituents of the blood-serum with which they are mixed; and although the required chemical manipulations are attended with many difficulties, some success has already been obtained in effecting this separation.

In the foregoing remarks, it has, however, been shown that even with the antivenene whose properties have been described, human life may be saved in a considerable, if not in a large, proportion of the cases of snake-bite, which would otherwise terminate in death. The attainment of this result is a satisfactory one; for the mortality from snake-bite is large, and is not restricted to the 20,000 deaths which annually occur in India, but includes additional thousands in all the tropical and sub-tropical regions of the world.

THOMAS R. FRASER.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Drapers' Company have voted £50 to Mr. Percy Williams, a student at University College, London, towards paying his expenses of post-graduate study. Mr. Williams was placed first in honours in his chosen faculty at the B.Sc. Examination of last year in connection with the London University.

IT is stated that the total subscriptions promised for the new building fund of the University College of South Wales and Monmouthshire amounts to over £16,000. The Treasury has authorised the payment of £10,000 to the building fund, this being half the sum promised by her Majesty's Treasury on condition that £20,000 was collected in South Wales and Monmouthshire by July next.

THE University of Utrecht will celebrate its "260th lustrum" during the month of June next. The occasion will be rendered specially interesting by the *fêtes* which will be given by the students, and which will include their traditional masquerade and an elaborate old world tournament. It is expected that the ancient city will be visited by numerous strangers during the commemoration.

A MUNICIPAL school of science and art was opened at Bideford on Wednesday, April 15. For some time past instruction in science and art has been given with great difficulty in ill-fitted and unsuitable rooms. The cost of the new school will be about £3000, towards which the County Council have contributed £500 (with a promise of £75 towards science apparatus), the Science and Art Department will grant £650, and a penny rate has yielded £700.

WE learn from the *Athenæum* that the Committee of the Aberdeen University Council, which has been considering measures for the extension and better endowment of the university, has issued a report enumerating, "among its more pressing wants," the enlargement of the library, laboratory, and museums, a botanic garden, residential halls for both sexes, seven new professorships, and fifteen lectureships. The report also advises the establishment of an Aberdeen University Association, on the model of the Edinburgh Association.

ON Tuesday, April 14, the Right Hon. Sir William Hart-Dyke visited Bath and opened the northern wing of the new municipal buildings which has been appropriated to the purpose of technical schools. The building, which cost £30,000, was commenced about eighteen months ago, and comprises four floors. The basement consists of workshops and mechanical and electrical laboratories; the ground-floor includes large and small lecture-rooms, and accommodation for the library and lecturers' and director's rooms. The first-floor constitutes the school of art, while the second-floor contains a domestic department and chemical and physical laboratories.

A CONFERERCE on Secondary Education was opened on Tuesday in the Senate House, Cambridge, under the presidency of the Vice-Chancellor of the University. A resolution generally approving of the scheme set forth in the report of the Royal Commission on Secondary Education, and expressing a hope that legislative measures in accordance with that report would be passed, was carried by 128 to 41 votes. A resolution approving the establishment of local authorities for secondary education was also carried, after considerable discussion. Resolutions were subsequently agreed to in favour of the establishment of a separate central authority for secondary education, and of the preservation of the freedom, variety, and elasticity which have hitherto characterised secondary education in England.

THE following are among recent appointments abroad:—Dr. Paul Czermak, *privat-docent* in Physics in Gratz University, to be extraordinary professor; Mr. James Edwin Lough to be

instructor in experimental psychology in Harvard University; Dr. Charles Palache, instructor in mineralogy, and Mr. R. J. Forsythe in metallurgy and metallurgical chemistry; Baron Eötvös to be full professor of experimental physics in the University at Buda-Pesth; Dr. O. Hildebrand to be extraordinary professor of surgery in Berlin University, and Dr. Oestreich to be *privat-docent* in general and anatomical pathology; Dr. Klecki to be *privat-docent* in general and experimental pathology at Cracow.

The new Franco-Scottish Society was inaugurated in Paris last week at the Sorbonne. The objects of the Society are to bring the universities of France and Scotland into connection with each other by study in the one and the other of their respective students, to bring about intercourse between their professors and other officers, to promote historical research concerning the ancient relations between the two countries, in general by periodical meetings held in France and Scotland, and all other means, to renew, as far as possible, the bonds of sympathy between them. About forty delegates attended on behalf of the Scottish universities and interest in higher education; and on the French side, the Paris University and Upper Schools were represented by their chief authorities. Among the subjects discussed was the place of political science in higher education. The congress terminated with a banquet, at which M. Jules Simon presided, given to the Scottish guests by their French colleagues on Saturday.

Referring to the late Mr. George Holt, whose death we briefly announced a fortnight ago, the *Lancet* remarks that he took the greatest interest in University College, Liverpool—an interest substantially shown by his first subscription of £10,000 which was requisite to complete its equipment for incorporation in the Victoria University. It was in its medical school that he took a special interest, and his benefactions to it have been numerous. The chairs of Physiology and Pathology were endowed by him in the amount of £10,000 each, to which was added a further sum of £10,000, for the maintenance of laboratories in those branches of investigation. In addition to these benefactions he presented its medical faculty in 1886 with the sum of £2000 for distribution during the ten succeeding years in tutorial scholarships of the value of £100 each. He further fitted up in a complete manner Ashton Hall as a pathological and bacteriological laboratory, which is one of the most complete of its kind in this country. This does not exhaust the list of his benefactions; a further sum of £1000 was given as a donation to the college library, to be expended in annual instalments of £100. He was also a generous contributor to the maintenance fund of the college and a warm friend of education in general. Indeed, it is probably as a benefactor of University College that his name will live longest in local memory.

The Teacher's Registration Act, which was recently introduced in the House of Commons without comment, is a direct outcome of the work of the late Commission on Secondary Education. Though the Registration Council which it is proposed to establish is not exactly that suggested in the Report of the Commissioners, it will prove quite satisfactory to most of those whose interests are concerned. The Council is to consist of eighteen members—six, appointed by Her Majesty with the advice of her Privy Council; six, elected by the Universities, one by each of the following—Oxford, Cambridge, Durham, London, Victoria, and Wales. Two members chosen by registered teachers engaged otherwise than in elementary schools, two chosen by elementary teachers, and two by registered teachers generally. It is provided by the Act that no person shall be admitted to the register unless he possesses (*a*) "a degree or certificate of general attainments which is granted by some university or other body recognised for that purpose by the Council, and is accepted as satisfactory by the Council; (*b*) a certificate or diploma of adequate knowledge of the theory and practice of education and of practical efficiency in teaching, which is granted by some university or other body recognised for that purpose by the council." Teachers in elementary schools are to be admitted to the register on the same terms as those engaged in secondary schools. It is further to be enacted that if any person (*a*) "wilfully makes or causes to be made any falsification in any matter relating to any register under this Act, or (*b*) by false representation procures himself to be registered under this Act, or not being so registered fraudulently represents himself as being so registered, he shall be guilty of misdemeanour, and shall on summary conviction be liable to be imprisoned with or without hard labour for any term not exceeding twelve months." Teachers of proved attainments and competence who are at present engaged in teaching are to be admitted to the first register.

SCIENTIFIC SERIALS.

The numbers of the *Journal of Botany* for March and April are again almost entirely occupied by descriptive papers.—Mr. G. Murray describes a new species of *Caulerpa* from South Africa. A number of new fungi are described by Mr. G. Massee, including a new genus *Clypeum*, with no near affinities.

The second part of vol. vii. of Cohn's *Beiträge zur Biologie der Pflanzen* contains three papers.—Dr. O. Kirchner describes the root-tubercles of the Soja-bean, which, like those of other plants belonging to the pea-tribe, are caused by a microbe; large quantities are found imbedded in the tissue of the tubercle, and he regards them as belonging to a new species, which he names *Rhizobacterium japonicum*, found in the soil of Japan. As in other cases, the relation of the microbe to the host is a symbiotic one, enabling it to absorb into its tissues the free nitrogen of the atmosphere.—T. Rosen contributes a chapter to his *Beiträge zur Kenntniss der Pflanzen-zellen*, in an account of the nuclei and nucleoles in meristematic and sporogenous tissues. It is a very important contribution to our knowledge of the intricate phenomena connected with cell-division, and of the part played by the nucleus and its nucleoles in the process.—Dr. E. Heinricher describes the structure and function of the haustoria of the parasitic genus *Lathræa* or toothwort, especially of the two species *L. squamaria* and *L. clandestina*. From various points of structure he concludes that *Lathræa* is more nearly allied to the typical *Scrophulariaceæ* through *Rhinanthus*, than it is to the *Orobancheæ*, under which it is usually placed.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 10.—"Helium: a Gaseous Constituent of certain Minerals. Part II. Density." By William Ramsay, F.R.S.

The gas obtained from the minerals bröggerite, samarskite, and fergusonite is rich in hydrogen, but contains only an infinitesimal quantity of nitrogen; carbon dioxide and helium are also evolved, but no gas of new spectrum, even in samples not passed through the usual absorbents, soda-lime and phosphoric anhydride. From 1 gram of clèveite, 7·2 c.c. of helium is obtainable; 1 gram of bröggerite yields less than 1 c.c.; 1 gram of samarskite, about 0·6 c.c.; and 1 gram of fergusonite 1·1 c.c.

The density of the samples of gas from these various minerals appears to show small, but real differences. That from clèveite was found to be 2·205 (oxygen = 16), but Langlet found a sample from the same source to possess the density 2. The helium from bröggerite has the density 2·18; that from samarskite 2·12, and that from fergusonite 2·14. These differences are small; but as they are the means of several determinations with different preparations, and as the individual determinations differ less among themselves than the densities of specimens from different minerals, there appears ground for the supposition that helium is a mixture. The possibility of this conclusion is strengthened by the fact that the relative intensity of the lines in the spectrum of the gas from clèveite is different from that of the samples from bröggerite, samarskite, and fergusonite; and this difference, indeed, is visible without the aid of a spectroscope, for the clèveite gas has a richer shade of yellow, tending towards orange, than that from the other minerals; the colour of such samples is a purer yellow. Moreover, there are certain faint lines in the blue-green in the spectrum of the clèveite gas, which have not been observed, even under the most favourable circumstances, with "end-on" tubes, in that of the gas from other sources.

The author is engaged in an attempt to separate the possible constituents of helium.

"Angular Measurement of Optic Axial Emergences." By William J. Pope.

The ordinary methods of determining the angle, α, between the direction of emergence of an optic axis into air and the normal to the crystal plate, being very inaccurate unless the plate has a highly polished surface, the author has devised a new method by which this angle, α, can be determined to within 2 or 3 minutes of arc. The crystal is mounted in the Fuess axial angle apparatus, and a reading taken for the air emergence of the optic axis; a cell containing oil of known refractive index, μ, is then brought up round the crystal plate, and a new reading taken for the oil emergence of the optic axis. From the difference of the two angular readings, $\alpha - \theta$, the angle α may be calculated from either of the formulæ

$$\cot \alpha = \cot (\alpha - \theta) - 1/\mu \sin (\alpha - \theta)$$

or

$$\tan (\alpha + \theta)/2 = \mu + 1/\mu - 1 \tan (\alpha - \theta)/2.$$

Series of test measurements are given, proving the efficacy of the method; when α is 53° 24′, and μ is 1 6473, the measured value of $\alpha - \theta$ is 24° 15′, a fairly large angle. Oil of the highest attainable index of refraction should be used in order to obtain maximum values of $\alpha - \theta$; the refractive indices are conveniently determined by aid of the Pulfrich total-refractometer.

March 26.—"Additional Report on Erect Trees containing Animal Remains in the Coal Formation of Nova Scotia." By Sir J. William Dawson, F.R.S.

Linnean Society, April 2.—Mr. J. G. Baker, F.R.S., Vice-President in the chair.—On behalf of Dr. F. Arnold, of Munich, the Secretary exhibited several photographs of typical lichens, received in continuation of a series which has been for some time past in course of issue by that well-known lichenologist.—Mr. M. F. Woodward exhibited a very young example of the "Spiny Ant-eater," *Echidna aculeata*, taken from the mammary pouch of the parent at Newcastle, Western Australia, by Mr. H. B. Woodward, Curator of the Perth Museum. It was intermediate in size between two stages described by Prof. Parker, but showed no trace of the calcaneal spur characteristic of the male, nor any trace of the mammary pouch peculiar to the female. He called attention to the flattened and beak-like character of the snout and the vestiges of the "egg-breaker," and to the disposition of the spine papillæ. For the purpose of comparison, Mr. Woodward exhibited also the heads of *Ornithorhynchus* and *Echidna*, and a male and female mammary fœtus of *Perameles*.—A paper was read by Mr. C. H. Wright, "On the Genus *Stemona*, Lour.," one of the few monocotyledonous genera whose flowers are constructed on a tetramerous type, and remarkable for the diversity of its vegetative characters, while its floral structure varies between comparatively narrow limits.—Lieut.-Colonel C. T. Bingham, in a paper on some exotic fossorial Hymenoptera in the British Museum (communicated on his behalf by Mr. W. F. Kirby), enumerated thirty-four species, of which no less than thirty were previously undescribed. The discovery of many of these was due to the researches of the author, who had spent twelve years collecting in Sikkim, Burma, and Tenasserim.—The President then gave a descriptive account of the Khasia Hills from personal experience, dwelling on their geological formation, the extraordinary rainfall of the district (120 inches in five days), and the chief characteristic features of the flora and fauna.

Royal Meteorological Society, April 15.—Mr. E. Mawley, President, in the chair.—Mr. W. Ellis, F.R.S., read a paper on the mean amount of cloud on each day of the year at the Royal Observatory, Greenwich, on the average of the fifty years 1841–90, in which he showed that a principal maximum occurs in winter and a principal minimum in autumn, with a secondary much less pronounced maximum in summer and a secondary minimum in spring. There is, however, considerable irregularity in the succession of daily values, the differences between which on consecutive days are in numerous cases relatively large. Cloudless days are most numerous in spring and autumn, and least so in winter and summer; days of little cloud are somewhat less numerous in winter as compared with other parts of the year, whilst days of medium cloud are much more numerous in summer than in winter. Days of much cloud are nearly equal in amount in all parts of the year; whilst overcast days are much more numerous and nearly equal in amount in the first and fourth quarters of the year, much less numerous in the second quarter, and again less numerous in the third quarter.—Mr. E. D. Fridlander gave an account of some observations of the amount of dust in the atmosphere made at various places during a voyage round the world in 1894–95. The experiments, which were made with a form of Aitken's pocket dust counter, showed that there are often considerable variations in the number of dust particles in a very short space of time. Not only did dust occur in the air of inhabited countries, over the water surfaces immediately adjoining them, and up to an altitude of 6000 or 7000 feet amongst the Alps, but it was also found in the open ocean, and that so far away from any land as to preclude the possibility of artificial pollution, and its existence has been directly demonstrated at a height of more than 13,000 feet.—Major H. E. Rawson gave an analysis of the Greenwich rainfall records from 1879 to 1890, with special reference to the declination of the sun and moon.

EDINBURGH.

Royal Society, April 6.—Rev. Prof. Flint in the chair.—A communication by Drs. Stewart and Young, of the Public Health Laboratory, Edinburgh University, on the bacteria in milk as supplied in Edinburgh, and the relative efficiency of different methods for their removal, was read by the former. Since 1894, samples of milk from dairies all over the town had been examined, and it was found that bacteria were most numerous between July and October. The milk from dairies with cowhouses in town contained, five hours after milking, more than eight times the number of micro-organisms in milk from dairies supplied from the country. Methods for sterilising were described, but each imparted a boiled taste to the milk. Scalding, at 176° F., would keep the milk sterile for twenty-four hours if great care were taken, but when performed on a large scale there could be no guarantee, owing to possible post-scalding contamination, that the bacillus of tubercle and diphtheria were not present.—Dr. J. Macintyre, Glasgow, indicated some new results which he had got with the Röntgen X-rays. He described his methods for reducing exposure and obtaining definition, and exhibited photographs of different parts of the skeleton of the living subject. Among these were that of one side of the head, obtained by putting the tube so near the other side that its image was eliminated, the sternum and ribs, and the vertebral column with scapula and clavicle. Dr. Macintyre described screens of different kinds which he had made, of which the one saturated with barium platinocyanide was the best. He suggested the use in surgery of fluorescent screens for the cavities, such as the mouth, throat, and maxillary antrum, and exhibited the result of an attempt at photographing tissue. In the kidney, from a cadaver shown, the distinctive in structure of the different parts, and the presence of a calculus, were quite apparent.—Dr. W. G. Aitchison Robertson read a summary of an investigation regarding the digestion of starch in the stomach. He showed under what conditions, normal and abnormal, amylolysis ceases in the stomach, and the effect which the gastric secretion has on the ferment ptyalin.—A communication from Lord Kelvin on impulsive fluid motion was held as read.

PARIS.

Academy of Sciences, April 15.—M. A. Cornu in the chair.—On fallow ground, by M. P. P. Dehérain. The ancient practice of allowing land to lie a year fallow after three years cultivation is shown to have rested upon a sound basis, the land increasing considerably in nitric nitrogen during the fallow year. With modern manures the necessity for this no longer exists, although the practice still survives in many parts of Europe.—Nitrates in spring water, by M. T. Schlœsing.—On a letter from Gauss, of date June 16, 1805, by M. de Jonquières. The letter was written to M. Delisle, Professor of Mathematics at Orleans.—On the products of combustion of an acetylene burner. Explosive mixtures of acetylene and air, by M. N. Gréhant. The combustion of acetylene in an ordinary fish-tail burner is complete, the products not comprising the least trace of a combustible gas containing carbon. With mixtures of acetylene and air the most violent explosion was produced when the volume of air was nine times that of the acetylene.—On certain classes of Laplacian equations with equal invariants, by M. A. Thybaut.—Verification of Kerr's law in absolute measure, by M. Jules Lemoine. By the use of a condenser having carbon disulphide as the dielectric, with potentials varying from 5000

to 35,000 volts, Kerr's law was found to be correct to within at least 1 per cent. The absolute value of the constant for carbon bisulphide is $3 \cdot 7 \times 10^{-7}$.—On electrified Röntgen rays, by M. A. Lafay. A verification of results previously published. It was found that it was a matter of indifference, in deviating the Röntgen rays, whether they were electrified before or after traversing the magnetic field.—The action of the Röntgen rays upon double and triple electric layers, by M. N. Piltschikoff. The rays discharge the double electric layer very slowly, if at all.—On the mechanical action emanating from Crookes' tubes, by MM. A. Fontana and A. Umani. A claim for priority.—Application of photography by the Röntgen rays to analytical researches on vegetable materials, by M. F. Ranwez. The adulteration of vegetable products with mineral substances, such as saffron with barium sulphate, is readily detected by the differences in the shadows cast by the X-rays.—On homolinalool and on the constitution of licareol and licarhodol, by MM. Ph. Barbier and L. Bouveault.—Action of the sodio-cyanacetates of propyl, butyl, and amyl upon diazobenzene chloride, by M. G. Favrel. The hydrazones obtained exist in two isomeric modifications, distinguishable by their melting points.—On the diurnal lunar wave and on the secular variation of the barometer, by M. P. Garrigou-Lagrange. The action of the moon on the atmosphere is well marked. On the tenth parallel of latitude, the waves caused by the moon may amount to 1·2 mm. of mercury.—On the principal results of the last ascent to a great height of the balloon *Aerophile* (March 22 1895), by MM. G. Hermite and G. Besançon. At a height of eight and a half miles the minimum temperature recorded was $-63°$ C., or a fall of $1°$ per ·597 feet.—Animal temperatures in the problems of evolution, by M. Quinton. The temperatures prevailing on the globe in the remote past were higher than at present, owing to the gradual cooling of the globe. An animal whose life process was in equilibrium with a given temperature when the temperature commences to fall, must do one of two things—either adapt its chemical and physiological changes to the surrounding temperature, as in the case of the pepsin of a reptile, which will act on a food at temperatures near 0°, or may tend to artificially maintain the temperature of the body, by developing heat. Thus in one group of animals, whose evolution had ceased before appreciable cooling had set in, the greater the antiquity the smaller ought to be their power of developing heat. With animals, on the contrary, whose evolution had been prolonged into the cold ages, the reverse would be the case, the body temperature being the lower, the older the animals. Experimental figures confirm these theoretical reductions.

Berlin.

Physical Society, March 13.—Prof. von Bezold, President, in the chair.—Dr. Lindau, of Munich, spoke on the cooling of gases during their adiabatic expansion, and showed that from this the specific heat of the gases may be determined. In opposition to this view Prof. Planck pointed out that the cooling does not depend solely on specific heat, but also on the extent to which the gas differs from the condition of a perfect gas.—Dr. Orlich demonstrated how every phasic variation of alternating currents may be shown by means of two of Rubens' vibration-galvanometers placed at right-angles to each other. He intends to carry out further experiments in order to see whether the variations are measurable by this method.—Prof. A. König made a communication on the absorption spectra of visual purple from various vertebrates, and on visual yellow, which he had only once been able to investigate as obtained from the visual purple of a human retina, whereas the visual purple of other vertebrates never yielded visual yellow. He hoped to be able to control this single observation, should the chance of so doing present itself.

March 27.—Prof Warburg, President, in the chair.—Mr. Archenholz reported on his experiments with a view to testing the statements of Le Bon as to black light. He showed how great is the difficulty of completely excluding all lateral light even by using metallic screens, and exhibited photographs in support of this, and came finally to the conclusion that Le Bon's black light is merely a false light. Experiments made with Balmain's material on the permeability of wood and metal by phosphorescent rays were similarly negative.—Prof. Goldstein spoke on the means for increasing the intensity of Röntgen X-rays, of which he mentioned two. The first consists in using the rays which are emitted forwards by the phosphorescent substances, since they are much more intense than those that have passed through the substances. The second consists in the employment of potassium platinocyanide, which emits a blue light acting very rapidly on photographic plates. Further, a plate had recently been prepared by Siemens and Halske, which gives a clear image of the hand in a few seconds by Röntgen's rays, and finally Kahlbaum has prepared a barium platinocyanide which similarly materially shortens the necessary exposure.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—The Treatment of Phthisis: Dr. A. Ransome (Smith, Elder).—Handbook for the Bio-chemical Laboratory: Prof. J. A. Mandel (Chapman).—A Compendium of General Botany: Dr. M. Westermaier (Chapman).—Modern Stone-Cutting and Masonry: J. S. Siebert and F C. Biggin (Chapman).—Meteorological Observations made at the Adelaide Observatory, &c., 1891, 1892, 1893 (Adelaide).—The Water Supply of the City of New York, 1658-1895: E. Wegmann (Chapman).—The U.S. Public Works: Captain W. M. Black (Chapman).—Cholera in Indian Cantonments, and how to deal with it: E. H. Hankin (Cambridge, Deighton).—James Clerk Maxwell and Modern Physics: R. T. Glazebrook (Cassell).—An Elementary Treatise on the Calculus for Engineering Students: J. Graham (Spon).—Les Tramways: R. Seguela (Paris, Gauthier-Villars).—Astronomie, Astrophysique, Géodésie, Topographie et Photogrammétrie: G. Towne, 2 Vols. (Paris, Bertaux).

Pamphlets.—Medical Inspection of, and Physical Education in, Schools: C. Roberts (Bale).—Weitere Ausführungen über den Bau der Cyanophyceen und Bacterien: Prof. O. THURSDAY, APRIL 30, 1896.

THE INTELLECTUAL RISE IN ELECTRICITY.

The Intellectual Rise in Electricity: a History. By Park Benjamin, Ph.D., LL.B., Member of the American Institute of Electrical Engineers. Pp. (with index) 611. (London: Longmans, Green, and Co., 1895.)

SINCE the days of the distinguished Joseph Priestley, no physicist has ventured to give us series of lessons on the history of the origin and progress of electrical science. In a large and admirable volume entitled "Priestley on Electricity" the author of it tried to introduce everything that was known up to his own time, and he is a poor electrician who is not fully conversant with this gigantic labour. At last another author has risen who has undertaken to supplement preceding authors, and to put before the world in one volume the subject of "the evolution of electricity"; that is to say, to describe the history of electrical science from its origin up to the present day. The author who has undertaken this task is Dr. Park Benjamin, LL.B., a writer from the other side of the Atlantic, who, it must be said, has made himself fairly acquainted with the many electricians who have preceded him, and who makes an excellent effort to instruct the world at large by bringing into what may be called a nutshell the many pieces of information which he has been able to collect and put together in a readable form. The work is a large octavo, and consists of 611 pages, the whole being written in a style which is as commendable to the general scholar as to the particular electrician. The greatest care has been taken, step by step, to supply such illustrations as shall make the text comparatively easy. There are also portraits of men who have been engaged in the practical work of electricity; and although we would not compare the book with that written by Priestley, we must candidly say of it that all teachers, especially physical teachers, are certain to be benefited by its perusal and intimate study.

Like preceding writers, Dr. Park Benjamin, in tracing back the history of electricity, believes that in the dawn of civilisation the discovery of the force was connected with the substance commonly known as amber. The discovery of beads in the royal tombs of the Mycenæ, and at various places throughout Sardinia and the ancient territory of Etruria, proves, he says, that trade in amber existed in prehistoric times; while the identity in chemical constitution of the ornaments at Mycenæ and the Baltic amber from the tertiary formation of the Prussian Samland, the coasts of Southern Sweden, and the Northern Russian provinces, indicate the far distant source from which the resin was anciently derived. Who first brought the resin from the Baltic Sea to the Levant is an undetermined question, as it is known to have come across Europe by land as well as round the continent by water.

Giving full credit to the Phœnicians for their enterprise, and with speculations as to the mode in which amber may have travelled after its properties were first discovered, Dr. Benjamin proceeds to consider the magnet, or lodestone, and explains that the phenomena of the lodestone are two-fold: it not only attracts iron objects, but it has its polarity, or in other words exhibits its opposite effects at opposite ends, by reason of which, when in elongated form and supported so as easily to turn, it will place itself nearly in the line of a meridian of the earth, that is to say in a north and south direction. This is its attractive tendency, or as William Gilbert called it in 1600, its "verticity," and upon this duality, as is well known, depends the use of the magnetic needle in the mariners' compass. In the close of Chapter I., in which reference is specially made to the magnet and to iron as the substance upon which it acts, there is a short but sound notice of history collected from Jewish and Egyptian writers, which, though not strikingly convincing, is of unquestionable interest.

Getting lower down, Dr. Benjamin, as a matter of course, quotes Thales, who many suppose to have been the first man in the electrical field—though he lived before Christ—who understood the phenomena of magnetic attraction, on which point Dr. Benjamin remarks:

> "It must be admitted that even if Thales had been cognisant of the amber phenomenon—that is to say, the effects of rubbing amber and presenting it, in the excited state, to the bits of straw which it attracts—it was not logically necessary, from his point of view, to include it specifically under his theory based upon the attraction of the lodestone, and hence lack of mention does, on his part, not imply lack of knowledge."

Wading through pages of matter touching largely on the Chinese origin of the compass and knowledge of the Chinese in regard to the lodestone, Benjamin asserts that no recorded evidence of the attraction of the magnet or amber appears in the Chinese books of earlier date than the fourth century of our era. He follows up scientific records from the decline of the divine school of Alexandria, which followed the period of the Ptolemies, and explains that through the earlier centuries of the Christian era we find the problem dealt with again and again, sometimes purely physically, more often metaphorically; sometimes by the poets, but with greater frequency by the fathers and historians of the Church. He quotes St. Augustine on the attraction of the magnet.

> "I was thunderstruck ('vehementer inhorrui'). I saw an iron ring attracted and suspended by the stone (lodestone), and then, as if it had communicated its own property to the iron it had attracted and had made it a substance like itself, this ring was put near another and lifted it up; and as the first ring clung to the magnet so did the second ring cling to the first. A third and fourth were similarly added, so that there hung from the stone a kind of chain of rings with their hoops connected, not interlinking, but attached together by their outer surface."

Gliding along and touching on the voyages of the Northmen and the scientific writings of the Anglo-Saxons, the works of William Appulus, the Anglo-Norman magnetic knowledge, the labours of Alexander of St. Albans (Alexander Neckham), the contemporary of Richard of England, son of Henry II., Dr. Benjamin puts before us the first mariners' compass; touches on the penalty for falsifying the compass, and taking up numerous statements and stories in relation not only to

magnetic phenomena, but to the men who studied them, including the discovery of variation by Columbus, the reasonings of Paracelsus as a speculator, and the work of physicians as discoverers, he brings us at last, as a necessity, to one of our first great Englishmen, William Gilbert of Colchester. He gives a little sketch of the life of William Gilbert, puts him down amongst the Fellows of the Royal College of Physicians, and states that he began to practise in London, establishing himself in a house on St. Peter's Hill, between Upper Thames Street and Little Knightrider Street. There Gilbert became a famous man, and, as we know, became physician to Queen Elizabeth, and was, it is said, the only man to whom she left a legacy. To Gilbert, Benjamin gives, naturally, a warm introduction and note of praise, and to Gilbert's original work, "De Magnete," he assigns as much credit as could be given by any one of the members of the new society founded in honour of his name, and which wishes to establish a monument to him in his native city. He also notes Gilbert's doctrine on the subject of the magnet, with his own criticism thereupon. Gilbert seems to urge, that the direction in space is such that the north pole of the earth constantly regards the pole star, so that if that pole were turned aside from this steadfast position it would go back thereto, from which it is apparent, says Benjamin, "that this doctrine rests upon the conclusion that the earth itself is a freely movable magnet, having poles, and amenable to the same laws as the compass needle."

Gilbert is capable of many errors which Dr. Benjamin is not slow to detect; while he makes, we must admit, a very fair and just statement or analysis of the work of Gilbert, supplying plates from his "De Magnete," and is very fair in reviewing the revelations of Bacon, who recognised Gilbert's eminence as a philosopher and discoverer.

All this is extremely interesting, and a grand introduction to the science of electricity as connected with the magnet, and when we get into the account of the way in which electric action and the discovery of electric propulsion, especially in reference to the discoveries of Cabæus on the magnetic spectrum, with Descartes' observations on the magnetic field, we arrive at the definite origin of electricity amongst English philosophers and their colleagues, of many of whom Dr. Benjamin has not the same knowledge, or, at all events, does not show the same sympathies as we ourselves do. We do not all consider, although his father was executed, that Sir Kenelm Digby, for instance, was an adventurer, conspirator, naval commander, and diplomatist, as well as man of science; neither do we take the same view of Sir Thomas Browne that our author seems to have taken, while, when we come to his description of Stephen Gray, we are forced to differ from him, in regard to his estimate of him, very sincerely. According to our own view, electricity was altogether chaotic as a science until this Charter House pensioner, Stephen Gray, appeared before the world, and revealed himself through the Royal Society. It was he who discovered conduction, induction, insulation, and minor thunder and lightning, and, indeed, almost all the basic facts, without which electricity could never have become a true science.

The story about Stephen Gray is fairly told, but it is far from complete, and should have tallied better with Emerson's sentence which the author has inserted on his title-page.

"Not the fact, but so much of man as is in the fact."

Gray, indeed, was himself an evolution, small though he may seem to have been to his contemporaries, and with them was, perhaps, petulant. He was just as great as Gilbert, and in any work on electricity deserves to be put on a level with him. It was he who first truly set up the electric telegraph, and, actually, between two and three hundred years ago, sent messages by it over ground which is still laid out in the front of an old mansion, Otterden Manor, near to Faversham. It was he who died relating to Mortimer, the Secretary of the Royal Society, his conviction that there was such a thing as an electric planetarium in the universe, and it is to him and his labours that we now owe the electric light which so brilliantly illuminates our darkness.

As we glance through the copious index with which this volume is concluded, and see name after name written down, for our edification, of men who have been engaged in electrical pursuits, the temptation is very great to follow Dr. Benjamin step by step, and to inquire on what ground some men are named at length, while others—Cavallo and Fowler, for example, are omitted altogether. We are not surprised that he dwells so long and favourably on one of his own countrymen, Franklin, whom we in England do not certainly ignore, and whose electrical knowledge is probably spoken of with an enthusiasm which few electricians have received. We do not object to the admirable picture of Franklin seated at his studies, which is given to us as a prelude to the sixteenth chapter, but we do regret that there should be any omissions of other men equally careful as Franklin, equally industrious, and quite as original; but we would not be severe with an author who has natural predilections, like all of us, and who is never wanting in industry. We would rather look over every omission and every possible error, and we commend our readers to place Dr. Benjamin's volume on their shelves as a book of electrical philosophy which cannot be too often read or too seriously studied.

It has for many long years past been felt by the teacher of electrical science, and we may add, by the learner also, that the course cannot be considered complete which does not include the beginnings as well as the endings of electrical advances. It is too often felt by those who teach, that it is necessary to deal solely with what is actually going on, and we must admit that when a professor stands at the lecture table with all the modern apparatus before him, and with the hosts of modern facts at his direct command, facts which he is anxious to illustrate and demonstrate, the temptation is great for him to confine himself to the subject immediately before him, and to show how, out of simple principles, he can explain some new and important truth or line of practice. At the same time he rarely ventures on this path without omitting, in the strangest way, a great deal of that wonderful past which Dr. Benjamin has made such fine attempts to describe. Of all words, again, we like the title he has chosen—evolution. "Evolution" is as applicable to electricity as it is to man himself, and, to be

quite sincere, it must be admitted that every detail in respect to electrical developments is an evolution. It is in this way that electricity has progressed and will continue to progress, that is to say, on the bare data propounded by one man another will proceed. The one will modify experiment; will get an advanced result, and from his result the next man will take up the parable and will progress. Thus, though there may be a thousand discoveries in electricity, there will never be one prophecy; and if Dr. Benjamin's book exposes this startling truth, it has performed a duty which probably its author did not expect of it, and for which the world will be grateful.

ARTIFICIAL COLOURING MATTERS.

Traité des Matières Colorantes organiques artificielles, de leur préparation industrielle et de leurs applications. Par Léon Lefêvre. Two vols. Pp. xx + 1648. (Paris: G. Masson, 1896.)

IN the early days of the coal-tar colour industry the French chemists, Coupier, Lauth, Girard and De Laire, and others did good work in the way of investigation, and certain standard books of reference which were indispensable in their time bore the names of French authors. Then the centre of activity in this field seems to have been shifted to Germany, and for some years we have been accustomed to look to that country for new discoveries and authoritative treatises. The author of the work now under consideration, M. Léon Lefêvre, who is "Préparateur de Chimie" in the École Polytechnique, has once again set the current of coal-tar literature flowing in France, and he is to be congratulated on having produced a treatise which may, without exaggeration, be described as the most comprehensive that we have at present in any language. The two bulky volumes under notice cover the ground occupied by several distinct German works; for not only is the subject dealt with in its purely chemical aspect, but the methods of production on the large scale, and the modes of application of the various colouring matters are likewise given in detail. It is impossible in these columns to give a critical review of a technical work of this magnitude, but a general statement of the method of treatment will enable those who are interested in the subject to form an idea of the extent to which they are indebted to M. Lefêvre.

The colouring matters are classified into groups in accordance with the scheme originally adopted by Nietzki, and now familiar to all chemists who are acquainted with this branch of their science. Each group commences with a preliminary statement setting forth the history, general characters and constitutional formulæ of the compounds dealt with; then follows the description of the individual colouring matters, and afterwards a tabular summary of the whole group, from which can be seen at one glance the mode of preparation, the formula, the commercial name, the appearance and properties, and the references to the literature, patent or otherwise. Following these extremely valuable tables, there is a section on the technique, *i.e.* the method of manufacture, the processes being described in sufficient detail to be of value to technologists, and the plant being figured by well-executed cuts. The reader having thus been led up from the history of the discovery of the colouring matters to their production on the large scale by the latest and most approved methods, is then let into the mystery of the dyer's art, and is given explicit directions how each colouring matter should be applied as a tinctorial agent. With each group there is also associated a tabular scheme of the diagnostic reactions of the colouring matters on the fibre, a list of bibliographical references, and lists of patents.

It does not often fall to the lot of the reviewer of a technical work to be raised to an enthusiastic state of mind by the treatise which has been submitted to his judgment; but in the present case, it was certainly with something akin to enthusiasm that we turned over the pages of M. Lefêvre's luxurious volumes. The synopsis of the mode of treatment which we have attempted to give will show that in one work we now have the chemistry of the coal-tar colouring matters on the lines adopted by Schultz in his well-known treatise of 1887–90, the tabular synopses made familiar by the tables of Schultz and Julius, edited by Green in 1894, the technique of manufacture for which we have had to refer to such works as that by Mühlhäuser, the tinctorial characters and modes of application for which we have been in the habit of consulting special treatises on dyeing and printing, and lastly, the diagnostic reactions which are generally looked up in some work on proximate organic analysis. To say that the author has covered all this ground in a perfectly faultless manner would be to attribute to him superhuman faculties; but, with the exception of a few doubtful statements of history, we are bound to say that no serious flaw is to be found in the 1648 pages composing the work. The dyed and printed patterns on wool, silk, leather and paper, of which there are over 260 specimens, make the volumes somewhat ungainly, and would perhaps have been better collected together into a distinct supplementary volume. The thirty-one illustrations of plant are executed with that clearness for which our French colleagues are so justly celebrated, but, as is so generally the case, they suffer from the defect of having no scale of size attached. The structural formulæ occupy a very much larger amount of space than we are accustomed to here, owing to the free use of the benzene hexagon, but this is a matter of luxury and not a point for critical complaint; it must, however, have added considerably to the cost of printing.

The work is introduced to the public by a preface from the pen of M. Edouard Grimaux, Membre de l'Institut, who at the close of his remarks says:—

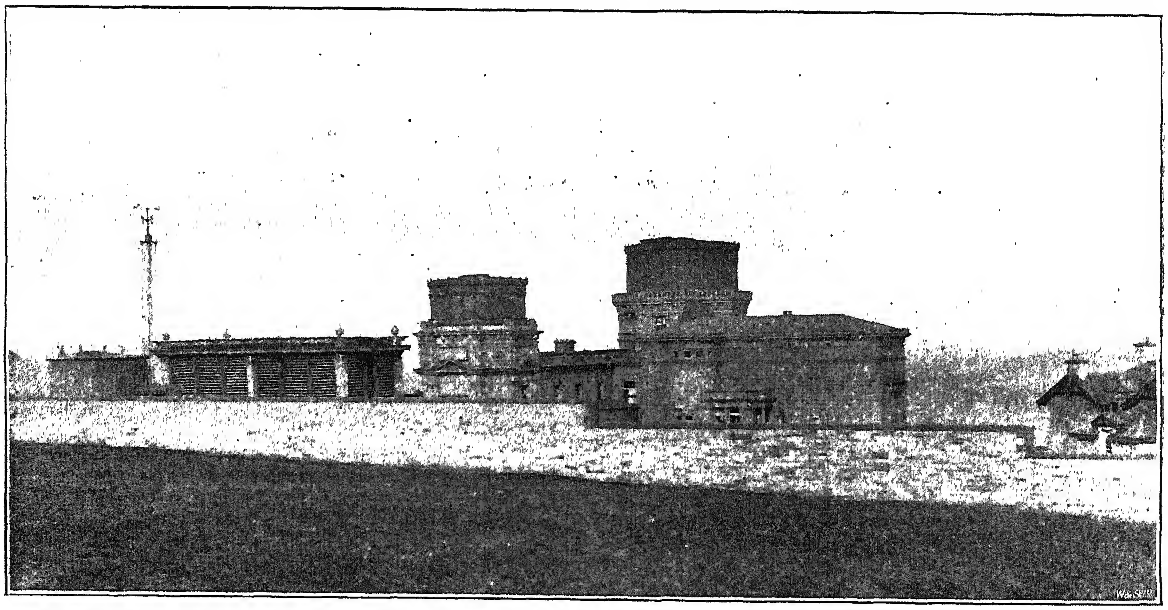
"En raison de l'intérêt que je porte à l'auteur, mon fidèle compagnon de laboratoire depuis dix années, il me serait difficile de faire l'éloge de son livre et de dire tout le bien que j'en pense; mais j'ai vu naître et continuer cet ouvrage sous mes yeux, et je puis témoigner de la conscience avec laquelle il a été fait; j'ai tout lieu d'espérer qu'il recevra du public savant l'accueil qu'il mérite."

The commendation which M. Grimaux modestly withholds may be supplied by this notice; and in directing the attention of English chemists to M. Lefêvre's treatise, we have not the least hesitation in stating that the author has succeeded in producing a coal-tar classic which must take precedence over every other work on the subject.

R. MELDOLA.

research, for which purpose a siderostat by Foucault, with a silvered mirror 16·3 inches in diameter, is mounted at the northern edge of the platform under a movable cover. Arrangements have, of course, been provided for darkening this room at pleasure. In the north wall of the room, and facing the siderostat, is fixed a massive iron frame capable of carrying lenses ranging from the 15-inch object-glass down to that of an ordinary camera, the lenses most frequently used being provided with adjustable rings so arranged that they need only be centred once for all. For 39 feet of the length of the room three lines of rails are let into the floor, on which travel three iron carriages for the spectroscopes, gratings, or cameras in use, the side rails being intended for apparatus to receive deviated rays. In addition to these a narrow gauge line runs along the centre of the room from end to end, 66 feet. This is intended for long-focus photographs. All these rails are carried by steel beams distinct from those which support the floor. Any one who has been at Dunecht will recollect the comfort with which the most delicate solar work could be carried out in the optical room there, of which the room at Edinburgh is a copy.

In the east tower is mounted the 15-inch Dunecht refractor. Amongst the adjuncts to this instrument may be mentioned the large stellar spectroscope made by T. Cooke and Sons (Fig. 2). As this spectroscope has not yet been described, the following particulars may be of interest. It is provided with three prisms: (1) one of 60° by the makers, giving a dispersion of 5° 7′ from A to H, and capable of separating the lines 488·81 and 488·84 of Angström's map. It shows also 43 lines between B and C. It was with this prism that D_3 and another helium line, 487·6 mmm. ±, were detected in the Great Nebula of Orion at Dunecht in the winter of 1886–87 (see *Monthly Notices*, vol. xlviii. p. 360). (2) A large compound prism by Sir H. Grubb, with nearly twice the dispersion of the prism first mentioned. (3) A Merz prism with an angle of 20°, intended for use on the fainter stars. The collimator has a focal length of 24 inches, and an aperture of 2 inches, the ratio being 12 to 1, the same as that of the 15-inch refractor. The viewing telescope is somewhat larger in aperture, to ensure catching the whole of the rays emerging from the prism. The tube of the collimator is made as rigid as possible, and is isolated from the large bronze tube which carries the whole spectroscope. The rays from the great object-glass may be intercepted, just in front of the slit, by a diagonal eye-piece, removable at pleasure, which allows the object to be viewed, and serves also as a finder. Attached to the same draw-tube is a second prism for throwing the light from any artificial source upon the slit. Only one prism can be used at a time, but it can be readily exchanged for another, without disturbing the adjustments. The prism is carried by a divided circle, so that its exact position is always known. The long rod shown in the figure rotates the prism; the shorter one moves the viewing telescope, the position of which may be read either by two opposite microscopes, or by a long reading microscope (not visible in the figure), carried close down to the observer's eye. The pointer in the field of view is illuminated by monochromatic light of any desired colour or intensity, produced by a small direct-vision spectroscope, on the plan devised by Prof. Smyth. No detail has been omitted that could contribute to the accuracy of the observations, such as focusing scales for collimator and viewing telescopes, eclipsing screens in the field of view as well as in front of the slit. A thermometer shows the temperature of the inside of the prism box. It will be seen from Fig. 2 that measures can be made on either side of the axial line by simply turning the viewing telescope and rotating the prism into the proper position.



6 in Refractor. Transit House. 24-inch Reflector. Siderostat. 12-inch Reflector. 15-inch Refractor. Optical Room. Library.

Fig. 1.—Royal Observatory, Edinburgh, from the South-west.

It would be scarcely possible to enumerate the various minor instruments, but the following may be mentioned. Two heliostats by Duboscq and Browning; photo-measuring instrument by Grubb; dividing engine by Dumoulin Froment, of 64 cm. range, showing the thousandth part of a millimetre; delicate Oertling balance and weights; standard mètre à 0° by Dumoulin Froment; standard yard by Simms; two excellent spherometers by

Hilger; Foucault apparatus for measuring the velocity of light; Ladd polariscope with large collection of crystals; two extra large Nicols; anemograph, King's barograph, and standard barometer by Casella; resistance coils, large electro-magnet and a great variety of electric and physical apparatus, including one of Prof. Rowland's magnificent gratings. Among the smaller telescopes are:

12-inch reflector by Browning-With,
6-inch refractor by Dallmeyer,
6 " " " T. Cooke and Sons,
4 " " " " "
3 " " " " "

All the foregoing are equatorially mounted with clockwork, and there is an object-glass prism by Merz, which fits either of the 6-inch telescopes.

A 4-inch reversible transit by Cooke and Sons, with stand for both the meridian and prime vertical, is mounted in a detached hut.

A Zöllner's astrophotometer, a 12-inch altazimuth by Simms, a variety of theodolites, sextants, reflecting

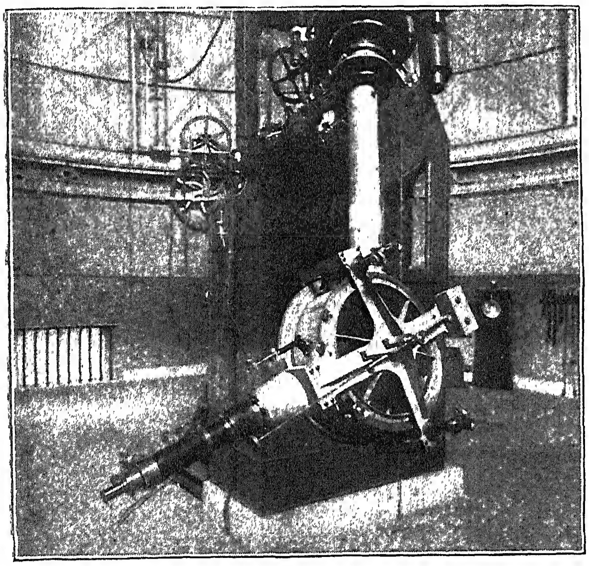


FIG. 2.—Stellar Spectroscope, by T. Cooke and Sons, attached to the 15-inch Dunecht Refractor. (The divided circle is 18 inches in diameter.)

circles, cameras, spectroscopes, and prisms from $4\frac{1}{2}$ inches downwards, complete the outfit for work at the observatory and on expeditions.

A word must be said about the clocks. Two of these, the Dunecht sidereal clock by Frodsham, and the excellent Makdougall-Brisbane clock by Dent, from Calton Hill, are mounted in the base of the pier of the larger tower, shut in by thick double doors stuffed with "slag-wool." This guarantees a nearly uniform temperature for both clocks, while the Brisbane timekeeper has the further advantage of being subjected to a uniform barometric pressure of 25 inches maintained inside a cast-iron case. This latter part of the arrangement has been most efficiently carried out by Messrs. Jas. Ritchie and Son, of Edinburgh. Automatic signals from this chamber serve to rate the mean time clock, which is kept to Greenwich time, and transmits currents to Edinburgh and Dundee for regulating the time signals.

The 8·6-inch transit circle by Troughton and Simms, formerly at Dunecht, is mounted in a detached double iron house 80 feet west of the observatory, with which it is connected by a covered way. It has two finely-divided circles—one of them movable. North and south of the instrument, but in the same room, are two 6-inch collimators, which can be pointed on each other through a hole in the $17\frac{1}{4}$-inch central cube of the telescope. The opening in the roof is 39 inches broad.

The great 4-barrelled chronograph by Cooke, from Dunecht, capable of recording six hours' continuous observations on each barrel, is mounted in the base of the west tower. It is supplemented by a small 3-pricker fillet chronograph by Fuess, of Berlin. Both instruments can be worked from six places in the observatory, and with either of the sidereal clocks. The clocks can also be compared automatically on the chronograph, or audibly by a sounder.

In the south wing the principal room is the library, 24 feet by 34 feet 6 inches, and 20 feet in height, which contains the astronomical library collected by Lord Crawford at Dunecht, comprising about 15,000 volumes. Divided amongst the computing rooms are the books removed from Calton Hill.

The observatory and instruments are lighted by electricity, generated by a 7-horse Crossley gas engine, charging 53 large storage cells.

Within the boundary wall of the observatory stand the house of the Astronomer Royal for Scotland, two semi-detached villas for assistants, and a gate-lodge for the care-taker and messenger.

The transit circle and reflector have only just been mounted, but the large refractor has been in use since last autumn, and in spite of the very unfavourable weather a considerable number of observations of comets have been secured with it. The provisionally-adopted coordinates of the transit house are: Latitude $+ 55° 55' 28''·0$. Longitude 12m. 44·2s. west of Greenwich. It is not likely that these will have to be materially altered.

THE PLACE OF SCIENCE IN EDUCATION.

THE Bishop of London should know something about education. He has been the Principal of a Training College, an Inspector of Schools, and Head Master of Rugby School, and he has written in a broad spirit on educational matters. No wonder, then, he modestly confessed at the London Diocesan Conference last week, that "he happened to know a good deal about education." There is one branch of knowledge, however, which he thinks should be cut off from the educational tree nurtured in elementary schools, and that is the branch of science. "He had very often felt," he said, referring to the Education Bill, "that it had been a very great evil that we insisted upon instructing little children in elementary schools in a great many scientific subjects, and he should not have been at all sorry if all these scientific subjects were got rid of entirely, and it had been left to the managers, and to the teachers under the managers, to introduce other subjects which would be more suitable." And, later on, he remarked: "Teaching of an advanced character might very well be permitted in some schools, but in regard to all these scientific schools, and the apparatus connected with them, the sooner they were got rid of the better."

Evidently Dr. Temple is moved by the oppression which schools suffer from science, and he desires to emancipate them. But to any one familiar with the facts as to scientific instruction in this and other countries, and the beneficial results which proceed from it, Dr. Temple's strongly-expressed desire will appear astounding. The schools in which science is successfully taught (and we count success not so much by examinational results as by the training of the mind and eye and hand, and the development of the spirit of inquiry), invariably contain the most intelligent scholars; the towns or districts which possess properly organised and equipped science schools contain

the largest proportion of skilled and inventive workmen. It is in the elementary schools that the foundations of natural knowledge should be laid, and there the faculty of observation should be trained to feed the mind; yet these are the schools which the Bishop of London would shut out from the light of science. For many years men interested in scientific education have been striving for a fuller recognition of science in our educational system, and not without a certain measure of success. But now comes Dr. Temple and says in spirit, if not in the exact words, "Away with all these abominations. Purge the elementary schools of everything scientific, and substitute dogmas and subjects more fitted to the stations of life in which it has pleased God to call the scholars." It is difficult to believe that sentiments so antagonistic to scientific study should have been uttered towards the end of the nineteenth century, and by one who is regarded as a friend of educational progress. But it is gratifying to know that Dr. Temple is only expressing the desire of a few ecclesiastics when he declares for the expulsion of science from elementary education. All who have the good of the country at heart, and who know the immense industrial harvest which Germany has reaped, and is reaping, as the result of generous provision for science in education, will regret that a man in the exalted position of the Bishop of London should have been the mouth-piece of words so narrow in their signification as those we have quoted—words which really lead one to think that he has not yet grasped the difference between "education" and "instruction." As it happens, we have received during the past week a copy of the address delivered by the Right Hon. A. J. Mundella to the members of the Association of Technical Institutions at their last annual general meeting, and we subjoin a few extracts from it, in the hope that they will lead Dr. Temple and his friends to a better appreciation of the value of scientific education.

Germany and Switzerland have, for more than half a century, been perfecting their educational system. They have trained up two generations in the most efficient and best manner that these two nations can afford, and they have profited very largely by it.

Now, to my mind, it is astonishing that this should be the case with such comparatively poor nations, because they have made their institutions accessible to every citizen, even to the poorest. There has been a lavishness amounting almost to extravagance in their expenditure. A few years ago I was in Berlin, and I was talking to my old friend Prof. Hofmann, who was then at the head of that great Charlottenburg Institution, the first technical institution in Europe. I remarked to him that I had been through various institutions in Germany and Switzerland the previous year, and it seemed to me that they were rather over-producing scientific men, the supply was in excess of the demand. "It is true," he said, "that we are producing more than we can absorb. We have a plethora of scientific men; only this year in my own department, two hundred Doctors of Science have taken degrees in the universities of Germany. But you must bear one thing in mind; *we have the export trade entirely to ourselves*."

"Go where you will throughout the world, you will find the German chemist at the head of every industry into which chemical science enters. I was in America, making a journey through the States some two or three years ago, and wherever I went I was entertained by German chemists and German scientific men, many of whom were old students of mine. They were at the head of every industry to which scientific knowledge is applicable, chemical works, gas works, breweries, whatever it was a German was at the head of it." And he said, "You know that pays. When a German scientific man wants plant or machinery, and that plant is manufactured in Germany, he goes to Germany for it, he does not go to England." That is quite true. The position that the German chemist, the German scientist, the German technologist has taken throughout the world, has done much to assist German industry.

The extent to which Germany and Switzerland have profited by technical teaching, is hardly realised by the English people. We are beginning to learn it; Switzerland, we are told by Sir O. Adams, in his excellent book on the "Swiss Confederation," exports a greater amount of manufactures per head for her population, than any other country in the world. It seems almost incredible that it should be so, that a country without natural resources, without iron, without coal, without a port or a navigable river, should nevertheless have a greater export of manufactures than any other nation in the world, not excepting England. But it is *true*, gentlemen, and she owes it entirely to her *education*. . . .

Look at Germany. What has Germany gained by her sacrifices? I have been reading the most recent consular reports from that country: they furnish a mass of testimony in proof of the advantages she is reaping from her persistency in an enlightened educational policy. Hamburg trades very largely with English-speaking countries. Years ago she made English a compulsory subject in her common schools. She has been unsparing in expenditure for the equipment of her citizens, and she is reaping her reward. If, thirty years ago, any one had ventured to prophesy that in 1895 the tonnage of sea-going ships touching at Hamburg would exceed that of Liverpool, we should have laughed him to scorn; but this "striking fact" was announced to us a few days ago. Our Consul at Stettin reports that the educational authorities of that city propose to devote four hours a week to the study of English in the common schools. What would be said in England if a School Board on the north-east coast was to make German a compulsory subject?

After stating a number of remarkable instances of the effects that foreign competition is having upon British trade and employment, Mr. Mundella continued:—

Let us ask ourselves why it is that our rivals are so successful? In the first place their elementary schools are thoroughly efficient. The teaching staff consists of trained adults, 90 per cent. of them being men. The scholars attend with astonishing regularity, and the school-life is sufficiently long to permit of their mastering the full curriculum of the school. When at the age of fourteen (in Switzerland it is often fifteen) the continuation school perfects, and adds to, the knowledge acquired in the elementary school. Then follows the high school, the technical school, and the university. There is no waste of effort; no overlapping; everything is co-ordinated; and everything is accessible to "the youth of pregnant parts." Fees are sufficiently low, or scholarships are provided, to admit of the humblest scholar of promise securing a thoroughly sound education. In Switzerland the high schools are free as well as the elementary, and the fees at the Polytechnicum at Zürich do not exceed £4 per annum. . . .

Well, gentlemen, what is our position? We are still the first industrial nation in the world. What is our educational position? Are we first? Comparisons are odious. They are in this case; one hardly likes to make them.[1] Having regard to our wealth, the magnitude of our industries and of our commerce, the vast interests that we have in our keeping, we ought to be the first. Why are we behind, and what ought we to do to obtain supremacy in education as well as maintain it in industry? Well, you must begin at the bottom, you must improve the elementary education. We, to a great extent, owe the present condition of things to the early leaving of school, to the half-time system, to the low standards which prevail, especially in the country districts, where the fourth standard is the standard of total exemption. Think of the numbers that enter factories at eleven years of age. Think how few stay at school until they are thirteen or fourteen. It is true we have done excellent work under Forster's Act. We should take shame to ourselves that we have not done more. but we have done as much as the country would allow us; and we have been always, I think, in advance of the opinion of the country.

We trust that these extracts from Mr. Mundella's address will bring the Bishop of London to a better understanding of the place and value of science in education.

[1] Dr. Virchow visited England four or five years ago, and on his return to Berlin he reported, "England is a century before us in sanitation, and a century behind us in education."

NOTES.

A PHOTOGRAVURE of Sir Joseph Lister, President of the Royal Society, accompanied by a biographical sketch, will appear in next week's NATURE, as an addition to the series of "Scientific Worthies."

THE "James Forrest" lecture of the Institution of Civil Engineers will be delivered on Thursday, May 7, by Dr. A. B. W. Kennedy, F.R.S., the subject being "Physical Experiment in relation to Engineering."

PROF. EHRLICH has been appointed Director of the new State Institute in Berlin for the testing of therapeutic serum.

THE Trustees of the late Earl of Moray have granted a donation of £1875 to the Ben Nevis Observatory.

THE Bill before the House of Representatives adopting the metric system of weights and measures as legal standards in the United States, has (says *Science*) been referred back to the Committee. The Bill was ordered to a third reading by a vote of 119 to 116, but this vote was afterwards reconsidered.

DR. J. E. AITCHESON, C.I.E., the naturalist who was attached to the Afghan Delimitation Commission, has returned to London from North-West India and Kashmir, where for the past four years he has been continuing the further investigation of the fauna and flora of those regions.

WE regret to announce that Prof. Dr. Adalbert Krueger, Director of the Kiel Observatory, died on Tuesday, April 21. He was in his sixty-fourth year.

THE deaths are announced of M. Joaquim P. N. da Silva, distinguished for his archæological works, at Lisbon, in his ninetieth year; M. Jules Lefort, Member of the Paris Academy of Medicine, and the author of many treatises on pure and applied chemistry and pharmacy, his most important work being in connection with water analysis; Prof. Dr. Ofterdinger, at one time Professor of Mathematics and Astronomy in Tübingen University; and M. J. B. Dureau, the founder, in 1860, of the *Journal des fabricants de sucre*. M. Dureau was also the author of a "Rapport sur l'Industrie de sucre à l'Exposition universelle de 1867," and of a valuable work entitled "l'Industrie du sucre depuis 1860."

WE learn from *Terrestrial Magnetism* that M. Moureaux has been entrusted by the Minister of Public Instruction, at the request of the Imperial Russian Geographical Society, with the investigation of a pronounced anomaly in the distribution of terrestrial magnetism, which certain observations have revealed in Southern Russia.

ARRANGEMENTS are being made in Limoges to celebrate this year the centenary of the introduction of porcelain into France, by means of an Exposition, in which the history of porcelain manufacture will be traced by specimens of work and processes. The Exposition is being organised by the Société Gay-Lussac, working in conjunction with representatives of the town of Limoges.

ON Tuesday next, May 5, Mr. C. V. Boys, F.R.S., will begin a course of lectures at the Royal Institution, on "Ripples in Air and on Water"; and on Thursday, May 7, Mr. W. Gowland, late of the Imperial Japanese Mint, will begin a course of lectures on "The Art of Working Metals in Japan." The Friday evening discourse on May 8 will be delivered by Prof. Silvanus P. Thompson, F.R.S., his subject being "Electric Shadows and Luminescence." That on May 15 will be on "Cable Laying on the Amazon River," Mr. Alexander Siemens being the lecturer.

WE learn from *Science* that Mr. William I. Hornaday, formerly of the U.S. National Museum, has been appointed Director of the proposed Zoological Park in New York. He enters upon his duties immediately, and will first consider and report to the Executive Committee upon the difficult question of location of the Park. At the last meeting of the Society the three first honorary members were elected as follows: Sir William H. Flower, Prof. Alexander Agassiz, and Prof. J. A. Allen.

OUR American correspondent writes under date April 17:—"Prof. Frederick A. Starr, of the University of Chicago, has just returned from a three months' tour in Central America. He found many genuine dwarfs, but not constituting a tribe, as they spoke nineteen languages in Oaxaca, thirteen in Chiapas, and twenty-one in Guatemala, indicating a lack of unity among them.

"The new remedy for consumption, aseptolin, the formula for which has recently been given to the world by Dr. Cyrus Edson, is now used in the New York State's prisons at Sing Sing, Dannemora, and Auburn, with marked success. At the last-named prison there was not one death from consumption during the entire month of March, which is quite unprecedented. Twenty thousand cases are under treatment, the larger number being outside the prisons, with two hundred cures reported.

"It is remarkable that with the abundant sea-life teeming about it, and within short distances, New York City has never possessed an aquarium. Castle Garden has now been converted to that use, and will be opened to the public within a few weeks with admirable equipment. It is peculiarly fortunate that the underlying strata are such as to filter the water from the adjoining harbour, thus providing an inexhaustible supply of pure sea-water for the tanks from an artesian well.

"The extraordinary weather, perhaps, deserves another note. While snow-storms still prevail at the West, and three feet of snow, being the heaviest snow-fall in many years, was reported on Monday from New Mexico, unprecedented heat has prevailed along the North Atlantic seaboard for five days, the thermometer reaching 85° at New York City on the 16th, and again to-day, which exceeded by 14° all previous records of same date, and was hotter than any April weather previously recorded. From other points still higher temperatures were reported: 90° at Hartford, Conn., and Moonsocket, R.I.; 92° at Manchester, N.H., and 94° at Middletown, N.Y."

THE summer meetings of the Institution of Naval Architects will be held this year in Hamburg, on Monday, June 8, and the following day. On Wednesday, June 10, the meetings will be transferred to Berlin, on the invitation of the Imperial German Government, and they will be continued there during the remainder of the week. Full particulars of the papers to be read, of the works and places of interest to be visited, and of the excursions and entertainments which are being organised, will shortly be issued. The meetings are receiving the warmest support from the Imperial Government, under whose direction the arrangements in Berlin are being prepared.

ON July 2 the Second International Congress of Applied Chemistry will open in Paris. In addition to strictly technical questions, the congress will discuss the analytical processes needed for the guidance of manufacturers and the benefit of the consumer. The proceedings will be conducted in ten sections, and, judging from the number and interest of the questions which will be brought up in each, there will be no lack of work. The sections represent such diverse subjects as chemical products, electro-chemistry, colouring matters and dyeing, pharmaceutical products, metallurgy and mining, sugar-refining, vintnery, brewing, distilling, agricultural chemistry, photography, alimentation, and milk-supply. The Association des Chemistes de Sucerie et de Distillerie, which is organising the congress, has formed a

Committee, comprising several members of the French Government, a large number of members of the Institute, and many of the foremost men in science and industry in France. Further information with reference to the congress can be obtained from M. Dupont, 156 boulevard Magenta, Paris.

THE Marine Biological Laboratory at Plymouth has been the scene of more than usual activity during the past month. In addition to the permanent staff of the laboratory, five botanists and zoologists have been engaged in biological research, and the students' laboratory, recently equipped for the accommodation of vacation parties, has had its resources taxed to the uttermost. Fifteen students in all—six from Cambridge, five from Oxford, three from the Owens College, Manchester, and one from University College, London—have formed Mr. Garstang's vacation class, and have made full use of the liberal provision made for them by the Director of the laboratory and his staff. The arrangements for the class have consisted of daily expeditions for trawling, dredging, tow-netting, and shore-collecting purposes to various parts of the neighbourhood, and of daily lectures and demonstrations on the results of the expeditions, and on general topics connected with marine biology. Especial attention has been paid to the life-histories of animals—to their bionomical relations and to problems of use and function—so as to comprise a body of instruction supplementary to the morphological studies of university laboratories. The class has admittedly been a great success, and the students have returned to their various universities not only with a store of new facts, but with renewed interest in biological pursuits. A similar class will be formed for August next. The *Busy Bee*, the new steamboat of the Association, has satisfactorily fulfilled all the tests imposed upon her, and proves to be eminently suitable for the routine work of the laboratory. Among the more interesting of recent captures may be mentioned the discovery of several examples of a species of the Amphineuran *Proneomenia*.

THE annual general meeting of the British Ornithologists' Union was held at 3 Hanover Square, on the 22nd inst. In the absence of Lord Lilford, the President, Mr. P. L. Sclater, F.R.S., took the chair. The report of the Committee stated that *The Ibis* (the journal of the Society) had been regularly published during the preceding year, and that the Union consisted of 269 ordinary members, besides honorary and foreign members. Twenty-nine new ordinary members and one new foreign member, were proposed and elected. Mr. Sclater brought forward a scheme for a new synopsis of the described species of birds, to be arranged in six volumes, corresponding with the six zoological regions of the earth's surface. This was referred to a Committee to report upon.

WE have received a copy of the draft programme of questions proposed for discussion at the International Meteorological Conference to be held in Paris in September next. Numerous questions in general meteorology, terrestrial electricity and magnetism, and international meteorology are down for discussion. Among these questions and propositions we notice that Dr. P. Schreiber (Chemnitz) will propose that the meteorological day shall be reckoned from 9 p.m. to 9 p.m., and designated by the same number as the civil day, while meteorological extremes and sums, *e.g.* of rain fallen, shall be measured at 9 p.m. Prof. Willis L. Moore (Washington) will put forward the solar magnetic period 26·67928 days as the natural mode of classifying solar, physical, and terrestrial meteorological phenomena, and suggest the desirability of its introduction for general use in the year 1901. The Royal Meteorological Society suggests (1) the desirability of more extended observations on infiltration into the soil, and uniformity in the same; (2) the general adoption of a standard anemometer for the determination of the velocity of the wind; (3) the general adoption of a uniform system of exposure for anemometers; (4) uniformity of conditions under which earth temperatures should be taken. Prof. H. Mohn (Christiania) will introduce the question of determining the pressure of the air by means of the observation of the boiling point of water (the hypsometer) with the accuracy necessary for meteorological purposes; and also that of the determination of the gravity correction for mercurial barometers by simultaneous observations of the hypsometer and the mercurial barometer. Dr. Billwiller (Zürich) will urge the necessity for the introduction of a uniform method of reduction of barometer readings to the sea-level for the construction of synoptic weather charts. Rev. Father Faura, S.J. (Manilla), will suggest that the time has arrived to settle the question of air motion in cyclones, and to finally disprove the theory of descending currents in these phenomena. Prof. E. Mascart (Paris) will treat of atmospheric electricity and terrestrial magnetism. Prof. von Bezold (Berlin), and Prof. Eschenhagen (Potsdam) will propose that certain general principles should be introduced for the publication of magnetic observations, and should be laid down for magnetic surveys. They will also suggest that it is desirable that all institutes which publish magnetic charts should give additional tables containing the magnetic elements, and, if possible, also the components for convenient points of intersection of the geographical co-ordinates. Other questions which they suggest for discussion are the distribution of magnetic observatories, and simultaneous international observations.

THE last published Report of the Central Physical Observatory of St. Petersburg gives particulars of the working of the vast and important meteorological service in Russia, and is the last summary which will be prepared under the efficient superintendence of Prof. H. Wild, who has now retired from the directorship. The number of stations returning regular observations amounted to 642, of which 438 were in Europe, and the remainder in extra-European localities. Before publishing these observations, they have been subjected to careful revision, *inter se*, and to comparison with synoptic weather charts. Storm-warning telegrams have been regularly issued to the Baltic and Black Seas, as well as to some inland seas, for which a success of 72 to 78 per cent. is claimed. Special attention is also paid to daily weather forecasts; the results are published for each separate element and for each month, the aggregate success being over 74 per cent. Special forecasts of wind and snow-storms are also issued to the railway companies. The report contains a long list of scientific investigations published under the auspices of the St. Petersburg Academy of Science.

WATER-CRESS is eaten by Caddis-worms, Caddis-worms by trout, and trout by Herons. The result of disturbing this balance of nature in a particular case is described by Miss E. A. Ormerod in the Cirencester *Agricultural Students' Gazette*. Three-quarters of a large crop of water-cresses were found to have been injured by the attacks of the water-grubs which are so well known as Caddis-worms. Isaac Walton gives evidence of the love of trout for Caddis-flies as baits, and this points strongly to their knowledge of the goodness of the larvæ for food in more natural circumstances. But in the case which Miss Ormerod investigated, the trout had been eaten by Herons, and by their removal the water-cress grower appears to have lost very helpful friends. The sequence of events consequent on local encouragement (beyond what is known as a natural balance) of one large species of birds of special habits, downwards, through destruction of insect-eating fishes, and overplus of vegetable-eating insects, to the great pecuniary loss of the grower of water-cress, deserves a place with Darwin's story of the relation between cats and clover.

DR. GREGG WILSON describes several peculiar cases of hereditary polydactylism, showing considerable variation in the position of the abnormality, in the *Journal of Anatomy and Physiology*. In one family, extra fingers or toes were so common that they were almost expected to appear upon some of the children. This abnormality persisted through six generations, and two interesting features connected with it are that it increased in the first four generations, and changed in position from the post-axial to the pre-axial side of the limb. In another case there was an increase of the abnormality, and also a change in the position from the post-axial to the pre-axial side of the limb. In a third case there was remarkable variability in the abnormality, a man with extra minimi on both feet having one son with extra great toes, and another son with extra minimi on the hands and a double middle toe on one foot. The instances studied by Dr. Wilson illustrate the variability of digital abnormalities, and in this regard they differ from the majority of cases of hereditary polydactylism, where the abnormality is very constant in position through several generations, though not in degree. In a few cases the abnormality has been found to pass in successive generations from the outer side of the hand to the outer side of the foot, and *vice versa*, but it is rare that it passes from one side of a limb to the other, as in the five cases sketched by Dr. Wilson.

ON April 13 a meteorite, weighing two kilogrammes, fell at Lesves, near Namur, Belgium. In its fall it very nearly killed a young man who was working in an orchard, and it embedded itself into the earth to a depth of 50 centimetres. The Abbé Renard, who examined the specimen, considers it to be a stony meteorite of chondritic structure. It consists of a whitish crystalline paste, from which are detached meteoric iron, troïlite, olivine, bronzite, and chondroi. An examination of the structure and the chemical composition of this aerolite is now being made in the laboratory of the University of Gand.

THE publication of Herr Gätke's theory of the moult in birds, in his work on Heligoland, seems to have induced other ornithologists, both in Europe and America, to turn their attention to this difficult subject. Mr. Witmer Stone has put forward his views "on the moulting of birds," in a communication made to the Academy of Natural Sciences of Philadelphia in January last. He has come to the conclusion that the annual moult at the close of the breeding season is a physiological necessity, and is common to all birds; whereas the spring moult and striking changes of plumage effected by abrasion are not physiological necessities, but depend in extent upon the height of development of colouration in the adult plumage, and do not necessarily bear any relation to the systematic position of the species. Mr. Stone scouts the idea of Gätke (adopted by Dr. Bowdler Sharpe) that feathers can actually change their colour without moult, unless it be by abrasion or bleaching. Mr. Stone gives us a large number of useful notes on the smaller land-birds of Eastern North America, based on his own observations.

A PAPER in the current number of the *Annales de Chimie et de Physique* gives the results of some recent determinations of the specific heat of boron, made by MM. Moissan and Gautier. Amorphous boron was used, and the specific heat measured by means of Bunsen's ice calorimeter. The boron was heated to three temperatures: 100°, 180°, and 230° C. The values for the atomic heat obtained at 50°, 146°, and 213° are 3·374, 4·153, and 4·766. By interpolation it is found that at a temperature of about 400° C. the atomic heat of boron would be 6·4, but the authors have made no attempts to make measurements at temperatures over 230°.

SINCE it has been shown that the velocity of propagation of an electro-magnetic disturbance in a dielectric is the same as that in a wire surrounded by the dielectric, the measurement of the velocity of such a disturbance in a wire is of great interest. M. Blondlot, who has already published the results of some experiments made on this subject, contributes an interesting paper to the current number of the *Annales de Chemie et de Physique*, giving the results of some recent experiments on the velocity of propagation of an electro-magnetic disturbance along a wire. The author employs the discharge between the outer coatings of two small Leyden jars (the "impulsive discharge" of Lodge), which occurs when a spark passes between the knobs connected to the inner coatings. Each of the jars has two outer coatings, one of which is connected to a small spark-gap by a short wire, while the other is connected to the same spark-gap by a wire about 1000 metres long. Hence on a spark passing between the knobs connected to the inside coatings, two sparks occur in the spark-gap, one produced by an electro-magnetic disturbance which has only traversed a few centimetres of wire, while the other, having started at the same time as the first, has passed along about 1000 metres of wire. An image of the sparks is thrown on to a photographic plate by a mirror rotating at a known speed. The speed of the mirror was determined by comparing, by means of a monochord, the pitch of the note produced by the vibrations of the axle in the bearings with the pitch of a tuning-fork. The "line" consisted of copper wires 3 millimetres in diameter, suspended on posts about 3 metres above the surface of the earth. The distance between each of the outgoing wires and the corresponding return, which was in the same vertical plane, was 80 cm., while the two circuits were at a distance of 40 cm. from each other. The mean of five sets of measurements gave 296,400 kilometres per second as the velocity of the disturbance, while three others in which the distance traversed was nearly twice as great, *i.e.* 1821 metres, gave 298,000 kilometres per second. The author considers that each individual measurement is probably correct to within 1 part in 100.

THE *Annals* of the Astronomical Observatory of Harvard College, vol. xl. part iv., contain an important appendix by Mr. S. P. Fergusson, upon anemometer comparisons made at Mr. Rotch's Observatory at Blue Hill, Massachusetts, in the years 1892–94. The object of the investigation was to determine the mean differences between anemometers used as standards in different countries, and to compare the results of recent whirling-machine experiments. The observatory in question is admirably adapted for the purpose, being situated upon an isolated hill, and is equipped with the best patterns of anemometers, in addition to which some instruments were supplied from other places for comparison. The anemometers, and method of comparison are fully described; very useful results were obtained, to which, however, we can only briefly allude here. The experiments show conclusively that the smaller anemometers are the most sensitive to sudden variations in velocity, the ratio of sensitiveness being nearly proportional to the size, in instruments of the same type. The fan anemometers are much more sensitive than the cup anemometers, and are therefore the most efficient for recording gusty winds; the Robinson pattern instruments, mostly used in this country, are least efficient in this sense, but they possess undoubted advantages for recording mean velocities. Dines' pressure tube anemometer was found to be an excellent instrument, especially for indicating maximum velocities. The comparisons clearly show the need of some standard form of anemometer, to which all observations heretofore made can be reduced.

THE results of much patient observation are recorded in *Bulletins* 129 and 130 of the Michigan Agricultural Experiment Station, which relate to fruit culture. Numerous varieties of fruits, embracing 156 of strawberries, 53 of raspberries, 30 of

blackberries, 44 of currants and gooseberries, 63 of cherries, 191 of peaches, 72 of plums, 37 of pears, 101 of apples, besides quinces, apricots, nectarines, mulberries, and others, were separately grown. Cultural notes were periodically written, whilst quality, vigour, and productiveness were numerically estimated according to a fixed scale. In every case, the weight of an average specimen of the fruit is tabulated, the information thus conveyed being regarded as preferable to a record of the size, and at the same time more easily and accurately acquired. The difficulties of nomenclature and synonymy are somewhat lessened by a strict following of the rules of pomology, as formulated by the American Pomological Society and the National Division of Pomology, and every effort is made to avoid ambiguity. Notes on insects and other pests—such, for example, as the currant eelworm, *Nematus ventricosus*—are added wherever necessary, and the useful effects of sulphate of copper sprayed as an insecticide are referred to. The *Bulletin* should be of great practical value to the cultivators of Michigan, a State the climate of which especially fits it for profitable fruit-growing.

Mr. David Flanery, of Memphis, Tenn., U.S.A., writes that on January 14 last, "while looking for certain stars in the east at 5.45 a.m., suddenly a great light shone behind and to the left of me, and after studying a moment to determine whether it was a flash from the trolley, or some other common occurrence, I turned around to the west, and looking up beheld a body of grey nebulous matter, such apparently as the Milky Way is made up of, slowly disappearing from view. It lasted a full minute, and without moving in any direction faded away. I heard no noise as of an explosion, but the light and the apparent smoke which had the form J plainly indicated that an immense meteor had fallen or had been consumed. The locality of the phenomenon was on the borders of the Great Bear, Ursa Major, and the Little Lion, Leo Minor, and around the two bright stars Lambda and Mu, which mark the hind feet of the Bear."

The phenomenal Eichener Lake in the Grand Duchy of Baden, which has the peculiarity of appearing and disappearing at uncertain periods, has recently again made its appearance after a lapse of time.

It will be fifty years next October since the first application of ether in surgical operations took place; and in honour of this scientific jubilee, Prof. C. Binz, of Bonn, has recently published in Richard Fleischer's *Deutsche Revue* a valuable historical sketch of the successive stages through which that beneficial discovery has gone in various countries.

Messrs. William Wesley and Son have just issued a valuable catalogue (No. 125) of works on zoology. Scientific men and institutions on the look-out for standard zoological books and papers will find the catalogue well worth consultation.

The Report of the Berlin branch of the German Meteorological Society for the current year contains, as usual, an interesting investigation into the climate of that city, by Prof. G. Hellmann, the Vice-President. The subject this year is the publication and discussion of the daily mean temperatures, and extreme values for the last forty-eight years.

The additions to the Zoological Society's Gardens during the past week include an Egyptian Jerboa (*Dipus ægyptius*) from Algeria, presented by Mr. F. J. Pringner; a Polecat (*Mustela putorius*) from Worcestershire, presented by Mr. F. D. Lea Smith; an Alexandra Parrakeet (*Polytelis alexandræ*) from Australia, presented by Mr. W. Pritchard Morgan, M.P.; a Natal Python (*Python sebæ*, var. *natalensis*), five Hoary Snakes (*Coronella cana*), a Rhomb-marked Snake (*Psammophylax rhombeatus*), a Cape Bucephalus (*Bucephalus capensis*), five Puff Adders (*Vipera arietans*) from South Africa, presented by Mr. J. E. Matcham; a Brown Mouse Lemur (*Chirogaleus milii*) from Madagascar, three Red Kangaroos (*Macropus rufus*, ♂ ♂ ♀), four Black Wallaroos (*Macropus robustus*, 4 ♂), an Alexandra Parrakeet (*Polytelis alexandræ*) from Australia, a Hamadryad (*Ophiophagus elaps*) from India, deposited; two Common Sheldrakes (*Tadorna vulpanser*), European, purchased.

Erratum.—In Prof. J. J. Thomson's article on Röntgen rays, p. 582, col. 2, line 5, for 4×10^{-8} centimetres, read 4×10^{-6} centimetres.

OUR ASTRONOMICAL COLUMN.

The Spectrum of Mira.—During the recent maximum of Mira Ceti, Prof. Wilsing was fortunate enough to obtain eleven photographs of the spectrum (*Sitz. Akad. Wiss.*, Berlin, March 26, 1896). The photographs are evidently very similar to those obtained by Prof. Pickering some years ago, hydrogen being represented by broad bright lines. The absence of the hydrogen line H_ϵ, which falls very near a broad line of calcium, is again very striking, and the simplest explanation of this fact is to suppose that the hydrogen light at that wave-length is absorbed by calcium vapour. This necessitates the supposition that there is a cooler layer of calcium outside the incandescent hydrogen, but the high atomic weight of calcium cautions us to regard this hypothesis as merely provisional. There is no certain evidence at present as to whether the hydrogen lines appear in the spectrum except about the time of maximum, and the Potsdam instruments are not of sufficient aperture to permit such an investigation to be made.

It is stated that there are no bright lines other than those of hydrogen, although there are parts of the spectrum (especially about wave-lengths 3894, 3906, and 4350) which give the impression of bright lines. The latter appearances are regarded simply as regions in which the continuous spectrum is thrown into relief by the absence of dark lines; similar effects, but not so marked, are said to be seen in the solar spectrum.

With the exception of the bright lines of hydrogen, the spectrum of Mira shows a nearly perfect agreement with that of the sun in the region more refrangible than $H\gamma$, while on the less refrangible side of this line the spectrum is characterised by dark flutings fading towards the red.

There is probably a slight displacement of the bright lines towards the less refrangible sides of their true positions, but the photographs are on too small a scale to permit any exact determination of the velocity in the line of sight. There is no suggestion of a doubling of the hydrogen lines such as is seen in the case of β Lyræ, but the occurrence of a strong dark line alongside $H\zeta$ reminds one of the appearance of this line in β Lyræ.

The paper concludes with a table of wave-lengths, extending from λ 3772 to λ 4755.

Comet Swift, 1896.—The comet observed by Swift on April 13 is a new one, and from its position on April 16, 19, and 20, Dr. R. Schorr has derived the following elements and ephemeris for Berlin midnight:—

$$T = 1896 \text{ April } 17.51 \text{ Berlin mean time.}$$

$$\left.\begin{aligned} \omega &= 1^\circ\ 12' \\ \Omega &= 177^\circ\ 55' \\ i &= 55^\circ\ 15' \end{aligned}\right\} 1896.0$$

$$\log q = 9.7515$$

	R.A. h. m.	Decl. ° ′	Brightness.
April 30	3 1.8	+51 55	0.72
May 2	2 51.3	+55 22	0.63

The unit of brightness is that on April 16. The comet will be very near to γ Persei on May 2.

This comet is now well placed for observation, and being circumpolar can be seen practically all night. Observations made at South Kensington by Mr. Shackleton, on the 28th inst., show that it is so bright that it can be seen with an opera-glass. The comet has a well-marked nucleus and a slight tail. Spectrum observations and measures made with a small 3-prism spectroscope, collimator 6-inch, showed three bright bands, but practically no continuous spectrum. Comparison was made with a spirit flame, and the carbon bands were seen to be identical with the bright bands of the comet, the one at λ 516 being especially bright.

RECENT WORK WITH RÖNTGEN RAYS.

IN our last week's number, Prof. J. J. Thomson brought together and discussed observations of prime importance selected from the mass of material recently published on Röntgen rays. As a supplement to this, and in continuation of the general summaries which have already appeared in NATURE, we present the following notes on papers and communications received during the past few days.

Prof. Oliver Lodge has sent us the following announcement, dated April 20.

"It has been asserted that the action of X-rays on a film is a photographic one, depending on the fluorescence of the glass backing. The truth is that a film on a ferrotype plate is just about as rapid as a similar film on glass. Thick films are much better than thin. It may be further interesting to state that if the platinum disk on which the kathode rays inside the bulb are converged is connected to the kathode, it fails to act as a source; if it be insulated, it acts fairly; while if it is connected to the anode, it constitutes a vigorous source."

It will be remembered that Prof. Röntgen found that "films can receive the impression as well as ordinary dry plates" (NATURE, January 23, p. 274), but he was doubtful whether the photographic effect was secondary or not.

From a number of papers dealing with various properties of Röntgen's rays, we learn that Herren V. Novák and O. Sulc (Prague) have observed the relative opacity for X-rays of different substances, both simple and compound (*Zeitschrift für Physikalische Chemie*, xix. 3). They conclude that the absorbing powers of the chemical element depend on their atomic weight alone, and that the absorbing power of a compound depends only on the atomic weights of the elements of which it consists, and not on the complexity of its molecules. It seems probable that the *average* atomic weight of a compound affords an index of its absorbing power. In the *Jenaische Zeitschrift für Naturwissenschaft*, Dr. A. Winkelmann and Dr. R. Straubel (Jena) have investigated the refraction of Röntgen rays, and by using prisms of various metals, obtain in each case a value of about 1 : 0·0038 referred to air. They also have measured the reflection produced by a sheet of tinfoil, and the relative transparency of different kinds of glass to Röntgen radiations. All glasses made with lead are found to be comparatively opaque. The same writers have experimented on the action of fluor-spar in intensifying the actinic effects of X-rays, and have found that the best results are obtainable with a coarse powder of the fluor-spar; finer powders producing a less marked effect. This effect is due to fluorescence, the spar emitting radiations whose index of refraction is about 1·48; indicating a wave-length of 219×10^{-6}. The March number of the *Atti della Reale Accademia dei Lincei* contains two papers, one by Signor Augusto Righi, and the other a joint paper by Drs. A. Fontana and A. Umani (Rome), both of which deal with the effect of Röntgen rays in stopping the action of Crookes' radiometer. The effect is found to be purely electrostatical, and to be due to the electrification of the glass bulb containing the radiometer; when the bulb is wetted, or electrification prevented by the interposition of a conducting screen, the radiation from a Crookes' tube does not affect the radiometer in any way whatever.

Mr. A. W. Isenthal has sent us the following letter, *à propos* of Winkelmann and Straubel's paper. He says:—"It may be of interest to your readers to learn that, within the last few weeks, Prof. Dr. Winkelmann and Dr. Straubel, of Jena University, have been successful in reducing the exposure required for the production of radiograms to a few seconds only. Acting on the few directions given, I have made a few preliminary trials, the result of which is very promising. By simply backing the sensitive plate with a most inexpensive material, I have obtained fair negatives of the finger-bones in about ten seconds, using only a 3-inch spark. As the rays in this method have first to pass through the glass of the sensitive plate, there is a probability of still further reducing the necessary exposure by substituting sensitive films (on celluloid) for the ordinary photographic plate."

With reference to the use of fluorescent screens in reducing the time of exposure, we have received the following letter from Dr. H. Van Heurck, of the Botanical Gardens, Antwerp, through Dr. Wynne E. Baxter:—

"I notice in your issue of April 16, that Messrs. L. Bleekrode and J. William Gifford announce that they have been able to reduce the time of exposure in radiography by the use of a fluorescent screen. Mr. Basilewski communicated the same fact to the Paris Académie des Sciences on March 23 last. Allow me, however, to lay claim to priority in this application of fluorescent screens, as the same was announced by me in various Antwerp journals on March 8, and again on the 12th of that month, in the *Annales (Belges) de Pharmacie*, an extract from which, in pamphlet form, I send herewith. You will also find described therein a chemical substance, viz. a newly-discovered double fluoride of uranyl and ammonium, with which screens can be made, at a nominal cost, of a luminosity and of a clearness superior to that of any screen now known to exist."

The combination of a fluorescent screen with a photographic plate was one to which every worker with Röntgen rays would naturally be led. Prof. M. L. Pupin gave a description of the combination before the New York Academy of Sciences on March 2. At a meeting of the Academy on April 6, reported in *Science* of April 10, he described an arrangement of apparatus by means of which it was found possible to produce very strong photographic effects, "but not sufficiently strong for penetration through the thigh and the trunk of the human body at reasonably short exposures and at long enough distances from the tube to obtain the desirable clearness in the pictures of these massive parts. A completely successful application of Röntgen's beautiful discovery to surgery depends for the present on a successful solution of the problem just mentioned. I have obtained one satisfactory solution with the method which I first described before the Academy on March 2. It consists in placing in contact with the photographic plate a fluorescent screen, and thus transforming most of the Röntgen radiance into visible light before it reaches the sensitive film. Photographs of the hand were thus obtained at a distance of twenty-five feet from the tube with an exposure of half an hour. At the distance of four inches the hand can be photographed by an exposure of a few seconds. It was in this manner only that I succeeded in photographing on a single plate the whole chest, shoulders, and neck of my assistant, with an exposure of seventy minutes and at a distance of three feet between the plate and the tube. The collar-button and the buttons and clasps of the trousers and the vest show very strongly through the ribs and the spinal column. This result seems to prove beyond all reasonable doubt the applicability of radiography to a much larger field in surgery than was expected a few weeks ago."

A communication on the same branch of the subject has been received from Mr. A. A. C. Swinton, under date April 22. We print his letter in full.

"The chemical action of the Röntgen rays upon a photographic film may be either a direct action or may be a secondary effect, due to the fluorescence produced in the support, or in the gelatine and silver bromide of the film itself. Be this as it may, the fact that an ordinary photographic film supported on celluloid is almost completely transparent to the rays, as may easily be proved with a cryptoscope, and also the fact that it is possible to simultaneously impress many super-imposed films, show that only a very small fraction of the energy in the rays is utilised under ordinary circumstances.

"As long ago as January 30, in some remarks that I made at the close of Mr. Porter's demonstration at University College, I suggested as a means of more completely utilising the energy in the rays, and thereby shortening the necessary exposure, the use of suitable fluorescent material applied either in the form of a screen behind the photographic film, or introduced into the substance of the film itself.

"Since I first made this suggestion, I have tried numerous experiments in the direction indicated. These were at first unsuccessful owing to the screens used not having been properly prepared. Some weeks ago, however, on renewing the experiments with a screen thickly coated with potassium platino-cyanide and gum, placed behind a celluloid photographic film, I obtained conclusive evidence that by this means the necessary exposure could be greatly shortened, and that in a less degree the same result could be accomplished by the employment of a screen thickly covered with powdered fluor-spar.

"The chief objection to this method lies in the fact that it is very difficult to avoid granular results. Unless the fluorescent material be in a very fairly divided condition, its grain shows distinctly and mars the detail of the finished picture. The platino-cyanide does not work so efficiently when finely powdered as when in moderately coarse crystals, but good results can be obtained by thickly coating a thin celluloid film with an emulsion of this salt ground to fine powder in collodion, and using the screen so prepared with its celluloid surface in contact with the

sensitive surface of the photographic film. I have obtained considerably better results with a finely ground sample of tungstate of calcium, prepared for me by Messrs. Hopkin and Williams. This may be used either in loose powder or made up with gum into a paste and dried.

"With this substance it is easy to obtain sharp and fully-exposed negatives of the hand in from five to ten seconds with a moderately excited tube, with which, with ordinary arrangements, one to two minutes' exposure would be necessary.

"I have also tried some special plates prepared for me by Messrs. Marion, into the sensitive emulsion of which fluorescent substances such as powdered fluor-spar and calcium tungstate were introduced before application to the glass. Though the results so far obtained by this method are not very satisfactory owing to granularity, the presence of the fluorescent substance in the photographic film appears undoubtedly to increase its sensitiveness to the rays.

"There is a wide field for further research on the lines above indicated, both with regard to suitable fluorescent substances and the best method for their application."

A paper by Dr. Ferdinando Giazzi, of the Regio Istituto Tecnico, Perugia, is of importance in this connection, and the following translation of it, by Mr. G. H. Baillie, will be useful to chemists who are preparing fluorescent salts for use with Röntgen rays:

"Some days ago Prof. Ruata called my attention to the telegram sent by Edison to Lord Kelvin, and published in NATURE, according to which calcium tungstate, when suitably crystallised, showed fluorescent phenomena under the action of X-rays in a far more marked degree than barium platino-cyanide.

"I immediately consulted Prof. Bellucci, who informed me that calcium tungstate could be easily obtained from either sodium tungstate or tungstic acid, two commercial products selling at a low price. Having obtained these from the firm of Bonavia of Bologna, I set to work and produced some calcium tungstate, but in an amorphous form, which was, as far as I could test with the coil at my disposal, insensible to X-rays. I shall not describe all the attempts I made by wet and dry processes to obtain the salt in the desired form. I merely say that I never have dealt with a body so intractable. The following is the process I finally adopted in preparing it for surgical purposes. I treated a dilute aqueous solution of sodium tungstate with a solution of calcium chloride, given to me by my colleague Prof. Corneliani; I thoroughly washed the resulting pure white precipitate, and dried it at a gentle heat in a porcelain capsule. Next I made a small hole in a piece of fresh retort-carbon, and filled it with the precipitate, which I fused and boiled by means of a small flame from an oxyhydrogen blowpipe. After boiling for some seconds (at a bright white heat), I gradually removed the substance from the hottest parts of the flame, so that solidification took place only after a few minutes. In this way I obtained five globules of calcium tungstate of the required structure. I powdered them in an iron mortar and sifted the powder on to a gummed card, which I exposed in the camera to Röntgen rays. The result was most striking; I saw at once the shadow of the skeleton of my hand more clearly than I ever have with other preparations. A surgeon with this product, good Crookes' tubes. a large coil, and an apparatus such as I have arranged, could certainly dispense with the tedious process of photography.

"I publish this note for the assistance of those who perchance have not yet succeeded in preparing the invaluable tungstate in the desired form."

So far as the utility of the method of reducing exposure by means of fluorescent screens is concerned, the advantage gained must be understood only in a comparative sense. Some investigators obtain excellent results without the use of the screen in less time than others with a screen. Dr. John Macintyre, who has sent us several communications previously upon his work with Röntgen rays, has something to say about the reduction of exposure by screens, in a letter just received. He remarks:

"The object of this note is not to minimise the importance of any aid which the physicist may place in the hand of the surgeon. I have been aware of this new method, but my experience in practice has not encouraged me meantime to pursue it largely, because of want of time in developing what I consider of greater importance, viz. a better Crookes' tube. In surgery what we require may be divided into two parts: (1) rapid views of objects, and (2) permanent records. In practice we must have for the former not photographs but direct vision, and for the second, of course, rapid exposures. Now it may occasionally happen that a permanent record is desirable of what must be done almost instantaneously. That point I think ought to be reached ere long.

"Some weeks ago I recorded a photo of the elbow-joint in $1\frac{3}{4}$ minutes, and that at a time when we did not understand the tubes as well as now. Since then I have obtained records of metallic objects in half a second, and the bones of the hand in six seconds, without the aid of fluorescent screens. What we desire most, however, in practice is a better Crookes' tube for fluorescent screens in direct vision. At present I go while the tube is being exhausted, and test the result before it is taken off the pump. When I am examining an object with the screen, or about to photograph, I heat the tube and keep the current passing through until the maximum effect is obtained. I have now seen by this means the different bones of the extremities and joints; moreover, I have no difficulty in seeing through the body itself. The spine ribs, sternum, clavicle and scapula can be seen; and I have shown to several medical men the shadow of a coin in the gullet (impacted for six months), opposite the fourth dorsal vertebra. Foreign bodies in the extremities are, as a rule, easily seen.

"For the examination of the cavities inside the head, *e.g.* the antrum, or mouth, or pharynx, also the teeth, I now place fluorescent screens in the mouth, and the Crookes' tube outside, either above or below the level of the buccal cavity as required, and sharp images are thus obtained on the screen of not only foreign bodies, but also of the bones of the face, and roots of the teeth as well.

"Other tissues than the bones are now yielding. I have photographed the side of the neck, and shown the tongue, hyoid bone, the pharygeal cavity, cartilages of larynx and trachea of the living adult subject.

"At present we cannot afford to ignore any aid, and hence we are glad to have such hints as the fluorescent screens in photography; but it is not unlikely that all such will be more or less dispensed with as a better source of the X-rays is obtained, viz. a still better Crookes' tube."

Since the above was written, and in consideration of the question at issue, Dr. Macintyre informs us that he has made a further series of experiments on the question of rapid exposures. The tube used was one of the now well-known ordinary focus tubes, made in Glasgow. He has obtained a well-defined image of metallic objects, and distinct, though faint, image of the bones of the fingers with one flash of the Crookes' tube, produced by a single vibration of the mercury interrupter, a large coil giving an eleven-inch spark, and, of course, without using any fluorescent screen. What the extent of the time of exposure was cannot be said, but he describes it as an unknown, unmeasured, small fraction of a second. In another experiment he was able to obtain a distinct image of the bones of the forearm with sixty similar flashes of the tube.

Prof. O. N. Rood found indications of reflection of Röntgen rays from a platinum surface on March 9, and on March 13, after an exposure of ten hours, he obtained a good negative, capable of furnishing prints, of a piece of iron wire netting reflected from a sheet of ordinary platinum foil and through a plate of aluminum (*Science*, March 27). The conclusion he arrived at from inspection of the image was that "in the act of reflection from a metallic surface the Röntgen rays behave like ordinary light." Experiments made to ascertain the percentage of the rays reflected, indicated that platinum foil reflected the 1/260th part of the X-rays incident on it at an angle of 45°.

Upon the question of reflection and refraction of Röntgen radiance, Prof. Pupin pointed out in his paper read before the New York Academy of Science, on April 6, that it was discussed by Prof. Röntgen in Sections 7 and 8 of his origina essay. Neither by photography nor by the fluorescent screen could Prof. Röntgen detect an appreciable refraction with certainty. A reflection from metallic surfaces in the immediate vicinity of a photographic film was detected, "but," translating Röntgen's own words, "if we connect these facts with the observation that powders are quite as transparent as solid bodies, and that, moreover, bodies with rough surfaces are, in regard to the transmission of X-rays, as well as in the experiment just described, the same as polished bodies, one comes to the conclusion that regular reflection, as already stated, does not exist, but that the bodies behave to the X-rays as muddy media do to light." "In face of these observations," continues Prof. Pupin, "Prof. Rood's and Mr. Tesla's experiments must be interpreted as a confirmation of Prof. Röntgen's results, and not as a

demonstration of the existence of a regular reflection. Mr. Tesla infers regular reflection from his theory of bombardment. His experimental method is the same as that of Prof Rood; that is, he places a reflecting plate at an angle of forty-five degrees to the direct ray, and then places the photographic plate at right angles to the direction in which the reflected ray should pass if regular reflection existed. On account of the greater power of his apparatus, his time of exposure was one hour, whereas that of Prof. Rood was ten hours. It is evident, however, that an effect upon the photographic plate does not prove the existence of regular reflection."

In his own experiments on reflection, Prof. Pupin aimed at getting rid of the photographic plate and substituting the fluorescent screen in its place.

He concludes as follows:—"These experiments prove beyond all reasonable doubt that the Röntgen radiance is diffusely scattered through bodies, gases not excepted. We may call it diffuse reflection, if we choose, provided that we do not imply, thereby, that we must necessarily assume an internal inter-molecular regular reflection, in order to explain the phenomenon. For if a puff of smoke be forced through a pile of wood, some of it will come out pretty well scattered, although we cannot speak here of a reflection in the ordinary sense, but rather of deflection, reserving the term 'reflection' for those particular cases in which the angle of incidence is equal to the angle of deflection. It might turn out, for instance, that the X-rays are due to a circulating motion of ether, and that the stream lines are deflected and diffusely scattered within the molecular interstices of ponderable substances. Appearances seem to speak more in favour of this view than in favour of a wave motion of ether. The diffuse scattering of the Röntgen radiance by bodies placed in its path may be also described by saying that *every substance when subjected to the action of the X-rays becomes a radiator of these rays*. . . . The fact that opaque bodies, like metals, are less effective in producing this secondary radiation, leads to the conclusion that there is in these bodies an internal dissipation of the Röntgen radiance much greater than in the case of transparent dielectric substances. A properly constructed bolometer should give us much information on this point, and it is my intention to take up this subject as soon as time and facilities will permit. These diffusion effects, which are present even in air, bring the Röntgen radiance into still closer resemblance to the principal features of the kathode rays which were studied by Prof. Lenard. The difference in their behaviour towards magnetic force is still to be explained. Is it not possible that this magnetic effect in air is masked by the diffuse scattering of the X-rays?"

Our American correspondent says:—"Tesla has found that the X-rays are reflected from certain metals tested in the same order as in Volta's electric contact series in air. Zinc reflects 3 per cent. at an angle of 45°. Below it stand lead and tin, but his observations do not yet show which reflects more highly. Below these in order come copper and iron about the same, then silver. His first observations led him to infer that magnesium would reflect still more than zinc, and sodium most of all. Subsequent experiment has verified the conjecture as to magnesium; but sodium has not yet been tested. By availing himself of the reflection from a zinc cone, he has taken a picture of the ribs of an assistant at a distance of four feet from the vacuum tube, and with an exposure of forty minutes. His apparatus is so constructed that the bulb or bulbs are at the large end of the cone, and the subject at the small end, where the rays are concentrated. The cone or funnel is constructed at an angle less than 30°, so that the incident rays are reflected more than 3 per cent; and especially more the small end of the funnel the rays approach within a very few degrees of parallelism with the reflecting zinc. Prof. Tesla thinks the theory that the X-rays consist of streams of radiant matter, is confirmed by these results. He has not yet been able to detect any refraction of the X-rays."

In the summary of work done in connection with Röntgen rays (page 522), we give an account of experiments made by Prof. Joly, which demonstrate the existence of reflection.

"In confirmation of these experiments," writes Mr. Alfred W. Porter, "may I point out that a similar phenomenon to that described by Prof. Joly has been present on all my skeletal radiographs. Immediately surrounding the sharp geometric shadow of the flesh of the fingers a black line exists on the *negative*. This is especially noticeable where two fingers overlap one another; the partial shadow cast by one finger preventing the deposit on the plate from becoming so dense as to obscure h presence of the black line. I enclose a *positive* which shows the presence of the corresponding white line very clearly. My attention was first called to the presence of this line on my pictures on January 28, by Mr. John T. Morris, of this College. I believe that the prominence of the finger-nails is due to the same cause. I have also taken graphs of over-lapping wood, metal, and ivory objects which exhibit the same phenomena."

We have received the prints referred to by Mr. Porter, and they entirely bear out his description of the appearance presented.

For some time past Prof. FitzGerald and Mr. Fred. T. Trouton, at Trinity College, Dublin, have sought evidence of crystalline action, both on transmission and reflection at grazing incidence of Röntgen rays. Though so far this has been without success, we learn that they have noticed a marked scattering of the rays in transmission through some substances. The following arrangement is convenient for showing this. "On a plate of lead, which has a slit cut in it, is placed a sheet of, say, solid paraffin 2 or 3 m.m. thick, so as to cover one end of the slit; over this is laid a strip of lead—but slightly wider than the slit—so as to just entirely cover the slit. No direct radiation then can pass from a Crookes' tube, placed vertically over the slit, to a sensitive plate placed behind the lead; but with a lengthened exposure (20 to 30 minutes) with a focus tube, a darkening is found on developing at the end where the paraffin is placed. If the paraffin be then moved to the centre or other end, so as to eliminate accidental effects, on again exposing the darkening action is found to follow the paraffin. Some darkening always occurs even where there is no solid body. How much of this is due to successive reflections from the lead sheet and strip, or how much is due to scattering of the rays by air, is not easy to say."

Mr. Dayton C. Miller has obtained some good results at Case School of Applied Science in Cleveland, Ohio, U.S.A., but the exposures he finds necessary are longer than those given by the foremost workers in Great Britain. The tube used by him is spherical in shape, and about five inches in diameter. The coil gives a six-inch spark in air, and is excited by a current of about sixty watts, obtained from fifteen cells of storage battery. The voltage used varies from twelve to twenty. With this apparatus and power, Mr. Miller says:—

"The bones of the fingers are distinctly shown with exposures of ten seconds, while exposures varying from two to ten minutes are regularly used in locating bullets and shot in the hand, and in examining injured or deformed hands. An excellent picture of a hand and fore-arm, placed diagonally across an 11 × 14 plate, has been made with twenty minutes' exposure. The entire detail of the lettering and design of an aluminium medal has been taken in five minutes. Numerous interesting surgical cases of fractured and diseased arm-bones have been examined with satisfactory results. Photographs of the chest and head have been made with exposures of one hour in each case. A surprising amount of detail is visible. The chest picture shows the shoulder-joint, the collar-bone, the spinal column with its articulations, and a dark streak along its length corresponding to the spinal cord, and eight ribs on each side of the spine. In the region of the heart the detail is less conspicuous, indicating that the heart is more opaque than the lung tissue."

Mr. W. L. Goodwin, of the School of Mining, Kingston, Canada, has sent us the results of experiments made to determine the relative opacities of various substances to Röntgen rays. The only details as to the method employed is that the results were obtained "by photography with a small Crookes' tube similar in shape to a radiometer, but constructed to show the revolution of a platinum vane covered on one side with mica." The relative opacities thus determined are as follows:—

I. Solids:—

Transparent: Paraffin wax, wood charcoal, coke (in part), asphalte, albertite, starch, diamonds.

Fairly transparent: Citric acid, jet, anthracite, amber, natrolite, caustic potash, caustic soda, borax, soda crystals.

Somewhat transparent: Silicified wood, Epsom salts, serpentine, staurolite, stilbite, lazulite, $H_2(NH_4)PO_4$, cryolite, Mohr's salt, analcite, Na_2CO_3, borax glass, nitre, Rochelle salt.

Somewhat opaque: Mica, tourmaline, wulfenite, axinite, spinel, calcite, aragonite, kaolin, $NiSO_4(NH_4)_2SO_4.6H_2O$, $NiSO_4.K_2SO_4.6H_2O$, &c.

Opaque: Roll sulphur, crystal of rhombic sulphur, fluor-spar, topaz, beryl, ruby, quartz, NaCl, chalco-pyrite, $H_2(NH_4)AsO_4$, H_2KAsO_4, K_3FeCy_6, $K_2Cr_2O_7$, orpiment, anhydrite, celestine, barite.

Sulphuric acid is as opaque as the same thickness of sulphur. Water is more opaque than paraffin wax.

A number of crystals of about the same thickness were photographed on the same plate, and an attempt made to judge of their relative transparency with a scale from 1 to 10, with the following results:—

H_2KAsO_4	1
$H_2(NH_4)AsO_4$...	2
$NiSO_4.(NH_4)_2SO_4.6H_2O$	3
$MgSO_4.K_2SO_4.6H_2O$...	3
$NiSO_4.K_2SO_4.6H_2O$	3·5

The different values of arsenic and phosphorus in the isomorphous acid arseniates and phosphates are to be remarked.

Thin sections of a granite composed principally of quartz and feldspar and of a hornblende-gabbro were photographed. In both cases the feldspar was found to be distinctly more transparent than the other constituents.

Prof. E. Doelter, of Graz, has communicated to the *Naturwissenschaftliche Verein für Steiermark* some observations relating to the opacity of different rocks and minerals for the Röntgen rays, and their use as providing a test of the genuineness of precious stones. Dr. Doelter finds that (1) the opacity does not always increase with the density, although minerals having a specific gravity greater than 5 are relatively opaque; (2) the complexity of the chemical constitution of a mineral affects its opacity, but no general law of relationship can be enunciated; (3) dimorphous minerals exhibit but slight differences in their behaviour with regard to the rays in their different forms; (4) in most crystals, the amount of absorption does not depend sensibly on the direction of the incident rays; (5) all minerals naturally fall into about eight well-defined groups, according to their opacity, the order being as follows: diamond, corundum, talc, quartz, rock-salt, Iceland spar, &c. The diamond is ten times as transparent as corundum, and 200 times as transparent as tinfoil.

Mr. W. Ackroyd and Mr. H. B. Knowles have systematically examined the opacity of a number of substances for Röntgen rays, with a view to determining whether it bears any relation to molecular weight (*Journal* of the Society of Dyers and Cleaners, April).

With this view they have compared the isomorphous sulphates, RSO_4, $7H_2O$ of the eighth group of metals, iron, nickel, and cobalt; the oxides, RO, of some members of the second natural group, viz. magnesium, zinc, and mercury; the isomorphous oxides, R_2O_3, of the metals aluminium, chromium, and iron. In each of these series there are presumably similarly shaped molecules for comparison, and the disturbing factor is the difference of molecular weight. The result of an hour and a half's exposure showed that the alumina was practically transparent, the chromium sesquioxide semi-transparent, while the ferric oxide was opaque. In other words, the opacity of the substance was in some direct relation to the molecular weight. There are here marked differences with big jumps in molecular weights. The same observation applies to the oxides of magnesium, zinc, and mercury. The isomorphous sulphates of iron, nickel, and cobalt are extremely interesting, because of the nearness of the specific gravity numbers, and also of the molecular weights. The iron compound, with lower specific gravity and molecular weight, appears to be the least opaque of the three, while the nickel and cobalt compounds of nearly the same specific gravity and molecular weight have approximately the same degree of opacity. The following table correlates these facts with other properties:—

Compound.	Sp. gr.	Molecular weight.	Colour.	Behaviour to Röntgen rays.
$FeSO_4$, $7H_2O$	1·85	278	Light green	Slightly less opaque than others in this group.
$NiSO_4$, $7H_2O$	1·95	280	Deep green	About the same relative opacity.
$CoSO_4$, $7H_2O$	1·92	281	Pink	
Al_2O_3	4·00	103	White ...	Transparent.
Cr_2O_3	4·99	153	Green ...	Semi-opaque.
Fe_2O_3	5·13	160	Brown ...	Opaque.
MgO	3·42	40	White ...	Transparent.
ZnO	5·47	81	White ...	Semi-opaque.
HgO	11·13	216	Red	Opaque.

The foregoing figures, conclude the authors, demonstrate the weakness of an unqualified law of density, as the denser oxide of zinc is more transparent than the less dense ferric oxide. But they point out that, adopting the legitimate method, which they have initiated, of comparing only compounds with kinship, each of the above bodies conforms to the law of density as well as of molecular weight in relation to opacity.

Dr. A. Sella and Dr. Q. Majorana (*Rend. R. Accad. dei Lincei*) describe certain experiments on the influence of Röntgen rays on the sparks produced by the discharge of an induction coil in air. The sparking distance is found to be shortened by the Röntgen rays, this effect taking place whenever these rays fall on the positive pole. In this respect the phenomenon is the reverse of that obtained by Hertz with ultra-violet light, the effect of which is to lengthen the sparking distance whenever it falls on the negative pole. The authors found that the simultaneous actions of Röntgen rays and of ultra-violet light could be made to neutralise each other by arranging the coil to give a spark of suitable length (in their experiments about 30 mm.). When the sparking distance was less, the Hertz effect predominated; when the sparking distance exceeded 30 mm., the Röntgen rays had the greater influence.

Dr. Filippo Campanile and Dr. Emilio Stromei communicate to the *Rendiconto dell' Accademia delle Scienze fisiche e matematiche* (Naples) a note on the phosphorescence and the Röntgen rays in Crookes' and Geissler's tubes. The conclusions arrived at are as follows: (1) When in the circuit of an induction coil, containing a Crookes' tube, a spark is thrown off from the positive pole, the phosphorescence of the tube and the efficacy of the Röntgen radiations are augmented. (2) As the length of the spark increases the phosphorescence at first increases to a maximum, and then decreases. (3) If, on the other hand, the spark is thrown off from the negative pole, the phosphorescence and the Röntgen rays are thereby diminished. The same experimenters have also succeeded in obtaining Röntgen rays with an ordinary Geissler's tube. These radiations possessed all the characteristics of those which emanate from a Crookes' tube.

Signor E. Villari, writing in the same journal, considers that the phenomena of discharges in tubes seem to indicate the existence not only of kathodic but also of anodic rays. While the kathodic rays travel in straight lines and produce a negative charge wherever they strike the tube, the suggested anodic rays diffuse themselves all round the anode, and communicate a positive charge to the whole surface of the tube over which they are diffused.

The fundamental character of the new rays has led speculators to make various surmises as to a possible connection between these radiations and the phenomenon of gravitation, and two lengthy memoirs have been written on the subject by Rudolf Mewes.[1] In the second of these the author claims to have proved experimentally that gravitation is propagated through the ether with the velocity of light.

Finally, attention may profitably be called in this summary to the April number of the *Proceedings* of the Physical Society. In the admirable collection of abstracts of physical papers there published, will be found concise descriptions of the scope and results of no less than forty papers concerned with Röntgen rays.

COLOUR PHOTOGRAPHY.

THE scientific event of last week was the description and demonstration of colour photography given by Prof. Lippmann before the Royal Society. On the occasion of the centenary celebrations of the Institute of France last year, Lord Kelvin invited Prof. Lippmann to give the Royal Society an account of his researches on photography in colours, and last Thursday's meeting was the result. The methods employed by Prof. Lippmann are well known among men of science, but few of the Royal Society were prepared to see such remarkable results as those obtained and exhibited by the distinguished French physicist. The honour and fine feeling which such visits bring to the Society, and the extreme interest aroused, should help to make similar occasions of more frequent occurrence. We print Prof. Lippmann's lecture below, and our only regret is that it cannot give an at all adequate conception of the striking achievement with which it deals.

The problem of colour photography is as old as photography itself. The desire of fixing the colours as well as the design of the beautiful image thrown on the screen of the camera, very naturally occurred to the earliest observers. Since the beginning of this century three distinct solutions of the problem have been realised.

The first solution, not quite a complete one, is founded on the peculiar properties of a silver compound, the violet subchloride of silver. E. Becquerel (1860) converted the surface of a daguerreotype plate into this silver compound, and by projecting on it the image of the solar spectrum, and other objects, obtained good coloured impressions. Poitevin substituted paper for the silver plate as a substratum. No other substance has been discovered that can play the part of the subchloride of silver. Moreover the image is not fixed, in the photographic sense of the word; that is, the coloured impression is retained for any length of time in the dark, but it is blotted out by the action of daylight. The reason of it is this: the Becquerel images are formed by coloured silver-compounds, which remain sensible to light; so that they are destroyed by the continued action of light, in virtue of the same action which gave them birth. Despite the numerous experiments made by Becquerel, Poitevin, Zenther, and others, no substance has been found that is capable of destroying the sensibility of the subchloride for light without at the same time destroying its colour.

The second method for colour photography is an indirect one, and may be called the three-colour method. It was invented in France by Ch. Cros, and at the same time by M. Ducos du Hauron (1869). German authorities claim the priority of the idea for Baron Bonstetten. Three separate negatives (colourless) are taken of an object through three coloured screens. From these three positives (equally colourless) are made; and, lastly, the colour is supplied to these positives by means of aniline dyes or coloured inks. Thus three coloured monochromatic positives are obtained, which by superposition give a coloured image of the model. In the ingenious process lately invented by Prof. Joly, the three negatives, and apparently the corresponding three positives, are obtained interwoven on one and the same plate. The three-coloured method can give a very good approximation to the truth, and has probably a great future before it. We may call it, nevertheless, an indirect method, since the colours are not generated by the action of light, but are later supplied by the application of aniline dyes or other pigments. Moreover, the choice of these pigments, as well as of the coloured screens through which the negatives have been obtained, is in some degree an arbitrary choice.

The third and latest method by which colour photography has been realised is the interferential method, which I published in 1891, and the results of which I beg to lay before you this evening. It gives fixed images, the colours of which are due to the direct action of the luminous rays.

For obtaining coloured photographs by this method, only two conditions are to be fulfilled. We want (1) a transparent grainless photographic film of any kind, capable of giving a colourless fixed image by the usual means; and (2) we want a metallic mirror, placed in immediate contact with the film during the time of exposition.

A mirror is easily formed by means of mercury. The photographic plate being first enclosed in a camera-slide, a quantity of mercury is allowed to flow in behind the plate from this small reservoir, which is connected with the slide by a piece of india-rubber tubing.[1] The slide is then adapted to the camera, and the action of light allowed to take place. After exposure the slide is separated from the camera, the mercury reservoir lowered so as to allow the mercury to flow back into it; the photographic plate is then taken out, developed and fixed. When dry, and examined by reflected light, it appears brilliantly coloured.

The sensitive film may be made either of chloride, iodide, or bromide of silver, contained in a substratum either of albumen, collodion, or gelatine. The corresponding developers, either acid or alkaline, have to be applied; the fixation may be cyanide or bromide of potassium. All these processes I have tried with success. For instance, the photograph of the electric spectrum now projected before your eyes, has been made on a layer of gelatino-bromide of silver, developed with amidol, and fixed with cyanide of potassium.

As you see, bright colour photographs may be obtained without changing the technique of ordinary photography; the same films, developers and fixators have to be employed; even the secondary operations of intensification and of isochromatisation are made use of with full success. The presence of the mirror behind the film during exposure makes the whole difference. From a chemical point of view nothing is changed, the result being a deposit of reduced silver left in the film, a brownish, colourless deposit. And yet the presence of a mirror during exposure causes the colourless deposit to show bright colours. Of course we want to know how this is done; we require to understand the theory of those colours.

We all know that colourless soap-water gives brilliant soap-bubbles; the iridescence of mother-of-pearl takes birth in colourless carbonate of lime; the gorgeous hues of tropical birds are simply reflected from the brownish substance which forms the feathers. Newton discovered the theory of these phenomena, and subjected them to measurement; he invented for the purpose the experiment called by the name of Newton's rings. Newton showed, as you know, that when two parallel reflecting surfaces are separated by a very short interval, and illumined by white light, they reflect only one of the coloured rays which are the constituents of white light. If, for instance, the interval between the reflecting surface is only $\frac{2}{10000}$ of a millimetre, violet rays are alone reflected, the rest being destroyed by interference; that is, the two surfaces send back two reflected rays whose vibrations interfere with one another, so as to destroy every vibration except that which constitutes violet light. If the interval between the reflecting surfaces be augmented to $\frac{3}{10000}$ of a millimetre, the destruction of vibration takes place for every vibration except that of red light, which alone remains visible in this case.

If we consider now this photograph of the spectrum, and especially the violet end of the image, we find that this is formed by a deposit of brown reduced silver. In the case of an ordinary photograph, this deposit would simply be a formless cloud of metallic particles; here the cloud has a definite, stratified form; it is divided into a number of thin, equidistant strata, parallel to the surface of the plate, and $\frac{2}{10000}$ of a millimetre apart. These act as the reflecting surfaces considered by Newton, and as they are at the proper distances for reflecting violet rays, and these alone, they do reflect violet rays.

The red extremity of the photograph is equally built up of strata which act in a like manner; only their distance intervals here amount to $\frac{3}{10000}$ of a millimetre, and that in the proper interval for reflecting red light. The intermediate parts of the spectral image are built up with intermediate values of the interval, and reflect the intermediate parts of the spectrum.

The appearance of colour is therefore due to the regular structure above described, imprinted on the photographic deposit. The next question is—How has this very fine, peculiar, and adequate structure been produced?

It is well known that a ray of light may be considered as a regular train of waves propagated through the ether, in the same way as waves on the surface of water. The distance between two following waves is constant, and termed the wave-length; each sort of radiation, each colour of the spectrum, being characterised by a particular value of the wave-length. Now, when a ray of light falls on a sensitive film, this train of waves simply rushes through the film with a velocity of about 300,000 kilometres per second; it impresses the film more or less strongly, but leaves no record of its wave-length, of its particular

[1] The glass of the photographic plate has to be turned towards the objective, the film in contact with the metallic mirror.

nature or colour, every trace of its passage being swept out of form by reason of its swift displacement. The impression therefore remains both uniform and colourless. Things change, however, as soon as we pour in mercury behind the plates, or otherwise provide for a mirror being in contact with it. The presence of the *mirror* changes the propagated waves into *standing* waves. The reflected ray is, namely, thrown back on the incident ray, and interferes with its motion, both rays having equal and opposite velocities of propagation. The result is a set of standing waves—that is, of waves surging up and down each in a fixed plane. Each wave impresses the sensitive film where it stands, thus producing one of these photographic strata above alluded to. The impression is latent, but comes out by photographic development. Of course the distance between two successive strata is the distance between two neighbouring waves; this, theory shows, is exactly half the wave-length of the impressing light. In the case of violet, for instance, the wave-length being $\frac{4}{10000}$ millimetres, half the wave-length in the above quoted distance of $\frac{2}{10000}$ millimetres; this, therefore, is at the same time the interval between two standing waves, in the case of violet light, the interval between two successive photographic strata, and at last it is the interval required to exist, according to Newton's theory, for the said strata reflecting violet rays, and making these alone apparent, when illumined by white light.

The colours reflected by the film have the same nature and origin as those reflected by soap-bubbles or Newton's rings; they owe their intensity to the great number of reflecting strata. Suppose, for instance, the photographic film to have the thickness of a sheet of paper (one-tenth of a millimetre), the fabric built in it by and for a violet ray is five hundred stories high, the total height making up one-tenth of a millimetre. Lord Rayleigh, in 1887, has proved *à priori* that such a system is specially adapted to reflect the corresponding waves of light.

How are we now to prove that the above theory is really applicable to the colour photograph you have seen? How can we demonstrate that those bright colours are due not to pigments, but to the interference, as in the case of soap-bubbles? We have several ways of proving it.

First of all, we are not bound to the use of a peculiar chemical substance, such as Becquerel's subchloride of silver; we obtain colours with a variety of chemicals. We can, for instance, dispense entirely with the use of a silver salt; a film of gelatine or coagulated albumen impregnated with bichromate of potash, then washed with pure water after exposure, gives a very brilliant image of the spectrum.

Secondly, the colours on the plate are visible only in the direction of specular reflection. The position of the source by which we illumine the photograph being given, we have to put the eye in a corresponding position, so as to catch the regularly reflected rays. In every other position we see nothing but a colourless negative. Now, as you are aware, the colours of pigments are seen in any direction. By projecting again a photograph of the spectrum, and turning it to and fro, I can show you that the colours are visible only in one direction.

Thirdly, if we change the incidence of the illuminating rays, that is, if we look at the plate first in a normal direction, then more and more slantingly, we find that the colours change with the incidence exactly as they do in the case of soap-bubbles, or of Newton's rings; they change according to the same law, and for the same reasons. The red end of the spectrum turns successively to orange, yellow, green, blue, and violet. The whole system of colours, the image of the spectrum, is seen to move down into the part impressed by the infra-red. This is what we expect to happen with interference colours, and what again we cannot obtain with pigments.

Fourthly, if while looking at the film normally, we suffer it to absorb moisture—this can be done by breathing repeatedly on its surface—we see that the colours again change, but in an order opposite to that above described. Here the blue end of the spectrum is seen to turn gradually green, yellow, orange, red, and finally infra-red, that is, invisible. The spectrum this time seems to move up into the ultra-violet part of the improved film. By suffering the water to evaporate, the whole image moves back into its proper place; this experiment may be repeated any number of times.

The same phenomenon may be obtained with Newton's apparatus, by slowly lifting the lens out of contact with the plane surface. The explanation is the same in both cases. The gelatine swells up when imbibing moisture. If we consider, for instance, the violet of the spectrum, the small intervals between the strata, corresponding to violet rays, gradually swell up to the values proper for green, and for red, and for infra-red; green, then red, then infra-red, are therefore successively reflected.

We will wet this photograph of the spectrum with water, project it on the screen, and watch the colours coming back in the order prescribed by theory.

It is necessary to use a transparent film, since an opaque one, such as is commonly in use, would hide the mirror from view; the sensitive substance must be grainless, or, at least, the grains must be much finer than the dimensions of the strata they are intended to form, and therefore wholly invisible. The preparation of transparent layers gave me at first much trouble; I despaired for years to find a proper method for making them. The method, however, is simply thus: if the sensitive substance (the silver bromide, for instance) be formed in presence of a sufficient quantity of organic matter, such as albumen, gelatine, or collodion, it does not appear as a precipitate; it remains invisible; it *is* formed, but seems to remain dissolved in the organic substratum. If, for instance, we prepare a film of albumeno-iodide in the usual way, only taking care to lessen the proportions of iodide to half per cent. of the albumen, we get a perfectly transparent plate, adapted to colour photography.

We want now to go a step further. It is very well for physicists to be contented with working on the spectrum, since that contains the elements of every compound colour; but we all desire to be able to photograph other objects than the spectrum—common objects with the most compound colours. We have again but to take theory as a guide, and that tells us that the same process is able to give us either simple or compound colours. We have then to take a transparent and correctly isochromatised film, expose it with its mercury backing, then develop and fix it in the usual way; the plate, after drying, gives a correct coloured image of the objects placed before the camera. Only one exposure, only one operation is necessary for getting an image with every colour complete.

A plausible objection was offered at first to the possibility of photographing a mixture of simple colours. The objection was this: a ray of violet gives rise to a set of strata separated by a given interval; red light produces another set of strata with another interval; if both co-exist, the strata formed by the red are sure to block out here and there the intervals left between the strata formed by the violet. Is it not to be feared that one fabric will be blurred out by the other, and the whole effect marred? The confusion would be still worse if we consider the action of white light, which contains an infinity of simple components; every interval here is sure to be blocked up.

Mathematical analysis, however, shows this objection to be unfounded; we have great complexity, but not confusion. Every compound ray, both coloured and white, is faithfully rendered. As an experimental proof of this, we will project on the screen photographs of very different objects, namely, stained-glass windows, landscapes from nature, a portrait made from life, and vases and flowers.

That the colours here observed are due to interference, and not to the presence of pigments, can be shown in the same way as with the spectrum. Here, again, we observe that the colours are visible only in the direction of specular reflection, that they change with the angle of incidence, that they change and disappear by wetting, and reappear by drying. Pigments remain equally visible and unaltered in colour under every incidence. If we attempted to touch up one of our photographs with oil or water-colours, the adulterated place would stand out on a colourless background by merely obscuring by diffused light. It is therefore impossible either to imitate or touch up a colour photograph made by the above described interferential method.

THE INFLUENCE OF ATMOSPHERIC AND OCEANIC CURRENTS UPON TERRESTRIAL LATITUDES.[1]

ALTHOUGH the following theorem should be implicitly contained in the formula for the rotation of a spheroid carrying a fluid on its surface, I have nowhere seen it explicitly stated.

Theorem.—Let an unconstrained, rigid sphere, with equal moments of inertia, be in a state of free rotation:

Let this sphere bear on its surface a sheet or sheets of continuous movable matter:

[1] Reprinted from the *Astronomical Journal*, No. 371, April 6.

Let this movable matter be kept in a state of steady motion relative to the sphere, by actions and reactions between it and the sphere, without the action of any external force :

Let P be the pole of the axis of rotation of the sphere, which will also be its momental axis :

Let Q be the momental axis of the total motions of the movable matter relative to the sphere :

Let I be the moment of inertia of the sphere, and M the total moment of momentum of all the movable matter around the axis Q :

Then shall the sphere take such a motion that the pole P, while remaining in a fixed direction in space from the centre of the sphere, shall move steadily relatively to the matter of the sphere around the pole Q, with an angular velocity M/I.

The application of this theorem to the case of the earth surrounded by its oceanic and atmospheric envelopes can now readily be seen. To obtain the value of M, we may roughly estimate the ratio of the moment of inertia of the earth to that of the ocean as 2600, and to that of the atmosphere as 1,000,000.

Observations, as discussed by Chandler, and interpreted by theory, indicate an annual change in the pole of the earth, which would be produced by a primary oscillation back and forth through a length of ten feet, or a revolution in a circle having a diameter of five feet. The former motion would, according to the theorem, be the necessary result of a general motion of the oceans on the two sides of the earth, which, at the point where the motion was a maximum, would be 2600 times as great. Approximately this motion would be represented by a continuous flow of the central parts of the Pacific ocean toward the pole of about 150 feet per day, with a correspondingly larger motion of the Atlantic in the opposite direction; followed by an opposite oscillation during the other six months. If, as may seem very likely, there cannot be so great a differential flow as this through Behring Strait, and between the American and Asiatic continents, it will be necessary to suppose a more rapid flow elsewhere, or a sufficient vortex in the currents of the Atlantic and Pacific oceans. Whether the currents in these oceans are deep enough to produce the observed effect must be left to hydrographers to decide.

Passing to the atmosphere, the excess of motion through one season over that of the other season, to and from the north direction, amounting to 4000 miles in six months, or say twenty miles per day, would also account for the observed change. In these statements respecting the required motions of the earth and atmosphere, I have presupposed a motion around an invariable momental axis. If the motions are such that their momental axis moves around the earth in the course of a year, the required differential motions between the opposite seasons would be only half as great.

In what precedes I have spoken of the earth as a sphere, and considered only differential motions. The actual earth being a spheroid, the motion of the pole already described would not be continuous. The actual effect of oceanic and atmospheric currents of a permanent character on the terrestrial spheroid would be to displace the mean pole of the earth from its pole of figure to such a point of equilibrium that the motion described in the theorem would be neutralised by an equal and opposite Eulerian motion, due to the ellipticity of the spheroid. The actual effect would be a revolution of the terrestrial pole, according to the known laws of rotation, around the central point of equilibrium thus fixed in 427 days. Just what the displacement is can be only a matter of guess-work; from the known magnitude of the ocean currents they might produce a displacement ranging from ten to twenty feet.

A brief statement of the character of the theoretical variations of the latitude, due to these causes, may not be inappropriate. Since the directions of the currents of the air and ocean go through an annual period, we should expect a corresponding period in the latitude. Since, however, the amount of the annual change varies irregularly from year to year, though remaining constant in the general mean, the amplitude of the annual term should be subject to small variations from time to time, while preserving its mean value unchanged from age to age.

On the other hand, the amplitude of the Eulerian motion being permanently increased or diminished by every meteorological change, may be expected to vary its amplitude in a slow and irregular manner from decade to decade. The Eulerian motion, having a period of 427 days, ought to be nearly circular, unless the equatorial moments of inertia of the earth differ much more than we can suppose probable. The annual motion may differ somewhat from a circle, and be somewhat less regular. There can be no strictly periodic changes in the latitude but these two, but it is quite possible that, owing to secular changes, or changes continued through several years, in the currents of the ocean and atmosphere, corresponding changes of irregular long period may be found in the latitude.

It will be seen that these conclusions are accordant with Chandler's results as regards the double period, but do not fully agree with them in other details. SIMON NEWCOMB.

THE PAST, PRESENT, AND FUTURE WATER SUPPLY OF LONDON.[1]

IN a discourse to the members of the Royal Institution on the subject of the metropolitan water supply nearly thirty years ago, I stated that out of every thousand people existing upon this planet three lived in London; and, as the population of London has, in the meantime, doubtless grown at a more rapid rate than that of the rest of the world, it will probably be no exaggeration to say that now, out of every thousand people alive on this earth, four live in London; and therefore, any matter which immediately concerns the health and comfort of this vast mass of humanity may well merit our most earnest attention. Amongst such matters, that of the supply, in sufficient quantity, of palatable and wholesome water, is certainly not the least in importance.

It is not therefore surprising that this subject has received much attention from several Royal Commissions—notably from the Royal Commission on Water Supply of 1867, presided over by the Duke of Richmond; the Royal Commission on River Pollution and Domestic Water Supply of Great Britain, presided over by the late Sir William Denison, of which I had the honour to be a member; and, lastly, that of 1892, of which Lord Balfour of Burleigh was the chairman.

The Royal Institution has, for nearly three-quarters of a century, been prominently connected with the investigation and improvement of the metropolitan water supply; no less than four of our Professors of Chemistry have been successively engaged in this work, namely Profs. Brand, Odling, Dewar, and myself, whilst three of them have been members of the Royal Commissions just mentioned. I may therefore perhaps be excused for bringing the subject under your notice again for the third time.

On the present occasion, I propose to consider the subject from three points of view, viz. the past, the present, and the future; and, for reasons which will appear hereafter, I shall divide the past from the present at, or about, the year 1883, and will not go back farther than the year 1828, when Dr. Brand, Professor of Chemistry in the Royal Institution, Mr. Telford, the celebrated engineer, and Dr. Roget, Secretary of the Royal Society, were appointed a Royal Commission to inquire into the quality and salubrity of the water supplied to the metropolis.

The Commissioners made careful examinations and analyses, and reported as follows. "We are of opinion that the present state of the supply of water to the metropolis is susceptible of, and requires, improvement; that many of the complaints respecting the quality of the water are well founded; and that it ought to be derived from other sources than those now resorted to, and guarded by such restrictions as shall at all times ensure its cleanliness and purity. (At this time the water was pumped from the Thames between London Bridge and Battersea.) To obtain an effective supply of clear water free from insects and all suspended matter, we have taken into consideration various plans of filtering the river water through beds of sand and other materials, and considering this, on many accounts, as a very important object, we are glad to find that it is perfectly possible to filter the whole supply, and this within such limits in point of expense as that no serious objection can be urged against the plan on that score, and with such rapidity as not to interfere with the regularity of the service."

Before the year 1829, therefore, the river water supplied to London was not filtered at all; but after the issue of this report the companies set themselves earnestly to work to improve the quality of the water by filtration.

[1] A discourse delivered by Dr. E. Frankland, D.C.L., LL.D., F.R.S., at the Royal Institution on February 21.

In the year 1832, and again in 1849, London was severely visited by epidemic cholera, and the agency of drinking-water in spreading the disease forced itself upon the attention of the observant portion of the medical profession. It was Dr. Snowe, however, who, in August 1849, first formally enunciated the doctrine that drinking-water polluted by choleraic matters is the chief mode by which cholera is propagated.

In every visitation of Asiatic cholera to London, the water supply was either altogether unfiltered or imperfectly filtered, besides being derived from highly polluted parts of the Thames and Lea; and the enormous loss of life, amounting in the aggregate to nearly thirty-six thousand people, can only be attributed to this cause; for it has now been satisfactorily proved that cholera is, practically, propagated by drinking-water alone; and that efficient filtration is a perfect safeguard against its propagation. Moreover, it is most satisfactory to know that, since the year 1854, no case of Asiatic cholera in London has been traced to the use of *filtered* river water. The first effect of Dr. Snowe's cardinal discovery was the removal of the intakes of the river water companies to positions beyond the reach of the tide and of the drainage of London. The second was the greater attention paid to the efficiency of filtration.

Such is the verdict in regard to cholera, and the same is true of that other water-borne disease typhoid fever. But unlike cholera, this disease is disseminated in several other ways, and its presence or absence in any locality may not, of necessity, have any connection with drinking-water; as is strikingly shown by the health statistics of Manchester, since the water supply of this city, derived as it is from mountain sources, is above all suspicion of this kind. These other causes have, during the last ten years, been much mitigated in London by various sanitary improvements; whilst, as shown in the diagram on the screen, there has been no corresponding mitigation in Manchester. There is no evidence whatever that, since the year 1869, when typhoid fever appeared for the first time as a separate disease in the Registrar General's report, it has been conveyed by the water supply of the metropolis.

Although very soon after the year 1856, all the water supplied to London was obtained from sources much less exposed to drainage pollution, it was still very carelessly filtered. Previous to the year 1868 there are no records of the efficiency, or otherwise, of the filtration of the metropolitan water supply derived from rivers; but at that time, I began to examine these waters for turbidity. In that year, out of 84 samples, 7 were very turbid, 8 turbid, and 10 slightly turbid; so that, altogether, no less than nearly 30 per cent. of the samples were those of inefficiently-filtered water. The metropolitan water supply then, up to the year 1868, may be shortly described as derived for many years from very impure sources with either no filtration at all, or with very imperfect filtration; and afterwards, when the impure sources were abandoned, the supply was still often delivered in a very inefficiently-filtered condition. But after the establishment of monthly reports, the quality of these waters gradually improved in this most important respect down to the year 1883, since which time the efficiency of filtration of all the river waters supplied to the metropolis has left little to be desired.

What is it, then, that separates the past from the present water supply of London? In the first place, there is the change of source—I mean the change of the position of the intakes of the several companies drawing from the Thames and Lea, and the total abandonment of the much-polluted Ravensbourne by the Kent Water Company. So long as the water was derived from the tidal reaches of the Thames and Lea, receiving the drainage of an immense population, the risk of infection from water-borne pathogenic organisms could scarcely be otherwise than imminent; for, although we now know efficient filtration to be a perfect safeguard, anything short of efficiency must be attended with risk in the presence of such extreme pollution.

Nevertheless, the line of demarcation between the past and the present water supply of the metropolis is, in my opinion, to be drawn, not when the intakes of the river companies were removed to positions beyond the possibility of pollution by the drainage of London; but, it must be drawn at the time when efficient filtration was finally secured and ever since maintained—that is to say, in the year 1884.

The removal of turbidity by sand filtration, however, refers only to suspended matter; but there are sometimes objectionable substances in solution, of which organic matter is the most important. River water and mountain water, even when efficiently filtered, contains more organic matter than spring or deep-well water; but this is reduced in quantity by storage and especially by filtration, although it can perhaps never be brought up to the standard of organic purity of spring and deep-well water.

The Present Water Supply.

At present London is supplied with water from four sources: the Thames, the Lea, the New River, and deep wells. Of these, the deep wells yield, as a rule, the purest water, requiring no filtration or treatment of any kind before delivery for domestic use. The river waters, on the other hand, require some kind of treatment before delivery—storage and subsidence in reservoirs, and filtration. The water from the Thames is abstracted at and beyond Hampton, that from the Lea is taken out at two points, viz. at Angel Road near Chingford, by the East London Water Company, and above Hertford by the New River Company, who convey it to Green Lanes by an open conduit twenty-five miles long, called the New River Cut, in which it is mixed with a considerable volume of spring and deep-well water.

Hitherto I have spoken of chemical purity, or comparative freedom from organic matter, only; but the spread of diseases, such as cholera and typhoid fever, through the agency of drinking-water, has no connection whatever with the chemical or organic purity of the water. These diseases are propagated by living organisms of extreme minuteness, to which the names bacilli, bacteria, microbes, and others have been given; and here comes the important question, how does filtration secure immunity from these water-borne diseases.

To Dr. Koch, of Berlin, we are indebted for the answer to this question. By his discovery of a means of isolating and counting the number of microbes and their spores in a given volume of water, we were, for the first time, put into possession of a method by which the condition of water as regards these living organisms, before and after filtration, could be determined with quantitative exactness. The enormous importance of this invention, which was first made known and practised in England in 1882 by the late Dr. Angus Smith, is evident when it is borne in mind that the living organisms, harmful or harmless, contained in water are of such extreme minuteness as, practically, to defy detection by ordinary microscopical examination. But, although the microscope cannot detect with certainty single bacteria or their spores, even the naked eye can easily discern towns or colonies consisting of thousands, or even millions, of such inhabitants.

Dr. Koch's method accomplishes at once two things: it isolates, in the first place, each individual microbe or germ; and, secondly, places it in conditions favourable for its multiplication, which takes place with such amazing rapidity that even in a few hours, or at most in two or three days, each organism will have created around itself a visible colony of innumerable members—a town, in fact, comparable to London itself for population. By operating upon a known volume of water, such as a cubic centimetre, for instance, the number of separate organisms or their spores in a given volume of the water under investigation can thus be determined.

In order to ascertain the effect of filtration upon the bacterial quality of the water, it is absolutely necessary that the sample should be taken immediately after it has passed through the sand filters; for, if it be obtained from the delivery mains in town—that is to say, after the water has passed through many miles of pipes—the rapid multiplication of these organisms, except in very cold weather, is such that a water which contains only a single living organism per c.c. as it issues from the filter, may contain 100 or 1000 in the same volume when, after several hours, it arrives at the consumer's premises.

Now, what is the effect of sand filtration, as carried out by the various water companies supplying London, upon the living matter contained in the raw river water? It is simply astounding—for water containing thousands of bacteria per c.c. (a single drop of Thames water sometimes contains three thousand separate living organisms) comes out from those filters with 50, 30, 10, or even less of these organisms per c.c., or the number of microbes in a single drop is reduced to 2, or even none.

Rather less than one-tenth of the total volume of water supplied to London is derived by the Kent Water Company from deep wells in the chalk. As it issues from the porous rock into the fissures and headings of these wells, this water is, in all probability, absolutely sterile; but by the time it has been

pumped up to the surface, it usually contains a small number of microbes. Thus during the year 1892 it contained, on the average, 6 per c.c.; in 1893, 13; in 1894, 15; and in 1895, 8.

Thus, although the deep-well water has, from a bacterial point of view, a decided advantage, the filtered river waters are not very far behind; and there is every reason to believe that, with the improvements which are now being carried out by the various river water companies, the Kent Company's water will, before long, be run very hard by the other supplies.

By the examination of the water as it issues from the filters, the utmost freedom from microbes, or maximum degree of sterility of each sample, is determined. This utmost freedom from bacterial life, after all sources of contamination have been passed, is obviously the most important moment in the history of the water; for, the smaller the number of microbes found in a given volume at that moment, the less is the probability of pathogenic organisms being present; and, although the non-pathogenic may afterwards multiply indefinitely, this is of no consequence in the primary absence of the pathogenic; but, it is only fair in describing the character of the present water supply of London to say that not a single pathogenic organism has ever been discovered even in the unfiltered water as it enters the intakes of the various companies, although these organisms have been diligently sought for. It is sometimes said that the non-pathogenic organisms found in water may be beneficial to man; but this idea is not borne out by their entire absence from the food which nature provides for young animals. Milk, if healthy, is absolutely sterile.

As it is at present impracticable to obtain water, uniformly at least, free from microbes, it is desirable to adopt some standard of bacterial purity, and 100 microbes per c.c. has been fixed upon, by Dr. Koch and myself, as the maximum number allowable in potable water. This standard is very rarely infringed by the London water companies, whilst I have every reason to hope that, in the near future, now that special attention is directed to bacterial filtration, it will not be approached within 50 per cent. This hope is based not only upon my own observations, but also upon the exhaustive and important investigations carried out at the Lawrence Experiment Station by the State Board of Health of Massachusetts, under the direction of Mr. George W. Fuller, the official biologist to the Board. More than six years have already been spent in the prosecution of these American experiments, and many thousands of samples of water have been submitted to bacterial cultivation.

These important experiments, and my own observations on the London waters continued for four years, lead to the following conclusions:—

(1) The rate of filtration between half a million and three million gallons per acre per day exercises, practically, no effect on the bacterial purity of the filtered water. It is worthy of note that the rates of filtration practised by the several water companies drawing their supplies from the Thames and Lea are as follows:—Chelsea Company, 1,830,000; West Middlesex, 1,359,072; Southwark Company, 1,568,160; Grand Junction Company, 1,986,336; Lambeth Company, 1,477,688; New River, 1,881,792; and East London, 1,393,920. Hence, not one of the London companies filters at the rate of two million gallons per acre per day; at which rate in the Massachusetts filters 99·9 per cent. of the microbes present in the raw water were removed.

(2) The effect of the size of the sand-grains used in the filters is very considerable. Thus, by the use of a finer sand than that employed by the Chelsea Company, the West Middlesex Company is able, with much less storage, to attain an equal degree of bacterial efficiency.

(3) The depth of sand, between the limits of 1 and 5 feet, exercises no practical effect upon bacterial purity, when the rate of filtration is kept within the limits just specified. Thus the New River Company, with 1·8 feet of sand on their filters, compares favourably with the Chelsea Company, the sand on whose filters is more than twice that depth. Placed in the order of thickness of sand on their filters, the Metropolitan companies range as follows:—Chelsea, Lambeth, West Middlesex, Southwark, East London, Grand Junction, and the New River. Placed in the order of efficient bacterial filtration, they range as follows:—Chelsea and West Middlesex (equal), New River, Lambeth, East London, Southwark, and Grand Junction.

(4) When there is such an accumulation of deposit on the surface of a sand-filter that, for practical purposes, sufficient water cannot be made to pass through it, the surface of the filter has to be scraped; that is to say, mud and about half an inch of the sand are removed from the surface. After this operation, there is often an increase in the number of bacteria in the filtered water, and it has been noticed that the increase is greater in shallow than in deep filters, and with high than with low rates of filtration; and there is no doubt that the effect of scraping is considerably magnified when the coarser descriptions of sand are employed, as is the case in the filters of the London water companies. I should therefore like to impress upon the engineers of these companies the desirability of using finer sands than are at present employed.

The lecturer here described a long series of experiments proving that the temperature of the water and the presence or absence of sunshine has little or no effect upon the number of microbes in river water, whilst the presence of flood water is almost invariably accompanied by an enormous increase in the number of microbes, showing that the microbial population of a river is directly dependent upon the volume of water flowing in its bed.

The Water Supply of the Future.

In view of the rapid increase of the population of London, fears have from time to time been entertained that the water supply from the Thames basin—that is to say, from the rivers Thames and Lea, supplemented by water from springs and deep wells within the basin itself—would soon be insufficient in quantity, whilst the quality of the water taken from the river has, up to comparatively recent date, been considered unsatisfactory. On these grounds various schemes have from time to time been brought forward for the supply of the metropolis from other river basins—from the Wye, the Severn, the river basins of North Wales, and of the lake districts of Cumberland and Westmoreland. It is worthy of note, however, that all the Royal Commissions have arrived unanimously at the conclusion that the quantity of water obtainable from the Thames basin is so ample as to render the necessity of going elsewhere a very remote contingency.

I shall now endeavour to put, very shortly, before you the facts which, in my opinion, prove that both as regards quantity and quality the Thames basin will, for a very long time to come, afford an abundant supply for the metropolis. There is, indeed, no river basin in Great Britain which affords such an abundant supply of excellent water as that available in the Thames basin. Besides that which flows directly into the rivers, this water is contained in the Chalk, Oolite, and Lower Greensand, which are the best water-bearing strata in the kingdom. From these strata it issues in copious springs of unsurpassed organic purity. For dietetic purposes there is no better water in the kingdom than the underground water of the Thames basin. For sentimental reasons, I should like to see it conveyed to the works of the various companies in special conduits; but we have seen that, on hygienic grounds, it may safely be allowed to flow down the bed of the Thames, if it be afterwards efficiently filtered.

So much for quality, now as to quantity. The basins of the Thames and Lea include an area of upwards of five thousand square miles. Of this, more than one-half, including the Oolitic, Cretaceous, and portions of the Tertiary formations, is covered by a porous soil upon a permeable water-bearing stratum. The remainder is occupied by the Oxford, Kimmeridge, Gault, and London clay; being thus covered by a clay soil upon a stiff and impervious subsoil. The annual rainfall of the district averages twenty-eight inches. The rivulets and streams of the Thames basin are formed and pursue their course on the clay land. There are no streams on the chalk. That which falls upon the porous stratum and does not evaporate sinks, mostly where it alights, and heaps itself up in the water-bearing stratum below, until the latter can hold no more. The water then escapes as springs at the lowest available points. Innumerable examples of these springs occur all round the edge of the Thames basin, and at various points within it. Thus from the Chalk they are ejected at the lip of the Gault, and in the Oolitic area by the Fuller's earth below it, or by the Oxford clay, geologically, above it.

According to the gaugings of the engineer of the Thames Conservancy Board, there passed over Teddington Weir, in 1892, 387,000 millions of gallons, equal to an average flow of 1060 millions daily. In the following year, 1893, there passed over this weir an aggregate of 324,227 millions of gallons, or a

daily average of 888 millions of gallons, the average for the two years being 974 millions of gallons; and this number does not include 120 millions of gallons daily abstracted by the five London water companies who draw their supplies from the Thames. Thus, in round numbers, we may say that, after the present wants of London have been supplied from this river, there is a daily average of nearly a thousand millions of gallons to spare. Surely it is not too violent an assumption to make that the enterprising engineers of this country can find the means of abstracting and storing, for the necessary time, one-fourth of this volume.

As regards the quality of this stored water, all my examinations of the effect of storage upon the chemical, and especially upon the bacterial quality, point to the conclusion that it would be excellent; indeed, the bacterial improvement of river water by storage, for even a few days, is beyond all expectation. Thus the storage of the Thames water by the Chelsea Company for only thirteen days reduces the number of microbes to one-fifth the original amount, and the storage of the river Lea water for fifteen days by the East London Company reduces the number, on the average, from 13,693 to 2752 per c.c., or to one-fifth. Indeed, quietness in a subsidence reservoir is, very curiously, far more fatal to bacterial life than the most violent agitation in contact with atmospheric air; for the microbes which are sent into the river above the Falls of Niagara by the city of Buffalo seem to take little or no harm from that tremendous leap and turmoil of waters; whilst they subsequently, very soon, almost entirely disappear in Lake Ontario. Thus it is not too much to expect that storage for, say, a couple of months, would reduce the number of microbes in Thames flood water down to nearly the minimum ever found in that river in dry weather; whilst, by avoiding the first rush of each flood, a good chemical quality would also be secured. There is therefore, I think, a fair prospect that the quantity of water derivable from the Thames at Hampton could be increased from its present amount (120 millions of gallons per diem) to 370 millions.

Again, in the river Lea, although here the necessary data for exact calculation are wanting, it may be assumed that the present supply of fifty-four millions of gallons could be increased by the storage of flood water to 100 millions of gallons per day. To these volumes must be added the amount of deep-well water which is obtainable from those parts of the Thames basin which lie below Teddington Lock; and in the Lea basin below Lea Bridge, and which was estimated by the last Royal Commission at rather more than 67½ millions of gallons. Thus we get the grand total of 537½ millions of gallons of excellent water obtainable within the Thames basin, the quality of which can be gradually improved, if it be considered necessary, by pumping from the water-bearing strata above Teddington and Lea Bridge respectively; instead of taking the total supply from the open rivers above these points. Such a volume of water would scarcely be required for the whole supply of the water area of London at the end of fifty years from the present time, even supposing the population to go on increasing at the same rate as it did in the decade 1881-91, which is an assumption scarcely likely to be verified.

In conclusion, I have shown that the Thames basin can furnish an ample supply for fifty or more years to come, whilst the quality of the spring and deep-well water and the efficiently-filtered river water would be unimpeachable. To secure these benefits for the future, storage must be gradually provided for 11,500 millions of gallons of flood water, judiciously selected, in the Thames Valley, and a proportionate volume in the basin of the Lea; whilst filtration must be carried to its utmost perfection by the use of finer sand than is at present employed, and by the maintenance of a uniform rate during the twenty-four hours.

The lecturer concluded as follows. There nothing heroic in laying pipes along the banks of the Thames, or even in making reservoirs in the Thames basin. They do not appeal to the imagination like that colossal work—the bringing of water to Birmingham from the mountains of Wales; and there is little in such a scheme to recommend it to the mind of the enterprising engineers of to-day. Nevertheless, by means of storage, by utilising springs, by sinking deep wells, and by such comparatively simple means, we have, in my opinion, every reason to congratulate ourselves that for half a century, at least, we have at our doors, so to speak, an ample supply of water which, for palatability, wholesomeness, and general excellence will not be surpassed by any supply in the world.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The Conference on Secondary Education, held in the Senate House on April 21 and 22, was largely attended by representatives of all the various educational authorities. The discussions were in some cases animated, and turned largely on the provisions of the new Education Bill; but the resolutions prepared, in support of the Report of the Royal Commission on Secondary Education, were in every instance passed by large majorities.

Dr. A. A. Kanthack, of St. John's College, has been appointed Deputy-Professor of Pathology for the present Term, in place of Prof. Roy, who is unable to lecture.

Dr. H. Frank Heath, Fellow of University College, London, has been elected Assistant Registrar in the University of London, in the place of Mr. Dickens, who has succeeded Mr. Milman as Registrar.

A special meeting of the Board of Governors of the Yorkshire College was held on Wednesday, April 23, in the Philosophical Hall, Leeds. The business before the meeting was to obtain the assent of the Governors to the borrowing by the Council of the College of £30,000 at 3 per cent. per annum on a mortgage of the real estate of the college situate in College Road (except such portion as is held in trust for the Clothworkers' Company), and of the new Medical School in Leeds. The motion was ultimately agreed to.

The annual report of the Whitworth Trustees has just been published, in which it is stated that a sum of £10,000, a portion of the surplus from the 1887 Exhibition, has been handed over to the Technical Instruction Committee of the Manchester Corporation for the purpose of erecting an additional wing to the School of Art in Cavendish Square of that city. We thought that satisfactory arrangements had been made for the accommodation of this art school in the new technical school which is being built at an estimated cost of £200,000.

The following are among recent appointments:—Dr. A. Fleischmann to be extraordinary professor of anatomy and zoology in Erlangen University, and director of the Zoologischen Universitäts, Anstalt; Dr. Pockels, *privat docent* in physics at Dresden Technical High School, to be professor; Dr. Oertel to be observer at the Königlichen Sternwarte in Munich, and Dr. Julius Bauschinger, of the same observatory, to be full professor of astronomy in the University of Berlin; Dr. H. W. Bakhuis Rosebom to be professor of chemistry at the University of Amsterdam, and Dr. A. Bistrzycki to be professor of analytical and technical chemistry in the University of Freiburg.

The Paris correspondent of the *Times* states that the General Council of the Paris Faculties has decided to send several delegates to the meeting of the Franco-Scottish Society to be held in Edinburgh in 1897. It has also decided to be represented at the jubilee of Lord Kelvin's connection with the University of Glasgow in June next. A similar decision was taken in reference to the Princeton College celebration *fêtes*. In this connection the Council passed a resolution in favour of closer relationship between French and foreign universities. It was declared that France held too much aloof from these international festivals, and did not sufficiently try to extend a knowledge of her scientific activity. But however this may be, it is certain that we have yet to cultivate the hospitality always freely and lavishly given when British men of science visit their French *confrères*.

The Report of the Council of the City and Guilds of London Institute upon the work of the Institute for the year 1895 has come to hand. Reference is made in it to the assistance which Prof. Huxley gave to the Committee appointed in 1877 to prepare an educational scheme. It was fitting that some permanent record of his connection with the Institute should be established, and the Council have been gratified to receive from the Fishmongers' Company an intimation that, in consideration of the eminent and important services rendered by Prof. Huxley to the cause of technical education, the Court of that Company have determined to found a Scholarship of £60 a year to be called the "Fishmongers' Company's Huxley Scholarship," to be awarded to a scholar of the Technical College, Finsbury, to enable him to proceed to the Central Technical College. In recalling the work of their late Chairman and of Prof. Huxley in the early years of the Institute, the Council are reminded of the great extension which this movement has undergone during

the past few years. In London alone the Technical Education Board of the London County Council, and the Central Governing Body of the City Parochial Charities are spending about £120,000 annually on technical education; and, probably, an equal amount is being spent in the same direction by the Livery Companies of London through the Institute or by individual action. Apart from the City and Guilds of London Institute, mention may be made of the Goldsmiths' Company's Institute, at New Cross; the support by the Drapers' Company of the People's Palace; and of the Skinners' and Saddlers' Companies of the Northampton Institute; the Carpenters' Company's Schools at Stratford and Great Titchfield Street; the Tanning School, recently established by the Leathersellers' Company in the Borough; and the technical schools and textile departments in Leeds, Bradford, Huddersfield, Halifax, and other towns in the north of England supported by the Clothworkers' Company, as a few of the institutions of a specially technical character to which individual Companies are devoting their funds. From a table given in the report to show the amount of the donations to the funds of the Institute since its foundation, we have extracted the following totals, running into four or more figures, which to some extent supplement the information given in a recent article on the grants of the City Companies to education and research. Goldsmiths' Company, £83,064; Clothworkers' Company, £71,500; Fishmongers' Company, £70,550; Drapers' Company, £50,500; Mercers' Company, £50,000; Skinners' Company, £25,835; Grocers' Company, £19,000; Corporation of London, £15,500; Salters' Company, £15,138; Merchant Taylors' Company, £14,657; Leathersellers' Company, £10,105; Carpenters' Company, £8155; Armourers' and Braziers' Company, £7700; Ironmongers' Company, £5973; Cordwainers' Company, £5878; Saddlers' Company, £5600; Dyers' Company, £4646; Coopers' Company, £2770; Vintners' Company, £2500; Pewterers' Company, £2019; Plaisterers' Company, £1537; Cutlers' Company, £1386. The present report furnishes the City Companies with food for congratulation upon the results of the generous provision they have made for technical education.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, April 24.—Captain W. de W. Abney, President, in the chair.—A paper by Mr. R. A. Lehfeld, on symbolism in thermodynamics, was, in the absence of the author, read by the Secretary. The author proposes a system of about twenty-four separate symbols for the different quantities in thermodynamics. Prof. Silvanus Thompson said he was not at all favourably impressed by the symbols proposed. In particular, it was becoming usual to restrict the use of Greek letters to the representation of specific quantities or angles, and the author's proposal seemed in this way a retrograde step. Prof. Perry said he did not care for the suggested symbols. Mr. Elder thought the author's system would be a very severe tax on the memory, for he did not make use of suffixes, as was ordinarily done, which in a great measure define the symbol to which they are attached.—Mr. Appleyard read a paper on the adjustment of the Kelvin Bridge. In a recent paper read before the Society, Mr. Reeves had described a modified form of Kelvin Bridge, in which a double adjustment was necessary. The author proposes to employ two wires stretched side by side, with a sliding contact in connection with the galvanometer on each. These contacts are rigidly connected together, so that the segments into which one wire is divided necessarily bear to one another the same ratio as do the segments of the other wire. Hence a single adjustment is sufficient to give balance. Mr. Reeves said that apparently the author had completely missed the object of his (the speaker's) paper. For the object there aimed at was to make use of such sets of resistance coils as are always to be found in any laboratory. In the author's arrangement it would be necessary to carefully calibrate the two wires, and also, since the resistances used must neceesarily be small, to determine the resistance of the contacts. Prof. Ayrton (communicated) said the author's suggestion was ingenious, but did not obviate the necessity for much of Mr. Reeves' "addition." Further, Mr. Reeves' proposal to employ ordinary resistance boxes was not made because such resistances are absolutely necessary, but because, since they are to be found in any electrical laboratory, their use saves the expense of such a wire resistance accurately calibrated as Mr. Appleyard employs. Mr. Appleyard, in his reply, said that his instrument was designed for use in a factory where the time saved in making a series of tests was of more importance than the cost of the instrument.—Mr. J. Frith read a paper on the effect of wave-form on the alternate current arc. The author finds that an arc has the power of modifying the wave-form in a circuit in which it is included. Thus in the case of a dynamo for which, on open circuit, the curve of E.M.F. was decidedly peaked, it was found that when this dynamo was employed to feed an arc that the curve became changed to a flat-topped form. It is interesting to remember that the candle-power of the arc is greater when the wave-form is flat-topped than when it is peaked. By altering the resistance in series with the arc it is possible to alter the character of the curve, for as the resistance in series with the arc increases the arc affects the wave-form less and less. In some recent experiments described by Dr. Fleming, a resistance of about 7 ohms was used in series with the arc, so that the wave-form of the generator, which is not an efficient form, was forced on the arc. In practice, however, where a resistance is not used in series with the arc, this is not the case, and the differences between the efficiency obtained for alternate current arcs in the laboratory and that claimed in practice may thus be accounted for.—Mr. Blakesley said it seemed as if the more nearly the alternate current resembles a direct current, *i.e.* the longer in each period the current remains constant, the greater is the efficiency of the arc.—Mr. Price asked what was the cause of the reaction of the arc on the wave-form.—Mr. Tremlett Carter asked whether previous observers' results were vitiated by this action of the arc on the wave-form?—Prof. Ayrton (communicated) considered the author's suggestion of great importance as bearing on the question of the efficiency of the alternate current arc.—Prof. S. P. Thompson said that the dynamo employed by the author was one in which there was a large quantity of iron in the armature, so that the self-induction was large. Was it not on account of this large coefficient of self-induction, which would tend to keep the current constant, that the arc was able to alter the wave-curve? If an arc is connected to the mains of a supply station in which a number of machines in parallel are feeding a number of lamps, would the arc still be able to affect the wave-form of the current?—Mr. Tremlett Carter asked if the author had tried the effect of replacing the arc by a resistance such that it would absorb the same volts as did the arc, and comparing the curves for the current and impressed P.D. with those obtained with the arc.—The author, in his reply, said that the effect of the self-induction of the machine was shown in the curves. Current curves had not been taken with the arc straight on the machine. The current and self-induction were the same for all the curves, the voltage of the machine being increased by increasing the field when a resistance was placed in series with the arc. When, as is commonly the case, special machines are used to supply arcs, and the load consists solely of arcs, the arcs could alter the character of the wave-form. If the arc is replaced by a resistance, the wave-form is of the same type as is obtained for the E.M.F. of the machine on open circuit.

PHILADELPHIA.

Academy of Natural Sciences, April 7.—Mr. J. Willcox described the process of obtaining quartz from the Oriskany sandstone of Pennsylvania to be used in the manufacture of glass.—Mr. G. Vaux, jun., called attention to recent additions to the William S. Vaux collection, which included superb crystals of calcite from the Joplin region, Missouri. They occur in caves opened for the working of lead and zinc. The several mines are characterised by distinct forms of the mineral. The sphalerite, which is largely present, is being deposited at the present time, the handles of shovels and picks left in the mines being found covered with crystals.—Mr. Theodore D. Rand described a fine collection of polished serpentines presented by him to the Academy from numerous localities in South-eastern Pennsylvania. They belong to two groups: one bordering the ancient gneiss, the other and the more recent occurring in the mica schists and gneisses. The former are altered igneous rocks, either crysolitic or pyroxenic, the chief material being Enstatite.—Dr. Bascom reported the microscopic examination of thin sections of serpentine from the Black Rocks of Lower Merion.—It was announced that Mr. G. Frederic Russell, accompanied by Dr. Juelal and a taxidermist, had started from Georgetown, British Guiana, March 11, on a collecting tour in the interior for the benefit of the Academy.

Paris.

Academy of Sciences, April 20.—M. A. Cornu in the chair.—On the subject of an unpublished letter of Gauss, by M. de Jonquières.—On a temporary case of parasitism of the *Glyciphagus domesticus* of Geer, by M. E. Perrier. An account of a case where this species of Acarus, usually free, became parasitic, with the result that two houses into which it was accidentally introduced became uninhabitable. Energetic measures of isolation and disinfection by sulphurous acid had to be adopted to stamp out the parasite.—The truffles (*Terfas*) of Mesrata, in Tripoli, by M. Ad. Chatin. — The extraction of the terpene alcohols contained in essential oils, by M. A. Haller. The essence is treated with a quantity of succinic or phthalic anhydride sufficient to convert the whole of the alcohol into the corresponding acid ether. Treatment of this with aqueous sodium carbonate gives the sodium salt of the acid ether, and this, digested with an excess of caustic soda, gives the alcohol free from hydrocarbons on appropriate purification. As an alternative method, the essence containing the alcohol is diluted with ether and treated with metallic sodium, then to the sodium derivative so formed the succinic or phthalic anhydride is added, and the salt worked up as before.—On the approximate value of the coefficients of terms of high order in the development of the principal part of the disturbance function, by M. A. Féraud. A study of the mutual influence of two planets upon each other, both of which are moving in elliptic orbits.—On the biuniform transformations of algebraic surfaces, by M. P. Painlevé.—On the diffraction of the Röntgen rays, by MM. L. Calmette and G. T. Lhuillier. By the use of two metallic screens pierced with narrow slits, photographs were obtained consistent with the assumption that the Röntgen rays exhibit the phenomenon of diffraction. The results obtained indicate that the wave-lengths are longer than those of light, but the photographs are hardly clear enough for exact measurement. The experiments are being continued.—Observations on a communication of MM. Benoist and Hurmuzescu, by M. A. Righi. A discussion of the conditions favourable to the discharge of an electrified body by the X-rays. The author maintains the accuracy of his earlier observations regarding the production of a positive charge upon isolated conductors by the Röntgen rays, and states that the potentials so produced are of the same order as contact electromotive forces. Hence a very delicate electrometer is required to exhibit these effects.—Photography in the interior of a Crookes' tube, by M. G. de Metz. The kathode rays in the interior of a Crookes' tube possess one of the properties of the Röntgen rays, inasmuch as they penetrate aluminium, cardboard and paper, but are stopped by platinum and copper.—Observations on the preceding, by M. Poincaré. The kathode rays, on striking the platinum or aluminium screen, may give rise to X-rays, which *then* go through the metallic plates. The kathode rays themselves may not necessarily possess this property.—On the compensation of the directing forces, and the sensibility of the galvanometer with moving coil, by M. H. Abraham. By attaching a small mass in front of the moving coil of a Deprez-d'Arsonval galvanometer so as to slightly displace its centre of gravity, and properly regulating the inclination of the instrument by means of its levelling screws, the effective sensibility is increased one hundred-fold, and is of the order of a Thomson galvanometer of equal resistance. —Rotatory dispersion of active non-polymerised liquid bodies, by MM. Ph. A. Guye and C. Jordan. An experimental study of normal and abnormal rotatory dispersion. The chief conclusions drawn are that active liquid bodies, not polymerised, present only normal rotatory dispersion, and that there is no simple relation between the refrangibility of the radiations and the rotatory dispersion.—On a new series of sulphophosphides, by M. Ferrand. These compounds, of which the copper, iron, silver, nickel, chromium, zinc, cadmium, mercury, lead, and aluminium salts are described, are thio-pyrophosphates, and possess the general formula $M'_4P_2S_7$.—The spontaneous adaptation of muscles to changes in their function, by M. Joachimsthal.—Influence of induced currents on the orientation of living bacteria, by M. L. Lortet. Living bacteria, in the form of mobile bacilli, are very sensible to the action of currents from a Ruhmkorff coil, and immediately set themselves in the direction of the current. This effect is only produced when the organisms are living, and is not observed after the introduction of an antiseptic, such as carbolic acid. Living organisms are unaffected by a constant current.—On the internal appendages of the male genital apparatus of the Orthoptera, by M. A. Fénard.—On the membrane of the *Ectocarpus fulvescens*, by M. C. Sauvageau.—On the abortion of the principal root in one species of the genus *Impatiens* (L.), by M. C. Brunotte.—The biochemical preparation of sorbose, by M. G. Bertrand. A specific organism, which can be obtained by exposing a mixture of wine and vinegar to the air for some time, is the cause of the conversion of sorbite into sorbose in the fermentation of the juice of various species of *Sorbus*. The direct production of sorbose in the fermentation of the latter is dependent upon the introduction of the organism by small reddish flies (the vinegar fly, *Drosophila funebris*).—On winter observations in the caves of the Causses (Padirac, &c.), by M. E. A. Martel.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—A Scientific Demonstration of the Future Life: T. J. Hudson (Putnam).—Studies in Ancient History: J. F. M'Lennan, 2nd series (Macmillan).—A Dictionary of Chemical Solubilities. Inorganic: Dr. A. M. Comey (Macmillan).—The Theory of Sound: Lord Rayleigh, Vol. 2, new edition (Macmillan).—Analytical Psychology: J. F. Stout, 2 Vols. (Sonnenschein).—Forschungsberichte aus der Biologischen Station zu Plön: Dr. O. Zacharias, Theil 4 (Berlin, Friedländer).—Know your own Ship: T. Walton (Griffin).—Annals of the Royal Botanic Garden, Calcutta, Vol. v. Part 1 (Calcutta).—The American Lobster: Dr. F. H. Herrick (Washington).—Artistic and Scientific Taxidermy and Modelling: M. Browne (Black.—Royal University of Ireland. Examination Papers, 1895: a Supplement to the University Calendar for the Year 1896 (Dublin).

Pamphlets.—The Physiology of the Carbohydrates: a Rejoinder to Dr. Paton's further Criticism: Dr. F. W. Pavy (Churchill).—City and Guilds of London Institute Report to the Governors, March 1896 (Gresham College). —Neber einige Eigenschaften der Röntgen, schen X-Strahlen: Drs. Winkelmann and Straubel (Jena, Fischer).

Serials.—English Illustrated Magazine, May (198 Strand).—Quarterly Review, April (Murray).—Good Words, May (Isbister).—Sunday Magazine, May (Isbister).—American Journal of Psychology, Vol. 7, No. 3 (Worcester, Mass.).—Encyklopædie der Naturwissenschaften, Dritte Abthg., 30 to 33 Liefg. (Breslau, Trewendt).—Journal of the Sanitary Institute, April (Stanford).—Longman's Magazine, May (Longmans).—Chambers's Journal, May (Chambers).—Terrestrial Magnetism, No. 2 (Chicago).—Journal of the Asiatic Society of Bengal, Vol. lxiv. Part 2, No. 3 (Calcutta).—Proceedings of the Academy of Natural Sciences of Philadelphia, 1895, Part 3 (Philadelphia).—Bulletin of the American Museum of Natural History, Vol vii. (New York).—Field Columbian Museum. Archaeological Studies among the Ancient Cities of Mexico, Part 1: W. H. Holmes (Chicago).—Natural Science, May (Rait).—Schriften der Naturforschenden Gesellschaft in Danzig. Neue Folge, Neunten Bandes, Erstes Heft (Danzig).
